When phosphomolybdic acid is added to the product of the reaction of hydrochloric acid and 20 grams of glutenfibrin, hemiprotein, oxyprotosulphonic acid, or egg-albumin, a precipitate is formed from which in all cases the above platinochloride and crystalline and amorphous silver salts may be obtained. The egg-albumin product contains other bases which have not as yet been isolated.

The amorphous silver salt, which appears to have the composition $C_{11}H_{17}N_4O_6Ag_3$, when decomposed by hydrogen sulphide and treated with hydrochloric acid, yields the compound $C_{11}H_{20}N_4O_6 \cdot 2HCl$, crystallising in short prisms; the platinochloride, $C_8H_{14}N_2O_3PtCl_6$, was found to contain 1 mol. alcohol of crystallisation, and has therefore the composition $C_8H_{14}N_2O_3 \cdot H_2PtCl_6 + EtOH$. On treating it with hydrogen sulphide and adding hydrochloric acid, it yields the hydrochloride, $C_8H_{14}N_2O_3 \cdot 2HCl$, crystallising in lustrous needles. The compound $C_8H_{14}N_2O_3 \cdot H_2PtCl_6 + MeOH$ has also been prepared.

When the platinochloride containing 1 mol. alcohol is freed from platinum and heated with baryta-water at 150° , a product is formed which yields a platinochloride containing no alcohol, namely, $C_8H_{14}N_2O_3 \cdot H_2PtCl_6$. If the corresponding hydrochloride is heated with alcohol and hydrogen platinochloride, it again, however, yields the original platinochloride. This is due to the fact that the base is converted by heating with baryta-water into an optical isomeride, for whereas the solution of the original base is strongly dextrorotatory, the solution, after heating, is practically inactive. This behaviour is analogous to that of the optically active amido-acids, observed by Schultze (*loc. cit.*).

Preservation of Oxyhæmoglobin. By L. FREDERICQ (*Trav. de Lab. de L. Fredericq, Liège*, 3, 109).—Solutions of crystals of oxyhæmoglobin can be kept unchanged for months in contact with the air provided that the atmospheric micro-organisms be excluded by careful antiseptic precautions. In sealed tubes, the pigment changes to methæmoglobin after the lapse of some months; if, however, putrefaction occurs, reduced hæmoglobin makes its appearance (compare Yeo, *Abstr.*, 1890, 1012).
W. D. H.

Preservation of Hæmocyanin. By L. FREDERICQ (*Trav. de Lab. de L. Fredericq, Liège*, 3, 194).—Hæmocyanin, when preserved in a closed vessel, even though putrefaction may occur, remains unaltered in its characteristic properties for at least six months.
W. D. H.

Electrolysis and Putrefaction of Bile. By G. N. STEWART (*Studies from Physiol. Lab., Owens College*, 1, 201—206).—When ox bile putrefies, the pigment changes to brown and ultimately to yellow, and Gmelin's colour reaction is no longer given. Bile pigment slowly undergoes the same change even if putrefaction is prevented. When bile is electrolysed in a U-tube, changes take place at the

negative pole similar to those just mentioned. In the earlier stages, reversal of the current restores the original colour. The anode has an oxidising, the cathode a reducing, action. During all these changes, however, the spectrum remains unaltered, except that the absorption bands become slightly less marked under anodic, more marked under cathodic, influence. Cholo-hæmatin, to which the bands of ox-bile are due, must, therefore, differ in stability from the bile pigments proper. The bile salts are electrolytes, and an acid constituent of these crystallises at the anode in long needles; but the conductivity of bile salts is small as compared with that of the inorganic constituents of the secretion (compare Haycraft and Scofield, *Abstr.*, 1890, 181).

W. D. H.

Physiological Chemistry.

Respiratory Exchanges in Animals. By H. C. CHAPMAN and A. P. BRUBAKER (*Proc. Acad. Nat. Sci., Philadelphia*, 1891, 13—44).—A series of analyses relating to the consumption of oxygen and the production of carbonic anhydride were performed with a Regnault-Reiset apparatus, on a number of animals, chiefly rabbits. It was found that on the average the rabbit consumes 2.01 grams of oxygen per hour, and 0.8 gram of oxygen per hour per kilo. of body weight, and produces 2.5 grams of carbonic anhydride per hour, and 1.1 grams of carbonic anhydride per hour per kilo. of body weight; the respiratory quotient averaging 0.9.

W. D. H.

Action of Organic Acids on Salivary Digestion. By O. JOHN (*Virchow's Archiv*, 122, 271—283).—The addition of minute quantities of organic acids (formic, succinic, acetic, oxalic, malic, lactic, butyric, &c.) to saliva, and the influence of such additions on the activity of its amylolytic ferment, were carried out in artificial digestion experiments, and the conclusions arrived at are the following:—

(1.) In very small quantities, these acids act, as hydrochloric acid has been shown previously to act (Chittenden and Smith, *Abstr.*, 1886, 638), favourably on the diastatic activity of saliva.

(2.) This action depends on the formation of a compound with the alkaline constituents of the saliva.

(3.) Very small quantities of free acid, however, retard the action of the ferment.

(4.) The coefficient of retardation stands in no relation to the chemical constitution of the acid. Oxalic acid, of the acids used, is the most powerful in this direction, and of the acids most commonly found in ordinary foods, acetic acid is the least powerful.

(5.) A comparison is drawn between the action of these acids on the salivary enzyme, and the similar action they have on bacterial activity.

W. D. H.

Hydrochloric Acid in Gastric Juice. By E. SALKOWSKI and M. KUMAGAWA (*Virchow's Archiv*, 122, 235—252). G. Klempner (*Zeit. Klin. Med.*, 14) states that none of the chemical methods for the estimation of free hydrochloric acid in gastric juice takes into account the possibility that the acid may be united to organic bases, such as leucine and glycocine, basic products of the lactic acid fermentation, and quinine. A repetition of some of Klemperer's experiments with artificial mixtures containing such bases led to the following results. It was found that, although the acid might be united to bases of the amido-acid series, as for instance, to form leucine hydrochloride, it still remains physiologically active, that is to say, digestion occurs as well in a mixture containing leucine hydrochloride as in one containing an equivalent amount of free hydrochloric acid. For all practical physiological purposes, the hydrochloric acid is as free in such compounds as if it were actually or chemically free. Those methods like Cahn and v. Mering's cinchonine method, or Sjöquist's method (*Abstr.*, 1889, 302), are therefore perfectly correct as a means of ascertaining the quantity of "physiologically free" hydrochloric acid. Among qualitative reactions, the methyl-violet test is in the same sense a trustworthy one; leucine hydrochloride gives, however, a slight violet tint to the blue colour produced. Günzburg's reaction, however, gives a negative result with these compounds.

Organic bases like quinine, when united with hydrochloric acid, form a compound which is neutral or weakly alkaline. Such a solution has, under no circumstances, any peptic activity; the acid is neither chemically nor physiologically free, and in this case Sjöquist's method of estimating the acid would lead to a false result. Hydrochloric acid which contains in solution half the amount of quinine necessary to saturate it, is physiologically inactive, although it is partly chemically free. Under such circumstances, Sjöquist's method is again inapplicable, and the qualitative reactions before mentioned are both untrustworthy.

Experiments such as these do not lead to the conclusion that these methods are not applicable to the investigation of human gastric juice. Until it is shown that human gastric juice contains organic bases which act like quinine, the methods at present in use must be regarded as perfectly trustworthy.

W. D. H.

Absorption of Fats in the Absence of Bile. By I. MUNK (*Virchow's Archiv*, 122, 302—325).—The classical experiments of Bidder and Schmidt showed that, without bile, fat was very badly absorbed. Since then, investigations by Voit and by Röhmman (*Pflüger's Archiv*, 29, 509) have confirmed this; Voit states that in dogs with a biliary fistula, in which no bile can, therefore, enter the intestine, the excess of fat found in the fæces is contained as such, and is only to a slight extent resolved into fatty acids and glycerol. Röhmman, however, who made accurate quantitative experiments on this point, states that before the operation one-fifth of the fatty substances contained in the fæces were present as neutral fats, and four-fifths as fatty acids and soaps; and after the operation these fractions were respectively one-eleventh and ten-elevenths.

Röhmman concludes that in dogs with biliary fistula, the chief mass of the fat is hydrolysed in the intestine by pancreatic juice and putrefactive bacteria, and the fatty acids so liberated are partly combined to form soaps.

Each of the experiments in the present research lasted three days; by feeding the animal (dog) on bone mixed with charcoal before and after the experiment, the fæces belonging to the time of the experiment would be easily recognised. The dog used had a biliary fistula, and was prevented from licking the bile from the external opening.

The following is a summary of the experiments performed:—

I. 3 grams of pork fat per kilo. of body weight *per diem*.

In the food, 1090 grams dry substance, 247.6 fat, 56.5 N.

In the fæces, 135.5 grams ,, 82.1 ,, 5.64 N.

60 per cent. of the dry fæces were fatty substances. The fatty substances were of the following nature:—

Neutral fat.....	7.85 grams.
Free fatty acids.....	61.84 ,,
Fatty acids in soap.....	10.93 ,,
Cholesterol	1.43 ,,

Thus the amount of disintegrated fat was ten times as abundant as that of neutral fat.

II. 3 grams of fatty acids (from pork fat) per kilo. *per diem* mixed with a little horse fat. The fatty substances in the fæces were:—

Neutral fat.....	6.4 grams.
Free fatty acids.....	45.01 ,,
Soaps	14.29 ,,
Cholesterol.....	1.40 ,,

Thus, of the total fatty material in the food (237.6 gram), 72.8 grams appeared in the fæces which contained 60 per cent. of their solid constituents as fatty substances. Comparing experiments I and II, the amount digested is rather greater in the latter than in the former.

	I.	II.
Percentage of dry material absorbed.....	87.6	89.7
„ fatty substances	66.9	72.8
„ nitrogen	90.0	92.4

In a dog without bile in his intestine, the absorption of fatty acids is thus better than that of neutral fats; in a normal dog, the substitution of an equivalent amount of fatty acid for fat causes no appreciable difference.

A similar series of experiments with mutton suet and an equivalent quantity of its fatty acids gave a similar result, except that this form of fat is not so well absorbed as pork fat. The percentage of fatty substances absorbed when given as fat was 35.5; when given as fatty acids, 42.2.

With larger doses of fat *per diem*, other series of experiments

showed that the percentage absorbed was about the same, and that more was absorbed if fatty acids instead of neutral fats were given.

In the course of the research, it was noted that the colour of the faeces was pitch black when the diet given was meat free from fat. This cannot have been due to any derivative of the bile pigment, but to haematin (or some other derivative) of the haemoglobin of the food.

W. D. H.

Digestibility of Meadow Hay, Bean, Barley, Swedes, and Rice Meal. By F. LEHMANN and J. H. VOUEL (*Bied. Centr.*, 20, 12—19; from *Journ. Landw.*, 38, 165).—The experiments were made with two sheep, under similar conditions to the previous ones. The feeding during the six periods of the experiments was as follows:—Period No. 4, meadow hay. No. 1, hay and beans. Nos. 2, 5 and 6, hay and beans with swedes, rice meal, and barley respectively. No. 3, hay, beans, barley, and swedes. The amounts and composition of the foods and of the faeces of the six periods for each sheep are given in tables. The following table shows the average percentage amount of dry substance, and of the various constituents digested.

	Dry matter.	Crude protein.	Fat.	Ash.	Crude fibre.	Non-nitrogenous extract.
Hay.....	62·24	53·36	12·93	52·10	60·71	67·68
Beans.....	80·02	58·64	49·05	49·41	—	88·76
Swedes.....	96·28	62·26	93·46	52·60	100·0	99·05
Rice meal...	66·02	41·45	83·15	10·00	31·37	83·81
Barley.....	90·80	63·17	77·81	11·35	100·0	96·16

The co-efficients for swedes are new. Those of hay and beans agree, on the whole, with the means in Wolff's tables. A slight error was made in the case of the crude fibre of beans. The negative result is explained by too high a coefficient having been found for hay. Barley and rice meal show greater differences from the numbers previously found. But the authors consider that, as regards barley, their numbers are nearer the truth than those obtained by Maoreker and Schulze (*Journ. Landw.*, 1875, 133), who tested barley against hay (the nutritive ratio being 1 : 8·4). In the case of rice meal, the authors have less confidence in their own results, inasmuch as the high percentage of fat in Period 5 may have been prejudicial to the relatively young animals.

Tables showing the amounts of water consumed during the experiments, and the amounts of urine produced, are given in the original paper.

The gain in the weight of the two sheep during the 84 days the experiments lasted was 0·20 and 1·45 kilo. The results show that a sheep of the South Hanover district, weighing about 31·5 kilos. requires, at a temperature of 10·1°, the following amounts of food—

2 2 2

constituents to retain its original condition:—Protein 74.1, fat 8.8, crude fibre 70.5, non-nitrogenous extract 301.4 grams.

With regard to the value of cellulose, the results of the experiments do not indicate any difference between it and the readily soluble carbohydrates as regards the saving of proteids. N. H. J. M.

Chemical Theory of the Coagulation of the Blood. By M. ARTHUS and C. PAGÈS (*Compt. rend.*, 112, 241—244).—If the soluble calcium compounds in blood are precipitated by adding an alkaline oxalate, the coagulation of the blood is prevented, but can take place if a soluble calcium salt is added. The action of the oxalates is quite different from that of such salts as sodium sulphate, magnesium sulphate, &c. The fibrinogen of the blood is not precipitated, and undergoes no change. From these facts, and the results obtained by previous observers, the authors conclude that under the influence of the fibrin ferment, and in presence of calcium salts, the fibrinogen of the blood plasma is decomposed into two substances, namely, an insoluble, calciferous compound, fibrin, and a soluble compound, globulin, which coagulates at 64°. C. H. B.

Destruction of Sugar in Blood. By R. LÉPINE and BARRAL (*Compt. rend.*, 112, 146—148; compare *Abstr.*, 1890, 1172).—The activity of the glycolytic ferment in the blood of the dog increases as the temperature rises from 15° to 54°, but at the latter point it suddenly stops, although the physical condition of the blood does not differ appreciably from that at 52°, a temperature at which the ferment is very active.

At 39°, the defibrinated blood of a dog loses more sugar in winter than in summer, and it follows that the ferment is either more active or is present in greater quantity.

At 39°, the blood from the portal vein loses much more sugar than the blood from the splenic vein and from the arteries under identical conditions, the difference being at least 20 per cent. It follows that the ferment is excreted from the pancreas, not only by the lymphatics of the pancreas, but also in considerable quantity by the venous rootlets.

Even in a dog deprived of its pancreas, the destruction of the sugar did not cease, although reduced to about one-sixth of its normal amount. It would seem, therefore, that the ferment is derived from other organs as well as from the pancreas. C. H. B.

Muscular Work and Proteid Metabolism. By D. N. PATON (*Lab. Reports, College of Physicians, Edin.*, 3, 241—249).—The question of the influence of muscular work on proteid metabolism has been recently reopened by Argutinsky (this vol., p. 350) and Krummacher (*ibid.*, p. 479). They found an increase in proteid metabolism sufficient to account for no less than 75 to 100 per cent. of the amount of energy required to raise the weight of the body to the height ascended. These experiments were, however, unsatisfactory, as the work of forward progression, the movement of the arms, and the

increased respiratory efforts are all left out of account. Both men, moreover, were on insufficient diet, and in bad condition, losing weight throughout the experiments. Munk also concludes from similar considerations that their results are of no value (*Centr. Med. Wiss.*, 1890, 738). Hirschfeld (*Virchow's Archiv*, 121, 501) has recently published three similar experiments; his diet was sufficient, and no increase of the excretion of nitrogen followed muscular work.

In the present experiment, the diet was simple and carefully analysed, the work done consisted in raising a weight, and to this must be added a certain amount of walking exercise which is allowed for on the data given by Marez and Demeny (*Compt. rend.*, 101, 905). With a slight amount of work, no increase occurred in the excretion of nitrogen; but when the work done was increased, especially after periods of comparative rest, the output was certainly increased. Thus the excretion of nitrogen on the four days preceding the work amounted to 60.144 grams, on the four days following the exercise to 61.3678, showing an increased excretion of 1.223 grams, equivalent to 7.949 grams of albumin, which is equal to 32.55 calories, or 13833.75 kilog. metres, or 85 per cent. of the energy required for the muscular work of ascending the stairs and raising the weight. W. D. H.

Electrolysis of Animal Tissues. By G. N. STEWART (*Lancet*, 2, 1890, 1264; and *Studies from Physiol. Lab., Owens College*, 1, 124—177).—It was found that practically the whole of the conduction in animal tissues is electrolytic, and the electrolytes are principally the mineral salts, changes in the proteids being produced by secondary electrolytic actions. In simple proteid solutions, conduction occurs with great difficulty if salts are absent or present in small proportions. The effects on the proteids themselves in saline solutions vary somewhat with the current density. Alkali-albumin is formed at the cathode, and acid-albumin at the anode; whilst in solutions of coagulable proteids there is also coagulation at the latter pole. With a strong current, the proportion of coagulated proteid to acid albumin is greater than with a weak current.

It was found that in bile and urine the conduction there also was chiefly due to electrolysis in the mineral, and not the organic, substances in those secretions. In blood, changes in the proteids occur similar to those just mentioned. There is also a formation of acid-haematin (mixed with or preceded by methaemoglobin with certain strengths of current) and of alkali-haematin at the anode and cathode respectively. There is no evidence that haemoglobin or any of its derivatives can act as an ion.

In muscle, the nuclei become apparent, and the sarcoous substance granular at the anode; this is the appearance always produced by a weak acid. At the cathode, the fibres become more homogeneous. The chief chemical changes in the proteids are an increase in the neutralisation precipitate of the aqueous extract, and a corresponding decrease of the globulin. At the anode, the neutralisation precipitate is increased, but the amount of globulin is more than correspondingly diminished, because part of this proteid is coagulated. The effects of electrolysis on the salts of the muscle were studied by estimat-

ing the ash. Striking changes were found to occur which, if produced within the living body, would profoundly modify nutrition.

The antiseptic action of the current was studied in the case of micro-organisms, and it was found to occur chiefly, if not entirely, around the anode. An attempt is made to connect this knowledge with the application of electrolysis in surgery, and a further communication on the physiological aspects of the question is promised.

W. D. H.

Human Bile. By D. N. PATON and J. M. BALFOUR (*Lab. Reports, College of Physicians, Edin.*, 3, 191—240).—The bile was collected from a woman who had had the operation of cholecystotomy performed for impacted gall-stone. The bile had a brownish-orange colour when fresh: it turned green after standing. It had an alkaline reaction. The urine was also collected daily, and the total nitrogen determined; its colour was usually high, and due to normal urobilin. Indican was abundant on several occasions. The fæces varied in colour from clay-white to slate-grey; they were offensive, and contained no biliary constituents. The nitrogen and fat in them were occasionally estimated. The following is the average of six quantitative analyses of the bile:—

Ether extract (cholesterol, lecithin, fat)	0.075 per cent.
Alcohol extract (bile salts, soaps, and some pigment)	0.349 ,,
Mucin, pigments, and other organic substances insoluble in ether or alcohol	0.461 ,,
Inorganic salts, insoluble.....	0.003 ,,
,, soluble	0.638 ,,

Estimations of certain individual constituents gave the following results:—

Cholesterol	0.053
Lecithin and fat	0.009
Glycocholic acid	0.356
Taurocholic acid.....	0.049
Fatty acids (from soaps).....	0.015

The following are the general conclusions drawn from this case relating to the physiology of bile secretion:—

1. The amount secreted varies greatly under the influence of many factors.
2. The introduction of biliary constituents within the alimentary canal has not so great an effect in increasing the bile flow as experiments on dogs would indicate.
3. The quantity of bile and of its solid constituents has probably been over estimated by previous observers.
4. The taking of food has no immediate effect in accelerating the flow of bile.
5. The flow of bile varies much during the 24 hours, being highest about midday, and lowest in the early morning.
6. The greatest amount of solids is produced in the liver during the

night. This is chiefly due to the organic constituents, the inorganic salts remaining fairly constant.

7. The amount of bile varies with the amount of fluid ingested.

8. The activity of metabolism has a distinct effect on the amount of bile solids produced, but not on the flow of bile.

9. Fever produces a marked and immediate fall both in the amount of bile and of its essential constituents. The mucin and inorganic salts remain unaltered.

10. Of the drugs used, sodium salicylate and calomel were most active in increasing the biliary flow: ox bile less markedly so.

11. The bile plays some part in promoting absorption of fat, but not on that of proteids and carbohydrates.

12. The pressure under which bile is secreted is higher than the blood pressure in the capillaries of the liver.

13. The bile is doubtless an excretion rather than a secretion, for its only digestive action (that on fats) is not very important, 70 per cent. of the fat ingested being absorbed when no bile enters the intestine. The constituents of the bile which are discharged *per rectum* come probably from the blood corpuscles; a correspondence between the amount of bile solids produced and the nitrogen excreted in the urine supports the view of their close connection.

W. D. H.

Oxyhæmoglobin in the Bile. By R. STERN (*Virchow's Archiv*, 123, 33—43).—Wertheimer and Meyer (Abstr., 1889, 636) and Filehne (*Virchow's Archiv*, 117, 415) have described certain poisons which cause the appearance of oxyhæmoglobin in the bile. In the present research, care was taken to avoid admixture of the bile with blood from operative procedures, and also by examining the bile either while the animal was alive or immediately after death, to avoid a source of error pointed out by Wertheimer and Meyer, which consists in the fact that some hours after death some blood pigment diffuses into the gall bladder. In the case of human beings, in which many observations were made, it was not so easy to avoid this latter source of error, though the post-mortem examinations were performed as soon as possible after death.

The previous observers named found that the hæmoglobinocholia which they were able to produce by aromatic drugs in rabbits was not found to occur under the same conditions in dogs. It is here suggested that this may be due to a difference in the readiness with which hæmoglobin is decomposed in different species of animals (compare Krüger, Abstr., 1888, 510).

The chief experiments in the present research consisted in injecting small quantities of oxyhæmoglobin into the circulation of rabbits, and observing when it was discharged into the bile and into the urine. The following table gives the mean results:—

Quantity of hæmoglobin injected per kilo. of body weight.	Hæmoglobin in	
	Bile.	Urine.
0.468 gram.	Present.	Present.
0.073 "	Present.	Traces present.
0.061 "	Present.	Absent.
0.059 "	Present.	Absent.
0.025 "	Traces present.	Absent.
0.019 "	None present.	Absent.

In other words, small quantities of hæmoglobin appear in neither secretion as such, being changed into bile pigment; larger quantities readily pass into the bile, usually some hours after the injection, and still larger doses are necessary to produce hæmoglobinuria. Subcutaneous injections of hæmoglobin solutions produce the same change, but larger doses are necessary than when it is administered intravenously.

The application of this knowledge to pathology depends on the fact that certain micro-organisms, like the *Bacillus anthracis* and the bacillus of diphtheria, have the power of liberating hæmoglobin in the circulation, and in rabbits oxyhæmoglobin was found in the bile though not in the urine after infection with these pathogenic microbes.

The bile of a large number of corpses was then examined, and in cases of diphtheria, typhoid, and empyema the blood pigment was constantly found in the bile. In other pathological conditions, tuberculosis, scarlet fever, apoplexy, &c., oxyhæmoglobin was sometimes found; but in all cases the source of error previously alluded to could not be excluded.

W. D. H.

Increased Output of Nitrogen in Cerebral Hyperthermia. Fever, and Artificial Overheating. By P. RICHTER (*Virchow's Archiv*, 123, 158—165).—A careful comparison of three conditions was made in connection with the question of nitrogenous excreta and its relation to increased body temperature. The three conditions were: (1) the febrile state, associated with nervous injuries in which presumably the mechanism that normally regulates the body temperature is deranged; (2) continued fever; and (3) artificial heating of the body so that the body temperature is raised. In all three cases there was an increased output of nitrogen in the excreta as well as increased gaseous exchanges (intake of oxygen and output of carbonic anhydride) in the lungs. The general, far sweeping conclusion drawn is that, as in artificial overheating, so also in nervous hyperthermia, and, to a certain extent, in all fevers, and especially in some forms of fever, the increased production of heat (due to an increase of metabolic changes) is the result and not the cause of the elevated body temperature.

W. D. H.

Excretion of Balsams in the Urine. By R. STOCKMAN (*Lab. Reports, College of Physicians, Edinburgh*, 3, 65—69).—The research carried out on human beings and rabbits with the four balsams of the

British Pharmacopœia (balsam of Peru, balsam of Tolu, prepared storax, and benzoin) is of interest, as use is made of these drugs in the treatment of tubercular disease, and nephritis is said to have been set up in certain cases as a result. It was found that balsam of Peru caused no disturbance of the kidneys, but the urine (if the dose given is large) gives a precipitate with nitric acid, as if albumin was present. The precipitate is, however, soluble in alcohol and in excess of acid, and no doubt it consists of the resin of the balsam, probably in combination with glycuronic acid. Prepared storax, which is used in the treatment of scabies as an ointment, causes a similar condition, which was mistaken by Unna (*Virchow's Archiv*, 74, 424) for albuminuria. Treatment with benzoin gave no positive results as, owing to the difficulty of dissolving it in suitable menstrua, it was impossible to give large doses. The same may be said for balsam of Tolu. In all cases, the urine contained a large excess of hippuric acid. W. D. H.

Hæmatoporphyrin in Urine. By E. SALKOWSKI (*Centr. med. Wiss.*, 1891, 129—130).—Three cases are briefly described of women patients who passed a dark pigment in their urine. The pigment was found to be hæmatoporphyrin, which was separated as a calcium compound; MacMunn (*Proc. Physiol. Soc.*, 1890, 13) and Ranking and Pardington (*Lancet*, ii, 1890, 607) have recorded similar cases. In the present instances, the phenomenon is attributed to the fact that sulphonal was being taken as a drug at the time. W. D. H.

Unusual Pigment in Urine. By V. HARLEY and S. TORUP (*Brit. Med. J.*, ii, 1890, 1169—1170).—Two cases are recorded of women who suffered from grave nervous symptoms (insomnia, coma, &c.), ending in death. They were treated with sulphonal and chloral, and passed urine of a port wine colour. The urine contained no albumin, sugar, bile, or blood. The abnormal urinary pigment is believed to be a precursory state of the normal urinary pigment, in fact, merely a less highly oxidised stage of it. W. D. H.

Note by Abstractor.—From the spectroscopic appearances described, and the general characters of the urine, there can be but little doubt that these were cases of hæmatoporphyrinuria (see preceding abstract).

Physiological Action of Saline Solutions and Various Drugs. By R. HEINZ (*Virchow's Archiv*, 122, 100—124).—In the investigation of the physiological action of drugs, it is often necessary to dissolve these in saline solutions before introducing them subcutaneously or intravenously into the body of an animal. The strength of the saline solution used is by no means unimportant. It is especially inadvisable to use concentrated saline solutions, as it is found that strong solutions of sodium chloride, the salt chiefly used, produce changes in the blood, especially in its coloured corpuscles, and changes of the nature of inflammation, infarction, and hæmorrhage in the alimentary canal and elsewhere. For subcutaneous injection,

more than a 5 per cent. solution of sodium chloride should be avoided, and for intravenous injection, "isotonic" solutions, or solutions but slightly hyperisotonic, should be employed.

Figures are given of the effect of a number of organic substances, chiefly derivatives and compounds of phenylhydrazine, on the red corpuscles of cold- and warm-blooded animals. The phenylhydrazine derivatives make the blood a brownish-green colour; spectroscopically, the bands of methæmoglobin are seen, the red corpuscles are shrunken; in the nucleated corpuscles of cold-blooded animals, the nucleus becomes oval, and the pigment collects around it in the same manner as when the corpuscles are treated with boric acid. In the non-nucleated red corpuscles of mammals, a brightly refracting globule is exuded, which adheres to the shrunken corpuscle, and is stainable a deep violet by methyl-violet.

With another category of organic substances (ammonia, diamines, hydroxylamine, amines, and amidines of the fatty and aromatic groups of compounds), the changes are somewhat different. The most characteristic change in nucleated red corpuscles is the appearance within them of numerous clear granules looking like vacuoles; these can be squeezed out of the corpuscles, and are found to be stainable by Bismarck-brown, and soluble in dilute hydrochloric acid, but not in dilute acetic acid, or in alcohol. In the non-nucleated discs of mammals, these little bodies are not formed, but the discs become mis-shapen and lose the greater part of their pigment in time.

The physiological action of pyridine is similar to that of piperidine, except that it acts more energetically. They both produce paralysis of the motor nerves, by their effect on the motor centres; there are also destructive changes in the blood corpuscles, and paralysis of the heart, especially in pyridine poisoning.

Quinoline and decahydroquinoline have analogous actions; they lead to a paralysis of central origin, a loss of excitability in the motor nerves, leaving the sensory nerve-endings and muscular substance almost intact; and, moreover, as with pyridine and piperidine, the non-hydrogenated substance quinoline is more powerful than the hydrogenated substance decahydroquinoline.

W. D. H.

Physiological Action of Antipyretics. By P. RICHTER (*Virchow's Archiv*, 123, 118—138).—The antipyretic action of kairine on animals with normal and febrile temperatures was investigated by calorimetric methods. The main result of the experiments is that the drug acts on the regulating mechanism which under normal circumstances keeps the body temperature at a fixed level. This is affected in the same manner, but with different degrees of intensity in normal and in febrile animals. The increase in the amount of heat lost is secondary, that is to say, it is dependent on the adjustment of the regulating apparatus; it is a means which assists the lowering of the body temperature, but is not the only cause of the antipyretic action of the drug.

Chemistry of Vegetable Physiology and Agriculture.

The Souring of Cream. By V. STORCH (*Bied. Centr.*, 20, 48—59; from *Tidskr. f. Landök.*, 1890, 352—416).—In order to ascertain the causes of certain defects in butter, especially "oily" butter, several samples were submitted to bacteriological analysis. The attempts to isolate an organism which produced the "oily" taste in butter were unsuccessful, but numerous fungi were found in butters with this defect, which were not found in others, and it is probable that these fungi are injurious. With regard to "tallowy" butter, a definite organism was found; it coagulates milk much as the usual souring-bacterium, which it also resembles in size and form. The turnip taste which butter sometimes has, although made from the milk of cows which receive no turnips in their food, is also probably due to a special micro-organism.

Tables are given showing the percentage numbers of defective butters under the headings "oily," "bitter," and butters with a "burnt taste," produced under a different systems of dairying.

In order to sterilise milk, heating at 107° for 5—10 minutes is not sufficient. Even a temperature of 120° for 10 minutes was in one case found not to have sterilised the milk; a pure cultivation of a small bacillus was obtained, whose thick, egg-shaped spores had resisted the high temperature.

Milk heated at 70° acquires a strong odour and taste. By discontinuous heating at this temperature, sterilisation may be effected.

Attempts were made to isolate a souring bacterium which produces the pure aromatic odour which well soured cream has. Bacteria were isolated from soured butter milk, and from two samples of butter, but the bacteria produced either only a slightly aromatic taste or none at all, although they all produced the right consistence and a pure acid taste.

Cream and butter from a farm distinguished for very aromatic butter were next tried, and the souring bacteria isolated. Of these, two (both from cream) were found always to produce the distinct aromatic taste. The one (No. 18) which also produced an especially agreeable, mild and pure acid taste was further examined, and is no doubt one source of butter aroma. On gelatin plates it forms small, pure white colonies which show a somewhat oval form. The temperature most favourable to it, is somewhat higher than that usually employed in dairies for souring. In shape, size, and mode of growth, the bacterium is in many respects similar to Pasteur's "ferment lactique"; but the power of motion, which the author's bacterium possesses, shows that it is not identical with Pasteur's ferment. The virulence of most of the souring bacteria is much weakened when they are kept in the same milk, but at once returns when the pure cultures are repeatedly inoculated in fresh milk. Souring bacteria which lose their virulence in one or two months when kept in the

usual way may be kept more than a year when finely powdered calcium carbonate is added to the nutritive solution.

The amount of acid produced in milk by various souring bacteria was determined, and the results are given in tables. The difference in the acidity produced by the different bacteria was only slight; but the bacterium which also gives rise to the aromatic taste, &c., gave the least amount of acid. The greater part of the acid was formed in the first 24 hours, and the production ceased after six days. It was found that a loss of 0.656 per cent. of milk-sugar corresponds with a production of 0.635 per cent. of lactic acid. No evolution of gas ever took place.

The souring bacterium (No. 18) is capable of producing in milk-sugar solutions, free from fat and proteids, and containing only a little peptone, the same aromatic taste which it gives rise to in milk or cream, so that the opinion, sometimes expressed, that this taste is due to volatile acids formed from butter fat, is erroneous.

The author proposes that in practice, fresh souring material should be prepared daily by means of pure cultivations. The danger of the contamination of butter with pathogenic bacteria would thus be much lessened.

N. H. J. M.

Assimilation of Mineral Salts by Green Plants. By A. F. W. SCHÖMPER (P. A. F. W. SCHIMPER) (*Bied. Centr.*, 20, 69—70; from *Flora*, 73, 207).—The nutritive salts of the soil do not at once reach the parts of the plants where they are wanted, but are generally stored up in the root stems and in the woody parts of the above-ground stems. The seeds contain the salts, especially phosphates, as organic compounds, which are, however, during germination, again split up. The power of plants of storing mineral substances differs much qualitatively as well as quantitatively. The object of lime is to convert the poisonous potassium oxalate, which is found in considerable amount, into calcium oxalate. The assimilation of nitric acid takes place in the green cells. Nitrogen migrates chiefly in the form of amides and amido-acids, which can be detected in the leaf parenchyma.

N. H. J. M.

Influence of Internal Causes on the Presence of Starch in Leaves. By E. MER (*Compt. rend.*, 112, 248—251).—The accumulation of starch in leaves of the Conifera is not dependent on the intensity of the illumination that particular leaves have received. In the case of the pines, firs, and Epicea, it is greatest in April and May; from June to mid-August the quantity is greatest in the young leaves, and is almost entirely localised in that face of the leaf which is in shadow. Sometimes the leaves in the shade contain more starch than those which are most exposed to sunlight. From the middle of August to the end of September, the quantity of starch in the leaves varies greatly with the species, but is always very low. In October the quantity is still low, but under favourable conditions of light increases somewhat, its distribution being very irregular. The quantity of starch that can accumulate in the leaves is determined by the ratio of the rate at which it is formed to the rate at which it is used.

up by the plant, also by the ease with which it can migrate into other parts of the plant, and by other causes at present not clearly made out. C. H. B.

Action of the Diastase Ferment on Starch Grains within the Plant. By G. KRABBE (*Bied. Centr.*, 20, 61—63; from *Jahrb. wiss. Bot.*, 21, 520).—As opposed to the view that the diastase ferment penetrates into the substance of the starch grain, and extracts it like an acid, the author considers that even in the cases where channels are found in the grains, the starch remains unchanged outside the hollows which are formed. The particles of ferment consist, not of molecules but of groups of molecules, much too large to penetrate between the starch mycellæ. Diffusion and other experiments indicate that diastase has not the power of migrating from cell to cell, but it must always first be formed at its place of action. Attention is drawn to the sweetening of potatoes, which is caused by the activity of the protoplasm, and the using up of the sugar being only very slight at 0° to 6°, whilst the action of the diastase in converting starch into sugar continues, and causes an accumulation of sugar.

It is concluded that the action of diastase is a chemical and physical one, comparable with the action of solvents on crystals.

N. H. J. M.

Formation of Phloroglucinol in Plants. By T. WAAGE (*Chem. Centr.*, 1890, ii, 1017—1018; from *Pharm. Zeit.*, 35, 694).—The author considers that the starch is converted in plant life into a monose, 1 mol. of water being absorbed. On the other hand, monose may lose 1 mol. of water forming starch, or 3 mols. of water forming a secondary, or pseudo-phloroglucinol, which forms a *trioxime*, $C_6H_3(NO_2)_3$. The author has experimentally proved that dextrose is converted in the leaf into normal phloroglucinol, by placing one end of a leaf strip (cut through so that the liquid can enter the veins) in water, and the other in a solution of grape sugar. It was kept in the dark for six days, after which period phloroglucinol was found in the water. Moreover, phloroglucinol was not found in the chlorophyll, but only the cell-sap, and principally at those parts where the life-process was most energetic. The author considers that phloroglucinol combines with 1 mol. of carbonic anhydride, forming phloroglucinolcarboxylic acid,

and that 2 mols. of this part with 1 mol. of water, forming diphloroglucinoldicarboxylic acid.

The author does not consider that phloroglucinol is a food to the plant, since, in autumn, when the leaves fall, it remains in them, and does not recede with the nitrogenous substance and the starch into the stem; on the other hand, he does not consider it a true excretory substance, since from it several substances, such as ethereal oils and sugary juices, are formed. From phloridzin, by the action, first of acid, and then of alkali, the author obtained glucose and phloretin, and from the latter, phloroglucinol and phloretic acid; and by similar

means he obtained from quercitrin, isodulcitol and quercetin; and from the latter, phloroglucinol and quercetic acid. J. W. L.

Presence and Function of Sulphur in Plants. By BERTHELOT and G. ANDRÉ (*Compt. rend.*, 112, 122—125).—The plants investigated were *Sinapis alba*, *Camelina sativa*, *Allium cepa*, *Lupinus alba*, *Urtica dioica*, *Tropaeolum majus*, *Avena sativa*, the total sulphur, sulphates, organic sulphur, and volatile sulphur being determined in the seed, and in the plant during germination, flowering, and fructification. In the case of *Sinapis alba*, these determinations were made separately in the stalks, leaves, and other parts of the plant.

The total quantity of sulphur increases continually from germination to inflorescence, but the relative quantity is about one-third higher in the earlier stages of growth. The organic sulphur reaches a maximum when the plant is in flower, and afterwards decreases. Since organic sulphur is found in the roots, especially during the time of flowering, it is probable that the sulphur is not absorbed from the soil entirely in the form of sulphates. The proportion of the two forms of sulphur in the seeds varies considerably in different species. The final reduction of the proportion of organic sulphur is due partly to elimination in the form of volatile compounds, and partly to reoxidation during fructification. C. H. B.

Fats obtained from the Fungi *Lactarius vellereus* and *L. piperatus*. By GÉRARD (*J. Pharm.* [5], 23, 7—12).—The fats yielded by these plants are chemically identical. They were found to contain oleic and stearic acids, both in the free state and combined as glycerides; the volatile acids, formic, acetic, and butyric; some, cholesterol and lecithin. The cholesterol does not differ from animal cholesterol, and appears to be identical with *ergosterin* obtained by Tanret from ergot of rye. J. T.

Constituents of the Seed Pods of *Pisum sativum* and *Phaseolus vulgaris*. By A. LIKIERNIK (*Ber.*, 24, 187—188). A compound has been isolated from the seed pods of *Pisum sativum* which agrees in properties with phytosterol.

From the seed pods of *Phaseolus vulgaris*, a mixture of two substances is obtained, which may be separated by fractional crystallisation from dilute alcohol; the more insoluble is termed *paraphytosterol*, the other *phasol*.

Paraphytosterol belongs to the cholesterol group, and crystallises with 1 mol. H_2O in broad, lustrous plates melting at 149—150°. In chloroform solution, the rotatory power is $[\alpha]_D = -44.1^\circ$; the formula appears to be $C_{27}H_{46}O$, or $C_{28}H_{44}O$.

The *benzoate* crystallises from ether in dull, thin prisms.

Phasol, $C_{28}H_{44}O$, crystallises in small, lustrous, anhydrous plates, melts at 189—190°, and has a rotatory power $[\alpha]_D = +30.6^\circ$; on treatment of a chloroform solution with sulphuric acid, a purple-red coloration is produced. *Phasol* appears to belong to the same homologous series as cupreol and quebrachol. J. B. T.

Root Nodules of the Pea. By A. PRAZMOWSKI (*Landw. Versuchs-Stat.*, 37, 161—238, and 38, 5—62).—The first paper commences with a review of the results of other investigators, and of the views held by them regarding root nodules. Schindler (*Bot. Centr.*, 18, 84) was the first to suggest that the nodules might be symbiotic formations between the leguminous plant and soil organisms. Brunchhorst (*Der. bot. Ges.*, 3) considers the nodules to be normal formations, in which albuminous substances in the form of bacteroids are accumulated; that the bacteroids serve the plant in some way, and that when they have performed their service they are resorbed by the plant. These views, which are generally accepted, are founded on microscopical observations only. Beyerinck (*Bot. Zeit.*, 46) succeeded in cultivating in artificial media, bacteria obtained from the nodules of several *Leguminosæ*, and concluded that these bacteria give rise to the production of nodules; and further, that the bacteria within the nodules, after increasing in numbers, become converted under the influence of the cell plasma into bacteroids (that is, metamorphic bacteria), which have lost the power of propagation, and which are finally resorbed by the plant.

In the author's first experiments (1885), peas and beans were grown in rich garden soil, in the same soil sterilised, and in the sterilised soil with the addition of garden soil extract. Nodules appeared in the roots of all the plants except those of the sterilised and non-infected soil. Other experiments, in which the same plants were grown in washed sand, under different conditions as regards sterilising, &c., gave similar results. Pure cultivations of the nodule organisms were then made, and peas grown in sterilised sand infected with them; in every case numerous nodules were produced. The bacteria, when in contact with the cell plasma of the roots, undergo successive changes; first, they assume the forked shape of the bacteroids; at a later period the substance of the bacteroids is found to contain strongly refractive grains (Lundstroem, *Bot. Centr.*, 33, and Beyerinck, *Bot. Zeit.*, 1888, 735), which are shown by their behaviour towards reagents to have the properties of proteids. This albuminous substance is subsequently resorbed by the plant. But only a portion of the bacteria undergo these changes; others multiply, and on the death of the plant, or when the nodule is injured by insects, &c., return in increased numbers to the soil. The production of the proteids and their resorption by the plant indicate that the bacteria are of use to the plant in supplying certain necessary food-constituents. It was observed that the nodules of plants growing in rich soil retain their freshness and red colour to a much later period than those of plants growing in sand.

The second paper commences with an account of the different ideas held regarding the biological meaning of the root nodules. Whilst Woronin, Eriksson, Kny, Frank (1879), and Prillieux held them to be a kind of disease, all other investigators associated the existence of the nodules with the fact that leguminous plants have the power of acquiring nitrogen from sources which are not available to other plants. De Vries, on the strength of microscopical observations, assumed them to be organs in which nitrogenous compounds taken

up by the leaves and roots are converted into proteids, a view also held by Schindler (*J. Landw.*, 33). According to Brunchorst (*loc cit.*), the nodules convert the organic matter of the soil into proteids; inorganic nitrogen compounds are assimilated by the plant without their intervention. Tschirch (*deut. landw. Presse.*, 1886) thinks the nodules store up albumin which is afterwards required by the plant when ripening. He attributes the enriching of surface soil in nitrogen by the growth of leguminous plants to the bringing up of subsoil nitrogen collected in the root-nodules. The author next discusses Hellriegel's results, which he accepts, as far as they go, whilst maintaining that some of his conclusions, which may be correct, cannot be considered as final without further evidence. In the author's experiments, sterilised sand was used, and great care was taken to maintain the state of sterilisation throughout the experiment. The plants were infected with pure cultivation of nodule-bacteria, grown in non-nitrogenous nutritive solutions. The pots had well-fitting covers, with four holes: a centre hole for the plant, and three others, into which glass tubes were cemented for supplying nutritive solution and sterilised air. One of the chief points of interest during growth was the observation that about 2—3 weeks after sowing the infected plants became unhealthy-looking, as compared with the non-infected plants; but after the fifth week, the infected plants became the stronger, and from this time to the end of the experiment remained healthy. In the water-culture experiments described below, it was found that the unhealthy period in the growth of the infected plants was coincident with the first appearance of nodules, and that the period of renewed vigour was coincident with the first emptying of the nodules. Returning to the sand-culture experiments, nodules were found in the roots of all the infected plants, and *vice versa*. The sand was examined at the end of the experiments, to ascertain whether other organisms than those added had got in. It was found that in the first series of experiments (pots 1 to 4 in table), owing to some defect, all the pots contained foreign organisms. In the second series (pots 5 to 9), the sand of pots 5, 6, and 8 remained free from foreign organisms, and that of 3 and 5 contained only a mould-fungus as impurity. There were fewer nodules where nitrate was applied than where not, but the nodules in the nitrate pots were better formed than the others.

The following table shows the amount of produce and the initial and final amounts of nitrogen in the sand culture experiments:—

	Dry produce (grams).	Length of stems (cm.).	Nitrogen.				
			Seeds sown.	Above ground growth.	Roots.	Whole plant.	Gain* or loss.
1. Not infected; nitrate	4.6310	106.7	0.012	0.1263	0.0080	0.1313	?
2. Infected; nitr- ate	6.0486	112.0	0.012	0.1688	0.0162	0.1850	?
3. Not infected ..	1.1660	97.7	0.012	0.0090	0.0042	0.0132	0.0012
4. Infected.....	3.5445	109.3	0.012	0.0680	0.0146	0.0826	0.0706
5. Not infected; nitrate	3.5492	103.2	0.009	0.0827	0.0065	0.0892	?
6. Infected; nitr- ate	5.2380	108.6	0.009	0.1145	0.0134	0.1579	?
7. Not infected ..	0.4124	36.4	0.009	0.0051	0.0021	0.0072	-0.0018
8. Infected.....	2.1755	92.0	0.009	0.0185	0.0098	0.0583	0.0193
9. „	1.6324	69.8	0.009	0.0319	0.0078	0.0397	0.0277

The water-culture experiments were made especially to test the accuracy of Brunchorst's view, that in water-culture the nodules have no function, an opinion which Hellriegel was also inclined to adopt (*Zeits. Ver. Rübenzuck.-Ind.*, 1888, 172). The results (water-culture) of the experiments do not support this view, being similar to those of the sand-culture experiments, although the assimilation of nitrogen was less than in sand. The numerical results are as follows:—

	Dry produce (grams).	Length of stem (cm.).	Nitrogen (grams).		
			Seeds sown.	Total produce.	(Gain or loss.
1. Infected; nitrate ...	4.9383	112.6	0.0090	0.1137	?
2. Not infected; nitrate	6.1436	132.8	0.0090	0.1746	?
3. Infected; nitrate...	4.5444	116.0	0.0090	0.1436	?
4. Not infected; nitrate	6.0133	132.8	0.0090	0.1914	?
5. „ „ no nitr- ate	0.4162	36.6	0.0090	0.0090	0.0000
6. Not infected; no nitr- ate	0.4721	45.0	0.0090	0.0085	-0.0005
8. Infected; no nitrate	1.0712	93.0	0.0090	0.0264	0.0174
9. „ „	2.2739	103.9	0.0090	0.0825	0.0735
10. „ „	1.0826	88.4	0.0090	0.0321	0.0231
11. „ „	1.1832	102.8	0.0090	0.0275	0.0185

* With regard to the pots which had nitrate, although the amount of nitrate in the nutritive solution is given, the exact amount of solution actually used is not. Moreover, the amount of nitrogen in the sand at the end of the experiment was not determined, so that the gain of nitrogen or loss (if any) cannot be ascertained.—N. II. J. M.

The most important conclusions are the following:—

1. The root nodules are symbiotic formations, which derive benefit from the plants by obtaining nourishment from them, and are thus enabled to propagate themselves, and on the death of the plant to return in greatly increased numbers to the soil.

2. The symbiosis is of use to the plant by enabling it, under the influence of the bacteria, to feed on atmospheric elementary nitrogen.

3. Inasmuch as only plants provided with nodules can acquire nitrogen from the free nitrogen in the air, it follows that the assimilation takes place with the intervention of the nodule bacteria.

4. The coincidence of the recovery of the infected plant from its state of weakness with the emptying of the oldest nodules, taken together with the changes which the bacteria were found to undergo within the nodules, indicate that the plant only derives benefit from the symbiosis when it has overpowered the bacteria, and that the resorption of the products of the bacteria is the main cause of the increased production of the plants.

5. The resorption of the bacteroids is the means by which the plant obtains atmospheric nitrogen.

6. Starch is present in the nodules in considerable quantity, as long as they possess vitality, and is directly taken up by the bacteria; it is probable that the bacteria are built up from this starch and elementary nitrogen.

7. In the absence of other sources, the nodule-bacteria (in pure cultivations) are able to assimilate free nitrogen, although to a much less extent than when in symbiosis with the plant (compare this vol., p. 358).

In a postscript the author criticises Frank's paper "On the Fungus-symbiosis of the Leguminosæ" (*Ber. deut. bot. Ges.*, 7).

N. H. J. M.

Nitrogen Compounds in Vegetable Soils. By BERTHELOT and G. ANDRÉ (*Compt. rend.*, 112, 189—195).—The authors have subjected vegetable soil to the action of acids and alkalis of various degrees of concentration for various periods of time. The soil used contained 19.10 grams of organic carbon and 1.669 grams of nitrogen per kilo., and if the nitrogen is regarded as existing in the soil in the form of proteid compounds, the particular soil contained approximately 1 part of proteids to 3 parts of humous compounds.

The action of cold concentrated aqueous potash indicated the existence of two groups of nitrogen compounds, one being much more easily decomposed than the other. The action of warm, dilute, aqueous potash results in a continual evolution of ammonia. In 26 hours at 100°, the alkali made 93.6 per cent. of the nitrogen soluble. Practically the same result was obtained by first treating with alkali, and afterwards with acid, and a slightly lower result by the action of acid followed by alkali. It would seem that several reactions take place simultaneously under the influence of the alkali. The nitrogen compounds at first split up and become soluble, but when the action is prolonged, the soluble products gradually lose

nitrogen in the form of ammonia or soluble amides, and again form insoluble nitrogen compounds. The latter are not stable, but gradually decompose and again become soluble. C. H. B.

Volatile Nitrogen Compounds evolved from Vegetable Soils. By BERTHELOT (*Compt. rend.*, 112, 195—197).—Clay soils kept moistened gradually lose nitrogen in the form of volatile products, but if the same soil is kept dry, the loss, although recognisable, is very much smaller. The nitrogen evolved in the form of volatile nitrogen compounds is greater than that evolved at the same time in the form of ammonia, a result contrary to that obtained with vegetable soils. It is probable that the evolution of volatile nitrogen compounds is intimately connected with the life of microbes or low vegetable organisms. C. H. B.

Formation and Properties of Humus. By P. A. KOSTYCHENKO (*Ann. Agronom.*, 17, 17—38; from *Trav. Soc. Naturalistes St. Petersburg*, 20, 1889).—The chief results of the author's study of the black soils of Russia are discussed in this paper. The decay of vegetable matter is brought about by attacks of moulds and bacteria, the former alone causing the production of dark-coloured matters. A characteristic of humus is its richness in nitrogen, the humus of the black Russian soils containing from 4.00 to 6.65 per cent. of that element, whereas meadow hay contains only 1.62 per cent., and clover in flower 2.00. When some hay from this land (composed of *Festuca ovina* and *Koeleria cristata*), containing 100 parts dry matter, was moistened with 75 parts of water and allowed to decay under a bell-glass, air being injected every day, it was found that in six months the dry residual matter weighed only 62.25 parts. There was no loss of nitrogen, 1.2711 parts being found as against 1.2700 at the commencement, but the percentage of nitrogen had risen from 1.27 to 2.04. Similar experiments made with oak, elm, and other leaves gave analogous results; little or no ammonia is formed, and no nitric acid, and the loss of nitrogen is in general *nil*. As hay and leaves contain proteids, and these quickly decompose with production of ammonia, it follows that this ammonia must be reconverted into other forms, and this is done by the agency of the living organisms, which find their nourishment in the decaying matter. The nitrogen is in fact reconverted into proteid compounds, and not into simpler combinations; thus, of the 2.04 per cent. of total nitrogen found in the decomposed hay, 1.893 was present as proteid, and only 0.149 per cent. as amidated compounds. Ammonia and amides when formed serve as nutriment to moulds, in the protoplasm of which their nitrogen is stored up, and this, decomposing in its turn, serves as food to bacteria, which still retain the nitrogen in proteid combinations. Sometimes, as in decaying oak leaves, the form of the leaf is preserved, but almost the whole structure is transformed into a mass of ramifying and interlacing mycelium. The soil, with its estimated 60 millions of organisms per gram, must contain much nitrogen in the proteid form, and one set or other of organisms will predominate according to variation in the conditions; thus, if soil is

moistened and kept under a bell-glass, masses of mould are quickly produced throughout. In general, the first development in decaying vegetable matter is that of bacteria, the reaction of the medium becoming acid; then follows the decay of these, the ammonia produced neutralising the acid, and moulds growing in the neutral medium; afterwards bacteria and moulds develop together. Thus humus always contains easily decomposable matter, and consequently the rate of decomposition observed at any period of the decay is nearly the same. Experiments on the rapidity of decomposition of humus from the black soils and humus from soils further north, made by moistening equal weights to an equal extent and measuring the carbonic anhydride produced *per diem*, show that the rate of decomposition is the same in each. In humus produced above the water level, all trace of vegetable structure is destroyed by the leaves being gnawed and passed through the bodies of earthworms, caterpillars, wireworms, &c.; under the water level, the vegetable structure is preserved, and peat results. Experiments with dead leaves pulverised by the action of these animals, in comparison with the same leaves not attacked by them, show that little or no influence on the rate of decay results from their action. After passing through their bodies, the organic matter is still fit to nourish moulds and bacteria, and when these have multiplied sufficiently to accumulate a fresh stock of protoplasm, earthworms, &c., attack it again, and so destroy all trace of structure. The soil of the black lands is permeable to a small depth only by water, and this circumstance retards decomposition and accounts for the accumulation of humus. The decay of humus is fastest in the best drained and most open soils; for this reason the presence of clay in a soil promotes accumulation of humus. Woods promote drainage by loosening the soil and abstracting water, and hence in plantations accumulation of humus is retarded, and the earth becomes lighter in colour. Inferior organisms are the means of diffusing organic matter throughout the soil; the mycelia of fungi, for instance, growing on a dead root, ramify laterally, and thus carry organic matter a little way outward; succeeding organisms extend this action, and the soil becomes darkened in proportion. The humic acid of the black earth is almost exclusively in combination with lime; this lime is, according to the author, carried to the insoluble humus as acid carbonate dissolved in water, and the acid carbonate is decomposed by contact with the moist humus. To the observation that vegetable matter is blackened under the attacks of moulds and not of bacteria, the author adds that some fungi have the power of blackening humus, but in other cases they simply change the reaction from acid to alkaline, when the blackening is produced by atmospheric oxidation, as in the similar case of pyrogallol.

J. M. H. M.

Economy of Phosphoric Acid in the Growth of Beetroot.
By M. MAERCKER (*Bied. Centr.*, 20, 4—11; from *Magd. Zeit.*, 1890).
—The object of the paper is to show the fallacy of the view that in the growth of beetroot heavy manuring with phosphates is necessary in order to compensate for the amounts removed by the crop. In the first place, beetroot is a crop which does not require a great amount

of phosphate; an average crop will withdraw from the soil 23.8 lbs. per acre; an average potato crop removes 28 lbs. per acre. Then, again, by far the greater part of the phosphate so taken up will be returned to the soil in the form of diffusion-residues, &c. As much as 91.1 per cent. may be returned. From examples given, it is shown that the average actual loss of phosphoric acid, that is, the amount removed by the crop minus that contained in the waste products which are returned from the sugar works, is about 10.6 to 12.3 lbs. per acre. This is very nearly compensated for by keeping cattle. One beast, consuming 5.5 lbs. of such food as oil cake and rice meal, &c., will yield 50 lbs. of phosphoric acid yearly. At the rate of one beast to five acres, this will correspond with 10 lbs. per acre. A further amount of phosphates will be derived from the hay consumed. It is thus seen that the large amounts of phosphates usually applied are unnecessary. There is no evidence to show that the excess of phosphoric acid has any effect on the quality of the roots.

The usual manuring with farmyard manure gives more phosphoric acid than the beetroot removes, and any further amount of phosphates added must be useless.

Extensive experiments are being made at the author's suggestion, and, until further evidence is obtained, he proposes that 17.6 lbs. of soluble phosphoric acid per acre should be given, except when the farmyard manure is preserved by phosphate gypsum.

With regard to the preservation of farmyard manure, phosphoric acid should be much more extensively employed. The loss of nitrogen from one head of cattle in a beetroot farm may be as much as corresponds with 2.70 cwt. of Chili saltpetre; 60.5 lbs. of phosphoric acid is sufficient to prevent this loss. With the average number of cattle (one to 5 acres), and the average loss of phosphoric acid (10.6—12.3 lbs. per acre), it happens that for the preservation of the farmyard manure exactly the same amount of phosphoric acid is required as is contained in the beetroot products which are sold.

Analytical Chemistry.

Weighing Dried Filters. By F. RÜDORFF (*Zeit. ang. Chem.*, 1890, 633).—The filters are dried in cylindrical vessels 75 mm. high and 34 mm. in diameter, with ground caps. After 30 minutes in the oven, the vessel is removed, capped, and allowed to cool without using a desiccator for exactly 30 minutes, the last 10 minutes being in the balance case. After collecting the precipitate, it is dried at 100° in the funnel, and then for 30 minutes in the same way as the empty filter. A constant weight is very soon obtained.

M. J. S.

A New Method of Estimating Uncombined Hydrochloric Acid in Gastric Juice. By A. JOLLES (*Monatsh.*, 11, 472—481).—

The fluorescence of a neutral solution of eosin is scarcely affected by the presence of considerable quantities of organic acids, whilst it is instantly removed by the addition of only a very minute quantity of hydrochloric acid. On spectroscopic examination, the neutral solution of eosin shows two black bands in the blue-green portion of the spectrum; these bands are greatly intensified in presence of alkalis, but if a few milligrams of hydrochloric acid is added to the solution they instantly disappear, whilst they are, however, unaffected by the addition of several grams of lactic, butyric, acetic, or formic acids.

The author makes use of the preceding facts in the following way:—1 c.c. of a solution of eosin (0.01 gram) in water (100 c.c.) is added to 100 c.c. of the solution under investigation, and the mixture titrated against aqueous alkali in a vessel with plain, parallel sides, so that the formation of the black bands may be spectroscopically determined. The quantity of hydrochloric acid, expressed in milligrams, contained in the solution which has been titrated is given by the equation $x = n \cdot a + c$, where n is the number of c.c. of alkali added, a the hydrochloric acid in milligrams which neutralises 1 c.c. of the alkali solution, and c a constant, depending on the thickness of the layer of the fluid and the concentration of the eosin solution used. When the solution is 40 mm. in depth, and contains the above given quantity of eosin, the constant is 20; that is to say, the addition of 20 milligrams of hydrochloric acid is necessary in order to make the absorption-bands disappear in a solution containing one-tenth of a milligram of eosin in 100 c.c. of water. The delicacy of the method is not affected by the presence of chlorides or phosphates, albumin, peptones, pepsin, or by lactic, butyric, acetic, or formic acid. In presence of these substances, so small a quantity of hydrochloric acid as 10 milligrams (0.01 per cent.) can be estimated with precision.

(I. T. M.)

Potassium Iodate as Original Standard for Iodometry, Acidimetry, and Alkalimetry. By M. GRÜGER (*Zeit. ang. Chem.*, 1890, 385—386, see this vol. p. 360).—The facility with which pure potassium iodate is prepared renders it an admirable basis for iodometric analysis. Sublimed iodine is dissolved in hot, pure, moderately strong potash as long as it does not colour the solution. The liquid is evaporated to dryness, and the residue exhausted with alcohol. The undissolved portion is repeatedly crystallised from hot water, until it no longer affects sensitive litmus paper, or gives a blue colour with sulphuric acid and starch. The alcoholic solution is used for the preparation of potassium iodide; for this purpose it is evaporated to dryness, the residue dissolved in water, and iodine added to strong yellow coloration; hydrogen sulphide is then passed through the liquid, the filtered solution evaporated, and the iodide crystallised until pure. A permanent iodine solution for standardising thiosulphate may be made by dissolving accurately weighed iodine in an excess of pure potash, and diluting to a known volume. The solution can be preserved unchanged, and the iodine liberated at any time by adding excess of acid.

M. J. S.

Potassium Bromide as Indicator in Chlorimetry. By G. DENIGÈS (*J. Pharm.* [5], 23, 101—103).—To avoid the use of alkaline solutions of arsenious anhydride, which do not remain constant, the more permanent hydrochloric solution may be prepared thus:—To 4.44 grams of arsenious anhydride 10 c.c. of soap solution are added and 100 c.c. of water; after a few minutes contact and agitation, the solution is complete in the cold; 500 c.c. of water and 100 c.c. of hydrochloric acid are then added and the mixture shaken again; finally it is made up to 1 litre, and again shaken. To make an estimation, 10 c.c. of the standard solution is placed in a flask, some drops of a concentrated potassium bromide solution added, and then the chlorine solution until a slight yellow tint just persists. This is much more convenient than the addition of sulphate of indigo.

J. T.

Technical Valuation of Bleaching Powder. By L. VANINO (*Zeit. ang. Chem.*, 1890, 509—510).—A rapid and fairly accurate estimation of the value of bleaching powder can be obtained by treatment with hydrogen peroxide, causing the oxygen evolved to displace water from a receiver, and measuring the water expelled. The weighed substance (2 grams), finely ground with water, is placed in a small flask; the hydrogen peroxide in a stopcock bulb, of which both the upper and lower ends are connected with the flask, so that no alteration of volume occurs when the liquid is admitted to the flask. The gas-evolution tube is connected with one neck of a Woulff's bottle full of water. Through the second neck passes a thistle funnel reaching nearly to the bottom of the bottle. Through a tubulure near the bottom passes a tube which, being bent at right angles, can be depressed by rotation in the cork until water begins to escape. On mixing the hydrogen peroxide with the bleaching powder, a quantity of water flows out equal in volume to the oxygen liberated. The tables published by the author (this vol., p. 246) allow the percentage of oxygen or chlorine to be read off without calculation.

M. J. S.

Estimation of Fluorine. By H. OFFERMANN (*Zeit. ang. Chem.*, 1890, 615—618).—The author gives a somewhat full recapitulation of the methods hitherto proposed, and then describes the following process, which, unlike some older ones, is equally serviceable when organic substances, carbonates, or chlorides are present. It is based on the expulsion of the fluorine as silicon fluoride, which, being then decomposed by water, yields hydrofluosilicic acid, which can be titrated with an alkali. The substance is mixed with 15 parts ignited quartz powder, and placed in a 200 c.c. flask furnished with tubes for the admission of air and escape of gas, and with a funnel tube for introducing sulphuric acid. Air, dried and freed from carbonic anhydride, is passed into the flask at the rate of about two bubbles per second. The escaping gases pass over sulphuric acid in a second similar flask, in which a thermometer is inserted. Both flasks stand on the same hot plate, and are heated to 150—160°. The gases next pass through an empty U-tube, then through one containing fused calcium chloride and pumice saturated with anhydrous copper sulphate, and thence through a tube reaching to the bottom of a

beaker, containing enough mercury to form a lute, and about 150 c.c. of water. The tube is liable to get stopped up. When the decomposition is complete, cochineal tincture is added to the liquid in the beaker and then standard alkali to a distinct alkaline reaction. 1 c.c. of normal alkali equals 0.019 gram of fluorine. M. J. S.

Gasometric Absorption of Oxygen. By L. L. DE KONINCK (*Zeit. ang. Chem.*, 1890, 727—728).—A solution of ferrous tartrate in excess of alkali absorbs oxygen with great rapidity, and is free from the inconveniences of many of the reagents proposed for that purpose. Three solutions are made, containing : (A) 40 grams of crystallised ferrous sulphate ; (B) 30 grams of sodium potassium tartrate ; (C) 60 grams of potash, each made up to 100 c.c. with water. One volume of A is poured into five volumes of B, and then one volume of C is added. A clear solution is thus obtained, which, when used in a Hempel's gas burette, absorbed the oxygen from 50 c.c. of air completely in four minutes, and in four experiments gave results comprised between 20.8 and 21.2 volumes per cent. M. J. S.

Estimation of Oxygen Dissolved in Water. By G. LIMOSIER (*J. Pharm.* [5], 23, 103—106).—The oxygen is absorbed by ferrous tartrate in alkaline solution, phenosafranin being used as indicator. A 500 c.c. flask, provided with a glass tap at the bottom, is charged with about 400 c.c. of mercury, 20 c.c. of sodium hydroxide solution of 36° B, 20 c.c. of a 20 per cent. solution of potassium sodium tartrate, a drop or two of alcoholic solution of pure phenosafranin, and finally water, to completely fill it. A caoutchouc stopper with two holes is placed in the neck, care being taken to exclude all air bubbles, and in one of the holes is inserted the jet of a burette previously completely filled below the stop-cock with standardised ferrous sulphate, and the other hole receives the tube of a stoppered funnel, the tube of which has been primed with the water to be examined. The whole should be perfectly tight, so that on opening the lower stop-cock no mercury runs out. Ferrous solution is now added drop by drop, until the rose tint just disappears ; then 50 c.c. of the sample is placed in the funnel and passed carefully into the flask, and ferrous solution is again added to the same point as before. After the apparatus is once prepared, several estimations can be successively made without renewing the solutions contained in the flask ; a fresh portion of the sample is added and more ferrous sulphate until the mercury is run out. Three estimations of the same sample should be made and the last one taken. To standardise the ferrous solution, water which has been in prolonged contact with air should be employed ; when its temperature and the height of the barometer are known, the amount of oxygen dissolved can be obtained from the known solubility of oxygen. A convenient solution contains 3 grams of ferrous sulphate and 10 c.c. of sulphuric acid per litre. Nitrates and nitrites do not affect the result. Substances like glucose which exert a strong reducing action in alkaline solution are the only obstacles ; the results are not affected by the addition of urine, albumin, or infusion of vegetable earth. J. T.

Volumetric Estimation of Sulphur Dichloride. By G. A. LUN ROY (*Chem. Centr.*, 1890, ii, 1027; from *Mon. Sci.* [4], 4, 1115—1116).—The following method is recommended by the author:—A weighed or measured quantity of the sulphur dichloride of commerce is added to a measured volume of sodium hydroxide of known strength. The dichloride is decomposed into sodium sulphide, thio-sulphate, sulphite, sulphate, and chloride, and free sulphur. The latter is readily dissolved by boiling the alkaline liquid. It is then cooled and hydrogen peroxide added, and the liquid gently warmed, whereby the sulphur and lower sulphur compounds of sodium are oxidised to sulphate. The excess of hydrogen dioxide is destroyed by boiling. The excess of alkali is now determined volumetrically, as also the chlorine, from which data the amount of sulphate corresponding with the sulphur in the sulphur dichloride is calculated.

J. W. L.

Purification of Sulphuric Acid for Kjeldahl's Process. By G. LUNGE (*Zeit. ang. Chem.*, 1890, 447—448).—The success obtained by Meldola and Moritz in purifying sulphuric acid from ammonia by heating with potassium nitrite (*Abstr.*, 1888, 628) was due to their using a quantity of nitrite almost exactly equivalent to the ammonia to be removed, so that no excess of nitrogen trioxide remained to be boiled out. The author shows by fresh experiments, as well as by reference to the known facts of sulphuric acid manufacture, that nitrogen trioxide cannot be boiled out from concentrated sulphuric acid, but, in consequence of the formation of the very stable nitrosyl sulphate, actually concentrates in the residue left after boiling down the strong acid.

M. J. S.

Estimation of Nitric Nitrogen by Aluminium. By A. STUFZER (*Zeit. ang. Chem.*, 1890, 695).—The conversion of nitric acid into ammonia by the action of aluminium and an alkali is one of the most convenient modes of estimating it, but it fails altogether with certain specimens of aluminium, which, there is reason to believe, are not made by the use of sodium. It is suggested that there may be traces of sodium in the aluminium made by the older process, and that their presence may be a condition of its suitability.

M. J. S.

Estimation of Nitric Acid by Reduction to Ammonia. By K. ULSON (*Chem. Centr.*, 1890, ii, 926—927).—The nitric acid is reduced by means of finely divided iron and dilute sulphuric acid. Not more than 0.5 gram of nitrate is introduced into a half-litre flask, dissolved in 25 c.c. of water and 10 c.c. of dilute (2:1) sulphuric acid and 5 grams of *ferrum hydrogenu reductum* added. The flask is then gently heated with a small flame, which, as the reaction moderates, is increased so that after about four minutes from the commencement the liquid is brought to boiling.

During the reaction, the neck of the flask is closed by a loose, hollow, pear-shaped glass stopper, containing about 25 c.c. of water, which acts as a condenser.

After the reduction, 50 c.c. of water and 20 c.c. of aqueous soda (sp. gr. 1.25) are added, and the ammonia distilled off. The whole

process occupies from 15 to 20 minutes. The results are as follows: of six determinations of potassium nitrate, the highest was 13.89, the lowest 13.82 per cent. of nitrogen (theory = 13.86); of four determinations of sodium nitrate, the highest was 16.52, the lowest 16.43 per cent. of nitrogen (calculated 16.47); two determinations with barium nitrate gave 10.65 and 10.60 per cent. of nitrogen (calculated 10.73). Hydrochloric acid, as a substitute for sulphuric acid in the reduction process, does not give such accurate results, although the presence of chlorides does not seem to affect the accuracy at all.

J. W. L.

Iodometric Estimation of Nitrates and Chlorates. By L. I. DE KONINCK and A. NIHOUL (*Zeit. ang. Chem.*, 1890, 477—481).—When a nitrate is distilled with a sufficient excess of hydrochloric acid of the highest concentration, the metal is wholly converted into chloride, all the nitrogen is given off as nitric oxide, and the remainder of the oxygen is represented by an equivalent quantity of chlorine, which can be estimated by absorption in potassium iodide and titration of the liberated iodine. The vessel A is for the generation of hydrogen chloride by the action of concentrated sulphuric acid

on ammonium chloride (*Abstr.*, 1881, 138). B is for generating carbonic anhydride, which must be perfectly free from air. The substance is placed in C with a sufficient, but not excessive, quantity of water (2—3 c.c. per decigram). Potassium iodide, of which too great an excess should not be used, is placed in the Volhard absorbers D, D', and the end tube is either connected with the Schiff's azotometer E, filled with strong potash, in which the nitric oxide may be measured as a control, or is dipped under mercury. The air is now completely expelled from the apparatus, and hydrogen chloride is then passed into C until the water is saturated. A slow stream of both gases is maintained, and the contents of C are boiled until the yellow colour of the nitrosyl and nitroxyl chlorides has disappeared.

The contents of C may even be distilled to dryness. The last traces of chlorine are then driven over by a more rapid current of gas, and the iodine in I and D' is forthwith titrated by thiosulphate. Since differences corresponding with 0.1 c.c. of N/100 thiosulphate (equal to 0.02096 milligram of nitric acid) can be estimated, the process is applicable to very small as well as large quantities of nitrates. The presence of chlorides and bromides is not injurious. When iodides are present, the residue in C should be added to the solutions in D before titrating. Chlorates can be assayed by the same process.

M. J. S.

Estimation of Phosphoric Acid in Urine. By B. GUILLAUME-GENTIL (*Chem. Centr.*, 1890, ii, 893; from *Schweiz. Wochenschr. Pharm.*, 28, 327—332).—The author recommends the estimation of the phosphoric acid in urine by precipitating it with magnesia mixture in a graduated tube; from the volume of the precipitate, the amount of the phosphoric acid is calculated.

J. W. L.

Detection and Estimation of Boric Acid in Milk and Cream. By C. E. CASAL (*Analyst*, 15, 230—232).—The usual tests suffice for the detection of boric acid and borates in milk and cream, but for their estimation the milk or cream is rendered alkaline, evaporated and incinerated, and successive small quantities of methyl alcohol are distilled from the ash previously acidified with acetic acid. The distillate is collected on a known quantity of ignited lime, which is subsequently re-ignited and reweighed: the increase in weight is boric acid.

D. A. L.

New Method for Decomposing Silicates. By P. JANNASCH (*Ber.*, 24, 273—278).—In order to obviate the necessity of fusion with sodium carbonate, and, in estimating the alkalis, of solution with hydrofluoric acid and sulphuric acid, in the case of those silicates which are incompletely decomposed by hydrochloric acid under ordinary conditions, the author recommends that the finely-divided silicate should be heated at 190—200° with hydrochloric acid (4 : 1) for 10 to 12 hours. The substance and the acid are placed in a platinum tube (a diagram of which is given), closed with a platinum capsule, and enclosed in a sealed glass tube also containing hydrochloric acid; the whole of the air must be expelled from the platinum and glass tubes by a stream of carbonic anhydride before sealing the glass tube, otherwise a considerable quantity of platinum is dissolved by the acid, and even when the air is expelled, the solution obtained contains about 0.5 per cent. of this metal, which has to be removed by precipitation with hydrogen sulphide after separating the silica. Two analyses of a sample of labradorite were made; the results agree well with those obtained by the usual methods.

F. S. K.

Estimation of Inorganic Salts in Small Quantities of Blood. By G. N. STEWART (*Proc. Physiol. Soc.*, 1890, 18—21).—The method depends on the fact that the blood, so far as its electrical resistance is concerned, is practically a dilute solution of the inorganic salts in it. In dilute solutions of a single electrolyte, the resistance is in-

versely proportional to the strength of the solution. If the total amount of ash varies, and the relative proportions of the different salts do not vary, then it would be sufficiently accurate for the purpose to determine the ash by incineration once for all, and to measure the resistance of a standard tube of the same blood. The relation between resistance and ash would then enable one to calculate the latter from the former in any other case. Even if considerable variations in the relative proportions of the different salts occur, the resistance is found to correspond very fairly with the amount of inorganic material. Thick-walled glass tubes of uniform and fine internal calibre were used. The fine column of blood in these was, by non-polarisable electrodes, connected with a galvanometer, or by platinum wires to an electrometer. W. D. H.

Estimation of Zinc and Nitrogen in Pickled Railway Sleepers. By A. GRITNER (*Zeit. ang. Chem.*, 1890, 386—387).—For estimating the zinc, the wood may be incinerated alone in a platinum basin at a dull-red heat, over a bunsen burner, or more rapidly by mixing 10 grams of fine raspings with 5 grams of sodium carbonate and 2 or 3 of potassium nitrate, and cautiously burning in a platinum basin. The charred mass is treated with acetic acid, the undissolved matter with the filter returned to the basin, and completely incinerated. The ash is dissolved in acetic acid, and the solution filtered into the former solution. The solution is mixed with a little sodium acetate, and precipitated by hydrogen sulphide. After 12 hours, the precipitate is collected on a close-grained filter, washed with water containing hydrogen sulphide and a little acetic acid, and weighed as usual. Test analyses showed a very satisfactory approximation.

The nitrogen in wood is best estimated by Kjeldahl's method. The following results show considerably less nitrogen than found by either Chevandier or Weber:—

	Summer wood.	Winter wood.
Pine, 25 years old	0.160	0.185
Beech, 130 years old	0.189	0.176
Oak, 120 years old	—	0.179

The steaming to which wood is subjected before impregnating with preservatives reduces the nitrogen by about one-fifth.

M. J. S.

Detection of Traces of Copper in Distilled Water. By H. THOMS (*J. Pharm.* [5], 23, 27—29; from *Pharm. Centralhalle*, 1890; after *Mon. Sci.*, 1880).—Copper to the extent of 1 : 200,000 in distilled water gave no indication with either ammonia or potassium ferrocyanide, but with potassium iodide solution, a faint yellow colour appeared which gave a distinct blue tint with starch paste. A comparative test with pure distilled water showed no coloration with iodide.

J. T.

Volumetric Estimation of Cobalt. By M. A. v. RUBE and F. WIGBERT (*Zeit. ang. Chem.*, 1890, 695—696).—In presence of an excess of zinc oxide, cobaltous salts are oxidised to cobaltic oxide by

permanganate, but the end of the reaction cannot be observed since the precipitate refuses to subside. On adding an excess of permanganate, however, and titrating back with a reducing agent, the precipitate settles well and the colour of the liquid is easily seen. The values of the solutions must be ascertained empirically, as the reactions do not correspond precisely with the equations. The best results have been obtained by the following mode of procedure:—The cobalt solution is freed from sulphates by barium nitrate, and then from excess of acid either by evaporation or by neutralising with soda. The liquid is diluted to 300 c.c., mixed with a small excess of zinc oxide, and heated to boiling. An excess (5–10 c.c.) of standard permanganate is run in and the boiling continued for 10 minutes. 30 c.c. of zinc chloride solution (made by neutralising a 19 per cent. hydrochloric acid with zinc oxide) is added, and the excess of permanganate titrated back by arsenious acid. The results are fairly satisfactory, but the method is, perhaps, capable of improvement. M. J. S.

Elementary Analysis by an Electrothermal Method. By J. OSER (*Monatsh.*, 11, 486–500).—The substance to be burnt is placed in a porcelain boat surrounded by a coil of platinum wire, which is contained in an ordinary combustion tube. A stream of oxygen is passed along the tube, and at the same time the platinum wire is heated to redness by means of an electric current, the wires being kept insulated by passing through narrow apertures in a porcelain cylinder fitting into the tube. In order to insure perfect combustion, the decomposition products and the excess of oxygen are led through a narrow aperture in the porcelain cylinder filled with granular copper oxide and heated to a high temperature by an electrically ignited platinum wire which also passes through the canal. The author gives details of the precautions necessary to ensure satisfactory results by the method, and accompanies his description with the numerical results he has obtained, and a sketch of the apparatus employed. The ultimate object is to effect in one apparatus the elementary analysis and the determination of the heat of combustion of the substance. The description of the manner in which the latter is to be simultaneously effected is reserved for a later communication. G. T. M.

New Potash Apparatus for Use in Elementary Analyses. By A. DELISLE (*Ber.*, 24, 271–273).—The new apparatus, a diagram of which is given, consists essentially of a small glass cylinder containing potash, and provided with a bulbous inlet tube and an inverted U-shaped outlet. The stem of the inlet tube is fused into the top of the cylinder, and passes to within a short distance of the bottom of the vessel; attached to this tube, and a short distance apart, are two discs (made by blowing bulbs on the inlet tube and then compressing them) slanting slightly downwards so as to form conical partitions which do not quite reach to the circumference of the cylinder. When the apparatus is in use, air collects under the discs and the potash becomes separated into three layers by two air chambers, so that the gas passes through the liquid three times. The exit is an inverted

U-shaped removable tube, one end of which is ground into the cylindrical vessel, the other being drawn out to a smaller diameter; one half of this tube is filled with solid potash, the other with calcium chloride or soda-lime.

The apparatus is easily filled and emptied and its weight when filled for use is about 65 grams. F. S. K.

Estimation of the Inorganic Constituents of Soils. By BERTHELOT and G. ANDRÉ (*Compt. rend.*, 112, 117—121).—The authors emphasise their previous statements (Abstr., 1888, 120, 384, 743) that accurate analyses of soils cannot be made by mere treatment with acids, even after calcination. For estimations of alkalis, iron, and aluminium, an elimination of the silica is always necessary, and this is true also in many cases for the estimation of calcium and magnesium. No accurate or useful distinction can be made between silicates that are attacked by acids and those that are not attacked. The organic acids in plant-roots decompose silicates, and utilise their constituents, even though the same silicates offer considerable resistance to the action of inorganic acids. C. H. B.

Estimation of Fusel Oil in Spirits. By A. SLUTZER and O. REIMMAIR (*Zeit. ang. Chem.*, 1890, 522—531).—The authors have sought to modify Röse's process (Abstr., 1885, 600) so as to make it capable of estimating smaller proportions of fusel oil. The influence of temperature variations was eliminated by making all the readings at as near 15° as possible, and applying a correction of ± 0.01 c.c. for $\mp 0.1^\circ$. With regard to the pure alcohol required to furnish a datum line for the increments in the volume of the chloroform, it was found that when specimens, purchased as "*purissimum*," were fractionally distilled, both the early and late fractions gave higher values than the intermediate ones. A large apparatus was used in which 250 c.c. of alcohol and 50 c.c. of chloroform could be shaken and in which differences of 0.01 c.c. could be estimated, corresponding with 0.0028 per cent. of amyl alcohol, but the experimental errors were assumed to amount to about four times this quantity, so that (since spirits of high alcoholic strength have to be diluted to 30 per cent. before testing) 0.06 per cent. in the original spirit is the smallest quantity that can be estimated with certainty. On distilling a spirit which did not indicate more than 0.1 per cent. of amyl alcohol, with a sufficient excess of calcined potash, 900 c.c. could be distilled from a litre without an appreciable amount of the fusel oil passing over, whilst the whole of the amyl alcohol could be obtained in the last fraction by distilling to dryness, then adding 100 c.c. of water to the residue in the retort, and distilling again. In this way, anything exceeding 0.01 volume per cent. could be detected with certainty. When more than 0.1 per cent. is present, it begins to pass over earlier, so that with 0.5 per cent. even the first $\frac{1}{3}$ of the distillate is distinctly contaminated. In examining samples of high purity, the middle fraction should be used as the standard alcohol. The earlier fractions often contain substances which give a negative result. The spirit to be tested should first be distilled with potas-

sium hydroxide. A portion of the distillate is then accurately diluted to 30 vols. per cent. (0.9656 sp. gr. at 15°), and 250 c.c., with 2.5 c.c. of sulphuric acid of 1.286 sp. gr., shaken with 50 c.c. of chloroform. With pure alcohol, the volume of the chloroform will increase to 54.5 c.c. If more than 0.15 per cent. of fusel oil is indicated, it will be necessary to remain satisfied with the accuracy thus obtainable; if less is shown, one or more litres with 100 grams of dry potash per litre is slowly fractionated. The first half of the distillate is rejected, the remainder is collected in fractions of 100 c.c., and when distillation ceases 200—250 c.c. of water is added, and 100 c.c. more distilled by the heat of a paraffin bath. This is used to dilute the last alcoholic fraction. Each fraction is diluted to 0.9656 sp. gr. and 250 c.c. shaken with acid and chloroform as above. M. J. S.

Analysis of Dynamite. By SCHEIDING (*Zeit. anorg. Chem.*, 1890, 614—615).—It is usually only necessary to estimate the nitroglycerol and the moisture. The former is extracted with ether, and weighed after evaporating the ether and drying over sulphuric acid. Warming must be avoided, since even at 40° nitroglycerol volatilises perceptibly. The mineral constituents are infusorial earth and barytes, with small quantities of sodium carbonate, chalk, or magnesium carbonate. When other substances soluble in ether are present, the nitroso-nitrogen may be estimated by means of Lunge's nitrometer, or better by the Schulze-Tiemann modification of the ferrous chloride process.

In gelatin dynamite there are both nitroglycerol and nitrocellulose, besides potassium nitrate. On treatment with ether, the nitroglycerol is removed. Water then extracts the nitrate, together with sodium carbonate and other salts: a mixture of ether and alcohol (2 : 1) then dissolves (from the re-dried substance) the lower nitrocelluloses, and finally, any trinitrocellulose may be dissolved by ethyl acetate. There may remain wood meal, chalk or magnesia, and sometimes red bole or

barytes, the last of which must be regarded as an adulterant. For collecting the nitric oxide when using Schulze's process, the author recommends the form of eudiometer here figured. The narrow tubes are fused in at the bottom. M. J. S.

Potassium Mercurio-iodide as a Reagent for Aldehydes. By L. CRISMER (*J. Pharm.* [5], 23, 29—30; from *Deuts. Chem. Zeit.*, 1889, 81; after *Mon. Sci.*, 1890).—The aldehydes give a pale-yellow to brown or black precipitate, according to the concentration, with an alkaline solution of potassium mercurio-iodide. The addition of baryta water to the solution of mercury chloride in potassium iodide is preferable to the employment of soda or potash; still Nessler's reagent serves very well. Rectified commercial ether, for example, always contains aldehyde, even that distilled over sodium. To remove this impurity, the ether is agitated with increasing quantities of the reagent until no further precipitate is produced. After decantation, the ether is dried over potassium carbonate and distilled, when it boils at 34.5° to 35°, and has a density of 0.718 at 17.5°. J. T.

Acetone in Urine. By SALKOWSKI and T. TANIGUCHI (*J. Pharm.* [5], 23, 194; from *Répert. de pharm.*).—Urine is often found to contain acetone, which may be estimated by adding 10 c.c. of concentrated sulphuric acid to 300 c.c. of the urine and distilling as far as possible; to the distillate aqueous potash is added, then a solution of iodine in potassium iodide, and the mixture allowed to remain 24 hours. The iodoform is then collected, dried, and weighed. The acetone does not appear to pre-exist in the urine, but is formed by distillation with an acid, and the amount varies with the amount of acid added, and with the total amount of distillate. J. T.

Urochloralic Acid in Urine. By WAGNER (*J. Pharm.* [5], 23, 115—116°; from *Arch. Med. et Ph. milit.*).—About 20 c.c. of urine is passed through a moistened filter, half of it evaporated on the water-bath, acidified with sulphuric acid, cooled, and repeatedly agitated with fresh portions of a mixture of one volume of alcohol and two volumes of ether. After distilling, the residue saturated with a slight excess of potash is exhausted three times with boiling absolute alcohol. This solution, filtered, and perfectly limpid, is precipitated by a large excess of ether. After about 24 hours, the sides of the flask are covered by minute, white, crystalline tufts. The ether is carefully poured off, and the deposit is dissolved in cold water; after filtration, a few drops of the solution can be applied to show the reducing action of the acid on alkaline copper or bismuth solution, or on an ammoniacal silver nitrate solution. In each case, very decided reduction is obtained. This reduction may, however, be due to dextrose, so that further treatment is necessary. The alkaline liquid is slightly acidified with nitric acid, and freed from chlorides by slight excess of silver nitrate. The filtrate is boiled for two hours with excess of potash and five or six volumes of alcohol of 95°. After removing silver oxide and alcohol, nitric acid and silver nitrate give a perceptible precipitate of silver chloride, which gives the amount

of the chlorine derived from the urochloralic acid in the urine. 500 c.c. of a normal urine gave negative results. J. T.

Bleaching of Beeswax; Composition of White Wax. By A. BUISINE and P. BUISINE (*Bull. Soc. Chim.* [3], 4, 465—470).—In the bleaching of beeswax, light is the chief factor, since the bleaching goes on in a vacuum, or in an atmosphere of carbonic anhydride, nitrogen, &c., but ceases in the dark even in an atmosphere of ozone. Pure beeswax becomes brittle when bleached by exposure; and to prevent this, it is customary to add 3—5 per cent. of suet, which also expedites the bleaching process; the addition of turpentine oil has a similar effect. Other agents made use of are:—Potassium permanganate, potassium dichromate, hydrogen peroxide, and animal charcoal. The following table shows the alteration in chemical character suffered by the wax in the bleaching process (p. 626).

Compare this vol., p. 131.

T. G. N.

Modified Fat Extraction Apparatus. By J. S. EDKINS (*Studies from Physiol. Lab., Owens College*, 1, 239—241).—The apparatus described and figured is somewhat different from Drechsel's; the ether circulates more rapidly, and there is less fear of explosion as the ether is completely condensed before reaching the upper flask, instead of filling it with a mixture of cold condensed ether and hot ether vapour. W. D. H.

Estimation of Fat in Milk. By J. GORODETZKY (*Zeit. ang. Chem.*, 1890, 418—421).—On a comparison of Röse's method (*Abstr.*, 1888, 1135) with that known as the "sand process," in which three hours' extraction with ether was used for the latter, Röse's method gave almost invariably the higher results. The extraction was therefore prolonged to five hours, and great care was taken to avoid losses when transferring the residue to the extractor. The difference now fell from an average of 0.08 per cent. to 0.04 per cent., and on further prolonging the extraction the numbers became still closer. With poor milk, the seven hours' extraction was found insufficient, quantities such as 0.02, 0.06, and 0.07 per cent. of fat being obtained by allowing the residue, after seven hours' extraction, to soak in ether during the night.

Comparing Soxhlet's areometric method (*Abstr.*, 1881, 656) with the others, the results agreed closely (difference 0.02 per cent.) with the sand process after three hours' extraction, but with five hours' the average difference is larger (0.05). Röse's method invariably gives a higher result than Soxhlet's, the differences lying between 0.012 and 0.21 per cent., with an average of 0.081. M. J. S.

The Oleorefractometer. By F. JEAN (*Bull. Soc. Chim.* [3], 4, 105—108). The instrument consists of a hollow prism placed in the centre of a vessel which can be filled with water, and by means of which oil introduced into the prism is heated to a definite temperature. A collimator and a telescope are attached to opposite sides of the vessel in the line of the prism, and the amount of refraction produced by the oil is measured by the deflection of the shadow of a

vertically-interposed shutter on an arbitrary scale placed within the telescope. An oil having the same refraction as the water being placed in the prism, the latter is heated to 22° , and the shadow is adjusted to the zero of the scale, the oil to be tested is then introduced, and the corresponding deflection is read off. Animal oils produce a deviation to the left, and vegetable oils to the right, and the deviation produced by various oils varies within wide limits, so that the detection of oils and of any falsification is rendered possible.

T. G. N.

Volumetric Estimation of Albumin in Urine. By F. VENTUROLI (*Chem. Centr.*, 1890, ii, 795—796; from *L'Orosi*, 13, 255—257).—The method depends on the fact that mercuric chloride precipitates albumin from urine acidified with acetic acid, before combining with potassium iodide. The standard solution of mercuric chloride is prepared by dissolving 1 gram in 100 c.c. of water, of which 1 c.c. is equivalent to 0.0245 gram of albumin, this value being determined by estimating gravimetrically the albumin in a sample of urine, and titrating it also with the standard mercuric chloride. The method is practised thus:—To 5 c.c. of urine, 6 c.c. of a 5 per cent. solution of potassium iodide is added, together with a few drops of acetic acid. The mercuric chloride solution is then run in drop by drop until a permanent yellowish-red coloration is produced. From the number of c.c. used, 1 c.c. is deducted for that which has combined with the potassium iodide, and the difference is multiplied by the factor 0.0245. If the urine should contain any alkaloid, the results are naturally too high.

J. W. L.

Estimation of Humus in Soil by Raulin's Process. By G. PATUREL (*Ann. Agron.*, 16, 558—571).—When a solution of manganese sulphate is heated with potassium permanganate, a black precipitate of manganese dioxide, called by Raulin "manganese bronze," is immediately produced, and the liquid becomes acid and colourless. The precipitate can be redissolved by running in standard oxalic acid to the hot liquid, and the oxalic acid used is exactly proportional to the dioxide formed. If a solution of soil humus be heated with double the necessary quantity of "manganese bronze," it is completely oxidised, and the quantity of oxygen taken from the precipitate to do this can be inferred by estimating the residual "manganese bronze" with oxalic acid. On this principle is founded the following process:—The manganese sulphate solution contains 16 grams of the pure anhydrous (calcined) salt per litre; the permanganate contains 10 grams of the salt per litre, and a decimal solution also is used, made by diluting this 10 times. Normal oxalic acid, and dilute sulphuric acid containing 150 grams of sulphuric acid per litre are required in addition. The manganese solution is titrated by heating for a moment in a flask 10 c.c. of the manganese sulphate with 10 c.c. of the permanganate; 100 c.c. of distilled water and 4 c.c. of the sulphuric acid are then added, the liquid boiled, and normal oxalic acid run in from a burette until the precipitate is just dissolved; the slight excess of oxalic acid required for this is estimated by titrating back with decimal permanganate, and deducted from the total quantity

used. The relation between the solutions being thus established, a precipitate of "manganese bronze" is obtained as before, in a liquid made up of 10 c.c. each of manganese sulphate and permanganate, 100 c.c. water, and $\frac{1}{4}$ c.c. dilute sulphuric acid. A measured volume of the humus solution to be estimated is added to this, the quantity taken being such as will consume the available oxygen of not more than half the "manganese bronze." The mixture is heated for eight hours on a sand-bath at a temperature near ebullition, water being added periodically to replace that evaporated. The estimation of the remaining "manganese bronze" by oxalic acid is conducted as before, the difference between the two quantities of oxalic acid being a measure of the humus. The quantities of normal oxalic acid equivalent to different weights of humus determined directly by extraction with ammonia and weighing is given by Raulin in the following table:—

Oxalic acid.	Humus.	Oxalic acid.	Humus.	Oxalic acid.	Humus.
c.c.	milligrams.	c.c.	milligrams.	c.c.	milligrams.
50	= 50	800	= 885	2500	= 2315
100	150	900	975	3000	2735
200	280	1000	1060	3500	3170
300	400	1200	1225	4000	3605
400	510	1400	1390	4500	4035
500	610	1600	1560	5000	4460
600	705	1800	1720	5500	4890
700	790	2000	1890	6000	5310
				6500	5745

The humic solution is prepared for the assay by treating 10 grams of the soil (fine earth?) with dilute hydrochloric acid to dissolve the calcium carbonate, collecting and washing the residue, and finally syringing it into a little flask with 20—30 c.c. of water; 20 c.c. of 10 per cent. solution of sodium hydroxide is added, and the mixture heated on the water-bath for six hours, diluted with water, filtered, and washed until the washings are colourless. The filtrate is nearly neutralised with sulphuric acid, keeping, however, the humus dissolved (the precipitation of silica is of no importance), made up to 500 c.c., and a suitable fraction removed for analysis. When the soil humus contains 46 per cent. of carbon and 5 per cent. of hydrogen (or a C : N ratio of 10 : 1), as is the case with the plots at Grignon, manured frequently with farmyard manure, the method gives exact results. In long unmanured soil, when the ratio C : N has fallen perhaps to 5 : 1 and the humus contains 40 per cent. C and 7 per cent. H, it is otherwise, Raulin's process giving 26—27 grams humus per kilo., and direct estimation 17.5 grams.

General and Physical Chemistry.

Refraction and Chemical Constitution of Gases and Vapours.

By J. W. BRÜHL (*Zeit. physikal. Chem.*, 7, 1—33).—In the first part of this paper, the author shows the inadequacy of the empirical expression for the molecular refraction $(n - 1) \frac{M}{d}$, as applied to gases and vapours. In passing from the liquid to the gaseous state, there is, with this formula, usually a sudden and often considerable change of value; so that relations which subsist between the molecular refraction equivalents of liquids are often lost when the substances are gasified. It is otherwise when the theoretical formula $\left(\frac{n^2 - 1}{n^2 + 2}\right) \frac{M}{d}$, due to Lorenz and Lorentz, is employed: here there is complete optical continuity between the liquid and gaseous states. The molecular refraction is, in the vast majority of cases, the same for both states of aggregation of the substance, and may be approximately calculated from its composition. The exceptions which do occur are considered by the author to be due to the insufficient accuracy of the measurements. He is, therefore, of opinion that the empirical formula should be dropped in all comparative optical chemical investigations, and the newer theoretical formula be substituted for it.

A very complete table of the refractive indices and constants of gases and vapours is given. From the material here collected, the author concludes that the molecular refraction of gaseous substances is only very roughly an additive property, the influence of constitution being at all times very great; indeed, it is only in compounds of similar constitution that the law of simple summation holds good, and even then it is only approximate. J. W.

Refractive Indices of Water. By J. W. BRÜHL (*Ber.*, 24, (344—349)).—Up to the present, no measurements of the refractive indices of water for the hydrogen line H_β and for potassium light have been made. The line H_β , $\lambda = 4101$, is nearly coincident with the violet potassium line, $\lambda = 4044$, so that measurement for the former renders that for the latter unnecessary.

The hydrogen spectrum is obtained by means of the U-shaped induction tube shown in the sketch (next page), a strong current being required to give lines of the necessary intensity. The tube is held in a stand which is constructed so that it can be made to hold tubes of different sizes by means of the clamp *a*.

The violet potassium line cannot be obtained of sufficient intensity to serve for measurement, but the line in the red, $\lambda = 7700$, can be obtained of intensity sufficient for this purpose by heating a mixture of potassium perchlorate and chloride in the Bunsen flame. Such a mixture, prepared by heating potassium chlorate in a platinum dish

until the first period of gas evolution is at an end, is particularly suitable for the object in view, as it is readily volatile and gives a very distinct spectrum.

The results obtained are given in the following table, in which the first column contains the temperatures at which the measurements were made.

<i>t.</i>	K.	Li.	H _a .	Na.	Tl.	H _β .	H _γ .	H _δ .
19.9°	1.32888	1.33088	1.33120	1.33305	1.33403	1.33720	1.34045	1.34230
23.7	1.32891	1.33077	1.33091	1.33280	1.33468	1.33602	1.34016	
25.3	1.32852	1.33041	—	1.33249	1.33447	—	—	
26.0	—	—	1.33050	—	—	1.33625	—	
27.0	1.32830	1.33033	—	—	1.33428	—	—	—

The results for the lithium, sodium, thallium, and hydrogen lines α , β , and γ are added for the sake of comparison, and for testing the general accuracy of the method. They agree very closely with those obtained by other observers. The above results are, therefore, most probably correct to the fourth decimal place. The water used had been repeatedly distilled (finally with potassium permanganate), and was always boiled before every new determination.

H. C.

Relations between the Spectrometrical Constants and Chemical Constitution of Epichlorhydrin, of Acetaldehyde and Paracetaldehyde, and of Benzene. By J. W. BRÜLL (*Der.*,

24, 656—668).—In a previous paper (this vol., p. 633), the author shows that a study of the heats of combustion is not sufficient for the determination of the chemical constitution of many organic compounds. This advantage he claims, however, to a much larger degree on behalf of the spectrometrical constants, the molecular refraction and dispersion. He discusses the case of acetaldehyde and paracetaldehyde, and that of epichlorhydrin, showing that the formulae assigned to these compounds on purely chemical evidence are also those which would be derived from the molecular refraction and dispersion. The latter case is of particular interest on account of the relation between epichlorhydrin and the alkylene oxides. According to their thermochemical behaviour, the alkylene oxides would have to be classed as unsaturated compounds, but the spectrometrical measurements support the usually accepted formulae for these substances, which represent them as saturated compounds. These results are, however, as already pointed out, not perfectly in accordance with the fact that the alkylene oxides readily form additive products and undergo polymerisation.

But the author holds that the power of forming additive products or undergoing polymerisation is not solely due to multiple linkage in the molecule, but to certain internal conditions in the molecule itself, and the state of tension existing between its various parts. It is this state of tension which chiefly determines the amount of heat developed when the molecule undergoes disintegration, and hence it may happen that saturated and unsaturated compounds, in which the tensions between different parts of the molecule are the same, will have also the same heats of combustion. The spectrometrical constants, on the other hand, depend chiefly on structural differences, and hence, unlike the heats of combustion, give real aid in ascertaining chemical constitution.

Further instances of the above are offered by the cases of trimethylene and benzene. The heat of combustion of trimethylene would lead to a formula for this compound similar to that of propylene, but this must be only taken as representing that a similar state of tension exists in the molecule of each, which may be caused by totally different peculiarities in the two cases. That this is so, is supported by the molecular refractions of the two compounds, which are very different, that of propylene indicating the presence, and that of trimethylene the absence, of a double linkage. Benzene furnishes another well-known instance, the molecular refraction pointing to the presence of three double linkages, and supporting Kekulé's formula, or assuming double and centric linkages to be equivalent, the centric formula proposed by Baeyer. H. C.

Basicity of Acids deduced from their Conductivity: Mono-basic and Bibasic Acids. By D. BERTHELDT (*Compt. rend.*, 112, 287—289).—The addition of excess of acid to solutions of normal salts of monobasic organic acids containing one-hundredth of a gram-molecule per litre, gives a conductivity agreeing with that calculated on the assumption that no chemical change takes place. In the case of formic acid alone is there a reduction below the calculated value.

It follows that acid salts of the monobasic acids do not exist in solution at the degree of dilution specified. The addition of an excess of alkali gives a reduction of about 5 per cent. for the first equivalent, but the second equivalent has practically no effect.

Normal salts of bibasic acids behave differently. When excess of acid is added, the conductivity is lower than the value calculated for a simple mixture, the reduction being due to the formation of acid salts. The actual values show, however, that the acid salt undergoes considerable dissociation into normal salt and free acid.

All these results agree with the conclusions deduced from thermochemical data. C. H. B.

Conductivities of Tribasic Acids. By D. BERTHELOT (*Compt. rend.*, 112, 335—337; compare preceding abstract).—The addition of excess of acid to normal salts of tribasic organic acids produces, as in the case of bibasic acids, a conductivity lower than that calculated for a mixture of normal salt and free acid, but the effect is more prolonged owing to the existence of a second acid salt. Measurements were made with tricarballic, citric, aconitic, and melleic acids.

If the molecular weight of an acid is known, its basicity can be determined by adding successive equivalents of alkali, and determining the point at which reduction of conductivity below that calculated for mere mixtures ceases. It is necessary to remember that excess of alkali added to the normal salt also produces a small effect, which ceases with the first equivalent in excess when the acid is monobasic, with the second when it is bibasic, with the third when it is tribasic, and with the sixth when it is hexabasic. C. H. B.

Conductivity of Organic Acids and their Salts. By W. OSTWALD (*Compt. rend.*, 112, 388—389, and D. BERTHELOT, *ibid.*, 390).—A question of priority.

Specific Heat of Mercury. By E. HEILBORN (*Zeit. physikal. Chem.*, 7, 85—87).—Experimental investigations have left undecided the question whether the specific heat of mercury increases or diminishes with rise of temperature. The author attacks the point from the theoretical side, and assuming that the total heat communicated goes to perform the work of expansion, arrives at the conclusion that the specific heat must diminish as the temperature rises. The formula he gives is $C_t = C_0/V_t^{\frac{1}{3}}$, V_t being the volume at t° , referred to $V_0 = 1$. J. W.

Heat of Combustion and Constitution of Organic Compounds. By J. THOMSEN (*Zeit. physikal. Chem.*, 7, 55—70).—The author showed in a previous communication (*Abstr.*, 1887, 761) that the heat of combustion of gaseous hydrocarbons of the fatty series could be expressed by means of a simple formula, in which it was assumed that the heat of combustion of hydrogen atoms was always the same, but that carbon atoms had different heats of combustion according as they were singly, doubly, or trebly linked to each other. He gave numerical thermal values for the single, double, and triple bonds, by introducing the hypothetical heat of combustion of an

isolated carbon atom, which, however, vanishes in the sum, no matter what value is attributed to it. Thus the agreement of observed with calculated heats of combustion affords no proof of the correctness of the thermal value taken as the basis of the calculation, as Dieffenbach imagines (*Abstr.*, 1890, 1206).

In this paper, the author extends the above method to the consideration of closed carbon chains, and shows in the first place that the bonds in the trimethylene ring are not ordinary fatty single bonds. He adopts Stollmann's numbers for the heat of combustion of the aromatic hydrocarbons in the solid or liquid state, and points out that whilst benzene, naphthalene, and chrysene belong to the same class of compounds, anthracene and phenanthrene are not directly comparable with these; for the difference in the heat of combustion corresponding with C_6H_2 is the same in the first group, but different in the last. With regard to benzene, he no longer contends that nine single bonds exist in the nucleus, but rather that there are six "single" and three "double" bonds; these, however, not being the same as the single and double bonds of the fatty series. The aromatic double bond has, in fact, a higher thermal value than the aromatic single bond, if the probable heat of combustion of the isolated carbon atom is taken to be 135.34 cal., as in the author's former calculations. Naphthalene contains four double bonds; anthracene, phenanthrene, and chrysene, six. The author considers it probable that the aromatic double bond is composed of two unequally strong bonds, one of which ("peripheral") is equal to the single bond, the other ("central") being somewhat weaker. "In any case, it is indubitable that the bonds in benzene and the other typical aromatic hydrocarbons cannot all have the same value." J. W.

Relations between the Heats of Combustion and Structural Formulæ of the Alkylene Oxides, Acetaldehyde and its Polymerides, Trimethylene, and Benzene. By J. W. HERRL (*Ber.*, 24, 650—656). The heat of combustion of ethylene oxide is 312.5 Cal., that of the isomeric vinyl alcohol being 308.8 Cal. (calculated), and of acetaldehyde 281.9 Cal. The heat of combustion of propylene oxide may be calculated from that of ethylene oxide, and will then be 468.5 Cal., those of its isomerides, allyl alcohol, acetone, and propenaldehyde, being 464.8, 437.2, and 440.7 Cal. respectively. It will be seen that the heats of combustion of the oxides in these two cases agree with those of the unsaturated isomeric alcohols and not with those of the saturated aldehydes. Since the heats of combustion of unsaturated are always greater than those of saturated compounds, it might from this be concluded that the alkylene oxides are substances of an unsaturated nature, a view which is supported by the readiness with which these oxides form additive products and undergo polymerisation.

The author holds, however, that conclusions like the above, drawn from thermochemical data, must be taken with great reservation. In illustration of this, he cites cases in which the thermochemical is obviously out of harmony with the other general chemical behaviour. Acetaldehyde, paracetaldehyde, and metacetaldehyde differ very con-

siderably, not only in chemical but also in physical properties, and yet the heats of combustion of these three substances are practically the same. The heat of combustion of trimethylene is approximately equal to that of propylene, and greater than that calculated for an unsaturated compound of this composition, a fact at variance with the accepted view of the constitution of trimethylene. Thomsen has endeavoured to arrive at the constitution of benzene from thermochemical considerations, but unsuccessfully, and in a recent paper (preceding abstract) comes to conclusions opposed to those which he formerly held. These facts serve to show the difficulty in the way of at present employing thermochemical data for the discussion of chemical constitution.

H. C.

Compressibility of Mixtures of Air and Hydrogen. By U. LALA (*Compt. rend.*, 112, 426—428).—For feeble initial pressures, which may increase with the proportion of hydrogen and may rise to 1750 mm. with 49·89 per cent. of hydrogen, the compressibility of mixtures of air and hydrogen is intermediate between those of air and hydrogen separately, but diverges from Boyle's law in the same direction as the compressibility of hydrogen.

As the final pressure increases, the divergence from Boyle's law retains the same sign, but becomes greater for the mixture than for hydrogen alone, the difference increasing with the initial pressure, so that the compressibility of the mixture is always less than that of hydrogen.

As the proportion of hydrogen increases, the compressibility diverges continuously but slowly from that of hydrogen. With proportions of hydrogen between 33·08 and 39·28 per cent., however, the compressibility not only shows no further divergence from that of hydrogen alone, but tends to approach it with initial pressures lower than 1800 mm. As the proportion of hydrogen increases beyond this point, the compressibility tends to approach that of hydrogen for all the initial pressures between the limits given below, and with 49·89 per cent. the compressibility becomes intermediate between that of hydrogen and that of air, with a higher initial pressure than with any other mixtures.

The phenomena are of the same order as those observed with mixtures of carbonic anhydride and air (this vol., p. 253), but with an inverse sign.

The pressures varied between 1050 mm. and 15,600 mm., the percentages of hydrogen being 16·38, 28·12, 33·08, 39·28, and 49·89.

C. H. B.

Compressibility of Hot Water and its Solvent Action on Glass. By C. BAUS (*Amer. J. Sci.* [3], 41, 110—116).—It has been found that the compressibility of water between 0° and 33° continually decreases, but that above the latter temperature it increases. The author proposed to measure the compressibility between 100° and 300°, but found that at 185° water attacks glass so rapidly as to make measurements in glass tubes worthless.

Pressures were applied by aid of Cailletet's large force pump. The thread of water is enclosed in a capillary tube, between two end

threads of mercury, and the distance apart of the two inner menisci, corresponding with any given temperature and pressure, measured by a cathetometer. The tube, suitably closed above, is exposed in a vapour-bath. At 185° , the thread of water soon loses its transparency, becoming white and cloudy. After the action has continued for about an hour, the column is solid at high pressures (300 atmos.), although it is probably only partially so at 20 atmos. In consequence of this, threads of mercury break off during advance and retrogression of the column. Further measurement is, therefore, not feasible. The glass was common lead glass, and distilled water was used.

The dissolution of the glass in the water at 185° causes a shrinkage in the volume of the system of pure water and solid glass of more than 11 per cent. up to the point of solidification. The hot, turbid column, after exposure at 185° for about 55 minutes, is absolutely shorter than the original clear, cold column at 24° . The hot compressibility, after 55 minutes, has increased to five times the cold compressibility, and to three times the original hot compressibility. Making allowance for the shrinkage due to chemical action, the normal compressibility of pure water at 185° is estimated as not greater than 70/10⁶. Above 100° , therefore, the compressibility increases at a very low rate with temperature, which the author thinks indicates exceptional stability of the water molecule.

The author regards the action above described as due to the instability of the glass molecule at 185° , and as a general deduction infers that in many instances a definite dissociation temperature of the solid must first be surpassed, before solution will set in.

H. C.

Determination of Vapour Densities. By G. LUNGE and O. NEUBERG (*Ber.*, 24, 729—737).—The gasvolumeter devised by one of the authors (*Abstr.*, 1890, 660) may be used in conjunction with V. Meyer's apparatus for the determination of vapour densities, and, since the reduction of the volume of gas measured to standard conditions is thus rendered unnecessary, a great saving of time is effected. It has, however, an additional advantage, for with but slight alteration in the apparatus itself, it becomes possible to effect the volatilisation of a compound under greatly diminished pressure with the greatest ease. A sketch is here given of the apparatus so arranged as to effect the above object.

The vapour density apparatus *A*, the bulb of which should have a capacity of from 300 to 400 c.c., is fitted with the arrangement *a*, formerly described by Meyer and Biltz (*Abstr.*, 1888, 1241) for allowing the substance under examination to fall into the bulb at any desired moment. *a* is in this case placed above the capillary tube *b*, and the latter, in place of being bent downwards, is kept horizontal and brought close up to the tube *d* of the measuring vessel *B*, the two being then connected by stout india-rubber tubing. The measuring tube *B* consists of a narrow upper and wide lower portion, the upper portion, which contains 15 or 16 c.c., being divided either into one-tenth c.c., or into divisions of 0.774 c.c., each of which corresponds with 1 milligram of dry air at 0° and 760 mm., these being again subdivided into tenths. By means of the tap *c*, *B* may be placed in communication with *d* and

b and thus with *A*, or may be connected with the small vessel *c*, and thus with the outside air. A wooden scale, *C*, 80 cm. long, and divided into millimeters, is fastened by means of the clamp *f* to the lower, wider portion of *B*. A moveable index needle, *g*, is placed on

the scale *C*, and can be held in any position of the scale by means of a spring. The rest of the apparatus consists of the reduction tube *D* and the pressure tube *E*, the functions of which were described in the former paper.

If *B* and *c* are placed in communication and *W* be then raised, the air will be driven out of *B* and the mercury will rise until it reaches the tap *c*. By closing *c* and lowering *W* until the mercury in *B* falls to the clamp *f*, which marks the zero of the scale, and then adjusting *g* to the level of the mercury in *E*, it is obvious that the reading on the scale of the position of *g* will be the barometric pressure at the time of the observation. From this is subtracted the pressure at which the vapour density is to be taken, and *g* is then adjusted in the position so found. For instance, if the height of the barometer is 750 mm., and the pressure at which the experiment is to be conducted is 50 mm., *g* would be adjusted at division 700 on the scale.

In conducting an experiment, *B* is first connected with *c*, *W* is raised, and the air driven out of *B*. *c* is now turned so as to put *d* and *B* into communication, and *W* is lowered as far as possible. *c* is then again turned and the gas which has entered *B* is driven out by

raising B . The above operations are then repeated for a number of times, until the desired pressure within the apparatus is reached. This can be done while A is being heated to the necessary temperature. The mercury in B is now adjusted so that it fills the whole tube to the tap c , which is then so turned as to put B and A into communication. When this is done, the substance, the vapour density of which is being determined, is allowed to fall into the bulb A . Volatilisation immediately sets in, and the mercury in B sinks, whilst at the same time it rises in B , but by lowering B it is possible to maintain the pressure within the apparatus practically constant while the gas is coming off.

When the evolution of gas ceases, c is turned so that communication with both A and c is cut off, b and d are disconnected, and the tube B is lowered to a height convenient for reading. The reduction tube D , which up to this time is neglected, is now raised so that the level of the mercury in this tube and B shall be about the same, and a sufficient time is allowed for the temperature in both tubes to become equal. B is then raised until the mercury in D stands at the mark 100, when the air in D is compressed to the volume occupied at 0° and 760 mm. At the same time, the level of the mercury in D is brought to that in the tube B , so that the gas in the latter tube is also under the conditions 0° and 760 mm. If B is divided into cubic centimeters, the desired vapour density will be $g/v \cdot 0.001293$, when g is weight of the substance in grams and v is the volume of the gas in B . If the divisions on B are each 0.774 c.c., corresponding with 1 milligram of air, the above formula will be simplified to g/v_1 , where g is the weight in milligrams and v_1 the volume measured.

The air in A may, of course, be replaced by any other indifferent gas, preferably not by hydrogen, before the exhaustion is commenced. In the following table is given the reduction in the boiling point which substances, boiling under ordinary pressure at the temperatures at the head of each column, will approximately undergo when the pressure is reduced to that given in the table:—

Ordinary boiling point...	below 100°	100—200°	200—300°	above 300°
Pressure in mm.	20 50 75	20 50 75	20 50 75	20 50 75
Reduction in boiling point.....	65° 55° 50°	80° 65° 60°	105° 90° 80°	130° 100° 90°

It is, however, best to heat the bulb A to about 20° above the point at which the substance boils under the pressure of the experiment.

A number of examples are given to illustrate the accuracy of the above method of determining vapour densities. It is proposed to employ it for the investigation of certain doubtful cases, such as those of ammonium chloride and sulphur.

H. C.

Kinetic Molecular Theory of Dilute Solutions. By H. A. LORENTZ (*Zeit. physikal. Chem.*, 7, 36—54).—Like Boltzmann (this vol., p. 389), the author endeavours to deduce the law of osmotic pressure from the molecular motions in dilute solutions. He also

treats of the freezing point and vapour pressure of such solutions from the same standpoint, and finds the theory of electrolytic dissociation in harmony with his conclusions. J. W.

Osmotic Pressure and the Kinetic Theory of Gases. By L. BOLTZMANN (*Zeit. physikal. Chem.*, 7, 88—90).—Lorentz (preceding abstract) raised an objection to a mode of proof adopted by the author in his paper (this vol., p. 389). The validity of the objection is admitted, and a stricter proof given. J. W.

Dissociation Hypothesis. By J. TRAUBE (*Ber.*, 24, 737—745).—A reply to Arrhenius (this vol., p. 521). The author does not regard the answers given by Arrhenius to the objections he brought forward against the dissociation hypothesis (this vol., p. 255) as satisfactory, and in this paper repeats and extends these objections. H. C.

Affinity of Bases. By E. LELLMANN and H. GROSS (*Annalen*, 260, 269—289; compare Abstr., 1889, 1104).—The authors have measured the affinity of various bases by the spectrophotometric method previously described by Lellmann (*loc. cit.*).

A dilute alcoholic solution (50 c.c.) of dimethylamidoazobenzene (butter-yellow), containing 2 milligrams of the base, is mixed with a known quantity of the hydrochloride of the base to be investigated, and the mixture made up to 100 c.c. This mixture attains a condition of equilibrium after a longer or shorter time (sometimes immediately, sometimes only after four to five days) on keeping at the ordinary temperature, but the distribution of the acid takes place more quickly on heating at 40° for one to two hours. The solution is then examined with a spectrophotometer, and its absorption compared with that of a solution of pure dimethylamidoazobenzene hydrochloride in a large excess of hydrochloric acid.

In the case of aniline, it was found, as the average of four different experiments, that equilibrium is attained when the number of molecules of hydrochloric acid combined with the dimethylamidoazobenzene, compared with the number of molecules of acid in combination with the aniline, is 1545 : 100,000, or $\kappa = 0.01545$, the acid and the two bases being present in the proportion of their molecular weights. When such solutions are kept for some days longer and examined again, the value of κ is found to have undergone a slight change in every case, but the variations are such that the average value remains practically the same. A similar variation is observed in the case of other bases, a fact which shows that the solutions are not actually in a state of rest; it may be noted that those solutions which at the first examination give a value for κ considerably above the average, on examination at a later period, give a value considerably below the average, and *vice versa*, whilst those which give values approximately the same as the average do so also at the later period.

The bases given in the following list were investigated; they are placed in the order of their affinity, commencing with the feeblest, and the figures give the value of κ .

Parachloraniline....	0.03595	Dimethylaniline....	0.01003
Metamidophenol....	0.02138	Paratoluidine.....	0.00990
Quinoline.....	0.02055	Quinaldine.....	0.009297
Orthotoluidine....	0.01818	Paramidophenol....	0.006856
Aniline.....	0.01565	α -Picoline.....	0.005838
Orthamidophenol...	0.01444	Hydroxylamine....	0.004715
Pyridine.....	0.01323	Ammonia.....	0.0003066

The results arrived at by the spectrophotometric method differ very considerably from those obtained by Walker by measurements of the electrical conductivity (*Zeit. physikal. Chem.*, 4, 319); experiments showed that this difference is not due to the fact that in one case dilute alcoholic, and in the other aqueous, solutions are employed. In the authors' opinion, Walker's series is probably incorrect, for various reasons.

The article continues with an attempt to explain various anomalies in the above list; the fact that ortho- and par-amidophenol are stronger, whilst metamidophenol is a weaker, base than aniline, may be accounted for by assuming that the hydrogen of the hydroxyl group is nearer to the amido-group in the ortho- and para-compounds than it is in the meta-derivative; in the first case, the atoms may be

supposed to be arranged thus, $\begin{array}{c} \bullet \text{---} \text{N} < \begin{array}{l} \text{H} \\ \text{H} \end{array} \\ \text{H} \end{array}$; and in the second case

thus, $\begin{array}{c} \bullet \text{---} \text{N} < \begin{array}{l} \text{H} \\ \text{H} \end{array} \\ \text{O} \\ \text{H} \end{array}$; the influence of the hydroxy-group being different in the two cases.

Numerous remarkable facts observed by Ostwald may be explained by a hypothesis of this kind.

Experiments seem to show that dimethylamidazo-benzene and other coal-tar colouring matters may be employed for studying various other phenomena; it has been found, for example, that of the three liquids, methyl alcohol, water, and ethyl alcohol, the first has the smallest, the last the greatest attraction for hydrochloric acid, and this in solutions so dilute that a chemical reaction must be considered out of the question. F. S. K.

Velocity of Reaction in Gelatin. By S. REFORMATSKY (*Zeit. physikal. Chem.*, 7, 34—35).—Parallel experiments on the catalysis of methyl acetate by hydrochloric acid were instituted in water and in agar-agar jelly. The concentration of the agar-agar solution (1.25 per cent.) was chosen so that at 35° it was liquid, but at 25°, the temperature of experiment, solid enough to allow the vessel in which it was contained to be inverted without any trace of fluid escaping. The coefficient of velocity was found to be the same in both cases, as was to be expected, considering the identical results obtained by Voigtländer (*Abstr.*, 1889, 817) for diffusion in such a jelly and in pure water. J. W.

New Automatic Mercury Air-pump, with Arrangement for Self-action by means of Water Pressure. By M. STUHL (*Ber.*, 24, 147—159).—A great disadvantage attending the use of the mercury air-pump is the necessity of constantly raising the mercury back to its former level, in order to keep the pump in action. This usually employs the whole time and attention of the operator, and often gives rise to accidents of all kinds. In order to overcome this difficulty as far as possible, the author has devised a method of keeping the pump automatically in constant action by means of water pressure. The arrangement used is illustrated by the accompanying sketch.

Water enters through the tube L, and three-way tap A, into the cylinder B, the air escaping into the glass vessel C, and by its pressure forcing the mercury into the pump D, and effecting exhaustion in the well-known manner. The long barometer tube is replaced by the glass valve H.

As soon as a sufficient amount of mercury has been pressed into the pump, the beam on which the vessel C is supported becomes heaviest on the left-hand side, and is depressed in this direction; this causes a rotation of the three-way tap in such a manner that the water supply is shut off, and the water which is under the pressure

of the air is removed by the tube A. At the same time, the moveable weight F also falls to the left hand, and serves so to increase the weight on this side that the whole of the mercury must flow from D into C, before the latter becomes the heavier; then rotation of the beam and tap again take place, the weight F falls to the right, and the pump is once more set in action.

To the moveable weight F is attached an arrangement by means of which the air collecting in the globe D can be transferred for five successive times into a small and perfectly vacuous receiver, R, and not until the sixth time of working the pump allowed to escape into the air. This is effected by attaching to the weight F a small, six-toothed wheel, having a deep incision between two of the teeth. Each time the weight falls to the right the wheel is rotated through the distance between two of its teeth, and a peg, which serves to stop the falling weight, comes for five successive times in contact with the circumference of the wheel. The sixth time, however, the peg enters the incision, and the weight thus falls further to the right. This time, therefore, a larger quantity of mercury must be forced out of C into D before the beam is over-balanced on the left-hand side, and this can be so arranged that the mercury now fills the whole of the small receiver R, and forces the air contained in it through the tube S into the atmosphere. In this way, very perfect exhaustion can be effected.

The above arrangement in connection with the weight F renders it possible to regulate the height to which the mercury will rise to within half a centimeter. The rate at which the mercury rises can very easily be regulated by means of the tap. Instead of allowing the air to escape directly into the atmosphere, it may first be passed into a second receiver, which is exhausted by means of a water-pump. The most perfect exhaustion is thus obtained. H. C.

Inorganic Chemistry.

Conversion of Sodium Pyrophosphite into Sodium Hydrogen Phosphite. By L. AMAT (*Compt. rend.*, 112, 527-530).—The conversion of sodium pyrophosphite in aqueous solution into sodium hydrogen phosphite follows the same law as the hydration of metaphosphoric acid (Abstr., 1889, 671), the equation being $\log \frac{l - \phi_0}{l - \phi} = kx \log e$; where ϕ_0 is the quantity of acid phosphite originally present, ϕ the quantity present at any given instant, l the maximum possible quantity of acid phosphite, and x the time in hours.

The change is more rapid the more concentrated the solution, but the velocity of transformation is such that k remains constant, the decrease in velocity owing to reduction being compensated by the accelerating influence of the acid phosphite.

In presence of free acid (sulphuric), the rate of change is greatly increased, doubtless because the acid liberates pyrophosphorous acid, which rapidly alters. Under these conditions, the value of k gradually decreases, and the equation already given only represents the results in a very general way. C. H. B.

Silicobromoform. By A. BESSON (*Compt. rend.*, 112, 530—532).—When carefully dried hydrogen bromide acts on crystallised silicon at a temperature below redness, the product consists of silicon bromide boiling at 153° and silicobromoform, in proportion which, even under favourable conditions, does not exceed 5 per cent. of the product. When air is allowed to enter the apparatus, a substance is formed which crystallises in yellow plates; it seems to be a silicon oxybromide.

Silicobromoform is a colourless liquid which does not solidify even at -60° , and boils without decomposition at $109-111^{\circ}$ in presence of an inert gas. In presence of air, it fumes abundantly and ignites spontaneously; its vapour forms explosive mixtures with air. It is decomposed by water, and also, with great violence, by alkalis.

Ammonia acts energetically on silicobromoform with development of heat and light, but the white product is indefinite in composition, and contains silicon, hydrogen, bromine, and ammonia. Hydrogen phosphide does not combine with silicobromoform at -40° under ordinary pressure, but under a pressure of 25 atmos. at $+15^{\circ}$, a white solid is formed, which persists for some time after the removal of the pressure. Silicochloroform yields a similar product, which, however, decomposes as soon as the pressure is removed, even at -22° .

C. H. B.

Sodamide and Disodammonium Chloride. By JOANNIN (*Compt. rend.*, 112, 392—394).—Sodammonium decomposes very slowly at the ordinary temperature into hydrogen and sodamide, the change being slightly more rapid when exposed to light than in the dark. The decomposition tends to a limit as the pressure of the hydrogen increases. As the hydrogen and excess of ammonia escape, the sodamide, NH_2Na , separates in white, transparent crystals, about 1 mm. long.

Sodium chloride interacts with sodammonium, but does not form the subchloride described by Rose. One equivalent of hydrogen is liberated for each equivalent of sodammonium used, and when the sodium chloride is in excess, the liquid becomes colourless. The precipitate, when washed with liquefied ammonia, is sodamide free from chlorine. The rapid decomposition of sodammonium under these conditions is due to the formation of an unstable disodammonium chloride, $\text{NH}_2\text{Na}_2\text{Cl}$, which can be obtained (mixed with excess of sodium chloride) by the action of excess of sodium chloride on sodium in presence of a quantity of liquefied ammonia insufficient to dissolve all the sodium chloride. It is decomposed by liquefied ammonia into sodium chloride and sodamide, and is also decomposed by water, without noise and without evolution of hydrogen, yielding ammonia, sodium hydroxide, and sodium chloride.

C. H. B.

Combination of Ammonia with Chlorides. By JOANNIS (*Compt rend.*, 112, 337—339).—Fused sodium chloride dissolves readily in liquefied ammonia at -10° , the vapour pressure of the solution being slightly inferior to that of the liquefied gas alone at this temperature. On further cooling to -30° , and allowing the ammonia to escape at ordinary pressure, slender, white needles quickly separate. After evolution of gas at -30° has ceased, the temperature is allowed to rise slowly. Very little gas escapes up to -24° , but beyond this point the evolution of ammonia becomes more rapid. The gas evolved above -24° was collected in dilute acid; it was found that the ratio $\text{NH}_3/\text{NaCl} = 4.998$, and hence a compound is formed of the composition $\text{NaCl}, 5\text{NH}_3$. It has the following dissociation pressures:—

-24°	-20.8°	-17.5°	-15.0°	-10.0°	-7.0°
777	892	1074	1305	1777	2130 mm.

No evidence could be obtained of the formation, even at -72° , of any compound of potassium chloride and ammonia recognisable by a specific tension of dissociation.

Barium chloride combines very slowly with ammonia, but if the anhydrous salt is brought in contact with the liquefied gas, combination takes place somewhat rapidly, and if the excess of ammonia is allowed to escape at 0° under atmospheric pressure, the residue has the composition $\text{BaCl}_2, 8\text{NH}_3$. Its dissociation pressure is 541 mm. at 0° and 1850 mm. at 28.4° , and if the ammonia is continually removed, the pressure remains constant at the latter temperature until decomposition is complete. C. H. B.

Dissociation of Magnesium Oxide by Means of Metallic Magnesium. By H. N. MORSE and J. WHITE (*Amer. Chem. J.*, 13, 128—129).—The authors have already described the dissociation of the oxides and sulphides of zinc and cadmium when heated in a vacuum with their respective metals (*Abstr.*, 1889, 755). The method employed for similar experiments on magnesium oxide was the same, except that an iron tube, closed at one end, was inserted into the back half of the glass tube to prevent contact of the magnesium vapour with the glass. The magnesium was distilled in a vacuum as described by Burton and Vorce (*Abstr.*, 1890, 850), and the oxide was heated to redness in a vacuum until it ceased to give off carbonic anhydride; from 4.5 to 10 grams of the metal was then dropped into the tube, followed by 1.5—3 grams of the oxide. The tube was exhausted and heated to bright redness, when the phenomena that presented themselves were similar to those observed in the previous experiments, the magnesium oxide being transported to the front part of the tube, in quantity varying with the thoroughness with which the metal and oxide were mixed. Carbonic anhydride (from the carbon in the iron) and from 1.5 to 3 c.c. of oxygen were evolved during the experiment. A. G. B.

Melting Point of certain Alloys. By F. C. WELD (*Amer. Chem. J.*, 13, 121—123).—Heycock and Neville (*Proc.*, 1889, 41) have

shown that the addition of each atom of lead to 100 atoms of tin lowers the melting point of the tin by 2.22° . The author finds that this rule only holds with quantities of lead up to 15 atoms to 100 atoms of tin, after which the melting points are not so low as they should be when calculated by the rule. The lowest melting point obtained is that of 38 atoms of lead to 100 of tin (180°).

The effects of this reduction of the melting point are not cumulative; thus, an alloy of 100 atoms of tin with 57.28 atoms of lead melts at 180° , whilst one of 100 atoms of tin with 57.28 atoms of lead and 5.89 atoms of mercury melts at 173° , not $180^\circ - 5.89 \times 2.3^\circ = 166.45^\circ$.

A. G. B.

Note.—The author seems to overlook the fact that Heycock and Neville referred explicitly to the addition of "small quantities" of lead. It is well known that Raoult's method only holds for dilute solutions. [EDITORS.]

Hydrated Lead Oxide. By C. LUEDERKING (*Amer. Chem. J.*, 13, 120—121).—Schaffner's hydrated lead oxide, $2\text{PbO} \cdot \text{H}_2\text{O}$, is obtained in large crystals when litharge is boiled with potassium hydroxide, and the cold solution allowed to slowly absorb carbonic anhydride by exposure to air; as the potassium hydroxide becomes converted into carbonate, short, thick, well-developed, colourless, transparent, tetragonal crystals ($a : b : c = 1 : 1 : 0.824$) are deposited; they are highly refractive and brilliantly lustrous; they are alkaline, and become opaque from formation of carbonate when exposed to air, and yellow from formation of oxide when heated, but in both cases they retain the original crystalline form. A. G. B.

Copper Arsenates. By A. HIRSCH (*Chem. Centr.*, 1891, i, 15—16; from *Inaug. Diss. Halle*).—*Tetracupric arsenate*, $4\text{CuO} \cdot \text{As}_2\text{O}_5 + \text{H}_2\text{O}$, has been already prepared by Debray, Friedel and Sarasin, and Coloriano. The author has prepared it by the action of disodium arsenate on an excess of cupric chloride in concentrated solution. It is white, very stable, and does not react with silver nitrate; with disodium arsenate, it becomes blue. It was also obtained combined with $3\frac{1}{2}$ mols. H_2O .

Tricupric arsenate is obtained by adding sodium acetate to the filtrate from the precipitation of disodium acetate with excess of cupric sulphate. It is also obtained by the action of trisilver arsenate on cupric chloride.

Several copper sodium arsenates were prepared: $2\text{Cu}_3\text{As}_2\text{O}_8 + \text{NaH}_2\text{AsO}_4 + 5\text{H}_2\text{O}$, from disodium arsenate and excess of cupric sulphate; $6\text{Cu}_3\text{As}_2\text{O}_8 + 2\text{NaH}_2\text{AsO}_4 + \text{Na}_2\text{HAsO}_4 + 13.5\text{H}_2\text{O}$, or $33.5\text{H}_2\text{O}$, or $16\text{H}_2\text{O}$, from cupric sulphate and excess of sodium arsenate. If the excess of cupric sulphate is very considerable, the compound $5\text{CuO} \cdot 2\text{As}_2\text{O}_5$ is formed. From cupric nitrate, with excess of disodium arsenate, the salts $6\text{Cu}_3\text{As}_2\text{O}_8 + 2\text{Na}_2\text{HAsO}_4 + 19\text{H}_2\text{O}$ and $4\text{Cu}_3\text{As}_2\text{O}_8 + \text{Na}_2\text{HAsO}_4 + 11\text{H}_2\text{O}$ were obtained; whilst, if the cupric nitrate is in excess, the salts $5\text{CuO} \cdot 2\text{As}_2\text{O}_5$ and $8\text{CuO} \cdot 3\text{As}_2\text{O}_5$ are formed. The following double salts were obtained by the action of cupric chloride on disodium arsenate in dilute solution: $3\text{Cu}_3\text{As}_2\text{O}_8 + 2\text{NaCl} + 13.5\text{H}_2\text{O}$ or $17.5\text{H}_2\text{O}$, $5\text{Cu}_3\text{As}_2\text{O}_8 + 3\text{NaCl} + 19\text{H}_2\text{O}$ or

$23\text{H}_2\text{O}$, and $\text{Cu}_3\text{As}_2\text{O}_8 + \text{NaCl} + 7.5\text{H}_2\text{O}$. The two last are obtained from the former by the decomposing action of water. The chlorine is combined with the sodium in these salts, since silver nitrate reacts with them to form silver chloride without precipitating any cupric oxide, as it would do if the chlorine were in the form of cupric oxychloride.

From all these salts, if they are washed first with cold and then with hot water, the white tetracupric arsenate is obtained.

J. W. L.

Hydrated Sodium Manganites. By G. ROUSSEAU (*Compt. rend.*, 112, 525—527).—Potassium permanganate at 200° splits up into an alkaline manganite and manganese dioxide, and when the action of heat is prolonged, the two products interact with formation of potassium manganite and free alkali. Sodium permanganate behaves in a similar way at about 300° , the change being complete after six hours. Boiling water removes from the product a brown, amorphous substance which probably corresponds with Gorgeu's colloidal manganese dioxide. After repeated lixiviation, the hydrated manganite $8\text{MnO}_2 \cdot \text{Na}_2\text{O} \cdot 5\text{H}_2\text{O}$ is left in black, microscopic crystals. It loses 4 mols. H_2O at 150° to 180° , and becomes anhydrous at 250° ; between this point and 440° , it undergoes no further change; but at dull redness, it begins to polymerise with loss of sodium.

Sodium manganate was prepared by heating 3 grams of sodium permanganate with 4 grams of sodium hydroxide and a small quantity of water, and when the effervescence due to liberation of oxygen ceased, 5 grams of sodium chloride was added, and the heating continued. Four to five hours heating at the highest temperature of a Bunsen burner yields silky, black needles of the hydrate

which becomes anhydrous between 130° and 170° . With a higher temperature and a larger proportion of sodium chloride, rhomboidal lamellae of a new hydrate, $16\text{MnO}_2 \cdot \text{Na}_2\text{O} \cdot 8\text{H}_2\text{O}$, are obtained; this loses 7 mols. H_2O between 150° and 180° , and becomes anhydrous at about 250° . At a yellow heat, the product consists of black needles, $12\text{MnO}_2 \cdot \text{Na}_2\text{O} \cdot 4\text{H}_2\text{O}$, identical in appearance and composition with those obtained at about 800° by means of a Bunsen burner.

When sodium manganate is heated from 300° up to a yellow heat, the series of changes is as follows: the first product is

which above 500° polymerises, and at 800° is converted into $12\text{MnO}_2 \cdot \text{Na}_2\text{O} \cdot 4\text{H}_2\text{O}$. At about 1000° , the compound

is formed, but between 1200° and 1300° it splits up into the compound, $8\text{MnO}_2 \cdot \text{Na}_2\text{O} \cdot 5\text{H}_2\text{O}$, that is formed at 300° . At a yellow heat, the hydrate $12\text{MnO}_2 \cdot \text{Na}_2\text{O} \cdot 4\text{H}_2\text{O}$ reappears, and tends to produce another cycle of the same kind.

The author has previously observed analogous variations in the condensation of the anhydrous manganites of the alkaline earths.

The Carbon of Spiegeleisen. By B. RATHKE (*Annalen*, 260, 333—337).—When a sample of semi-crystalline ferromanganese (30 grams), containing 66 per cent. of manganese, is reduced to a fine powder, covered with water, and bromine (185 grams) gradually added to the mixture with constant shaking, until no further action is observed, a slight development of heat takes place, but no gas is evolved; on adding water and distilling, a small quantity of carbon tetrabromide, which seems to contain a little carbon tetrachloride, collects in the receiver. The insoluble carbonaceous residue, after having been repeatedly boiled with hydrochloric acid, washed, and dried at 100°, is a black, granular powder (3·7 grams), similar in appearance to gunpowder. A sample of this powder was digested with hydrofluoric acid to free it from silica, washed well, dried at 110°, and analysed with the following result (in percentages):—Carbon = 49·97, hydrogen = 2·12, bromine = 21·25, chlorine = 1·47, and oxygen = 25·19; it also contains traces of iron and manganese and has a faint acid reaction. When treated with ammonia at 100°, it loses 13·8 per cent. of bromine and 0·82 per cent. of chlorine, and the residual powder retains ammonia even after having been dried at 110°. When the original carbonaceous residue is boiled with sodium carbonate (but not with sodium chloride), it loses 13·94 per cent. of bromine and 1·58 per cent. of chlorine; the undissolved substance has a neutral reaction and the following percentage composition:—Carbon = 50·71, hydrogen = 2·13, bromine = 7·41, sodium = 7·39, and oxygen = 32·36.

These results show that the carbonaceous residue obtained from ferromanganese in the manner described above has the character of an organic acid.

F. S. K.

Crystalline Ferromanganese. By B. RATHKE (*Annalen*, 260, 326—332).—Three samples of crystalline ferromanganese were analysed with the following results:—

	Carbon.	Silicon.	Iron.	Manganese.	Phosphorus.
I.....	7·47	0·18	9·48	82·45	0·10
II.....	7·45	0·15	16·99	75·73	0·12
III.....	6·48	0·52	47·93	44·99	—

F. S. K.

Atomic Weight of Rhodium. By K. SKUBERT and K. KOBBÉ (*Annalen*, 260, 314—325).—The atomic weight of rhodium has been determined by the method previously employed by Jørgensen (*Abstr.*, 1883, 1060), namely, by decomposing pure chloropurpureorhodium chloride, $\text{Rh}_2(\text{NH}_3)_{10}\text{Cl}_6$, in a stream of hydrogen.

Three different samples of metal were used for the preparation of this salt. The atomic weight was found to be 102·7 ($\text{O} = 15·96$) as the average of ten separate determinations.

F. S. K.

Mineralogical Chemistry.

Native Silver and Diopase from French Congo. By E. JANNEFIAZ (*Compt. rend.*, 112, 446—447).—Diopase of an emerald-green colour was found in some cases intimately mixed with quartz crystals of the usual form and chrysocolla, in others embedded in limestone. The diopase crystals have the usual form, and a crystal cut normally to its axis shows rings with a black cross of positive sign, as in the diopase from the Ural.

One of the specimens of calcium carbonate, crystallised in rhombohedrons, and obtained from the copper mine of Mindouli, about two leagues east of Comba, between Bonanza and Brazzaville, contained several grains of native silver, including a group of octahedra with very distinct faces. C. H. B.

Goethite, Serpentine, and Garnet from Canada. By B. J. HARRINGTON (*Jahrb. f. Min.*, 1891, i, Ref. 241—242; from *Ann. Rec. Sci.*, 4, 93—99).—*Goethite* occurs with hematite, limonite, proustite, pyrolusite, calcite, and barytes in veins in the lower carboniferous limestone at Clifton, Nova Scotia. Analysis yielded the following results:—

FeO ₃	Mn ₂ O ₃	H ₂ O.	SiO ₂
88.92	0.14	10.20	0.32

The sp. gr. of the mineral is 4.217, and its hardness 5.

Serpentine.—Narrow veins of white or apple-green serpentine occur in a dark serpentine in the asbestos mine at Coleraine, Eastern Townships. Fresh from the mine, the mineral is so soft that it can be moulded with the fingers. In the air, it becomes gradually harder, until it attains a hardness of 3.5. An analysis of dry material gave:—

SiO ₂	MgO.	FeO.	MnO.	NiO.	CaO.	H ₂ O.
43.13	42.05	0.37	trace	trace	trace	13.88

The sp. gr. of the mineral is 2.514.

Garnet is met with at Oxford, St. Jerome, and Grenville, and also in Ottawa Co., Ontario, in the well-known apatite region. Analysis yielded:—

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	MnO.	CaO.	Ignition.	Total.
36.22	18.23	7.17	0.63	37.39	0.70	100.34

B. H. B.

Manganese Ores of Transcaucasia. By N. KOZOVSKI (*Z. it. Kryst. Min.*, 18, 630, from the *Russ. Min. J.*, 4, 1—20).—The manganese ore, pyrolusite, occurs in a calcareous sandstone, and gave on analysis the following results:—

	H ₂ O.	Insol. in acids.	SiO ₂ .	P ₂ O ₅ .	Mn.	P.
I.	0.61	0.47	0.89	1.12	57.02	0.48
II.	1.04	5.04	4.36	1.02	55.00	0.45
III.	5.78	8.47	7.38	1.16	45.50	0.48

B. II. B.

Manganese Ore in Ekaterinoslav. By N. KOZOVSKI (*Zeit. Kryst. Min.*, 18, 631, from the Russian).—The ore, pyrolusite, occurs in a manganiferous clay, and gave on analysis the following results:—

	MnO ₂ .	P.	Fe ₂ O ₃ .	SiO ₂ .	CuO.	S.	MgO.	Total.
I.	85.07	trace	1.23	8.10	1.37	0.08	1.08	96.93
II.	81.03	0.36	1.90	9.33	1.95	0.07	0.85	96.43

B. H. B.

Breunerite and Bloedite, from Hall, in Tyrol. By H. v. FOULLON (*Zeit. Kryst. Min.*, 18, 658—659; from *Jahrb. k. k. Geol. Reichsanst.*, 38, 1).—With galeua, breunerite occurs in anhydrite in aggregates resembling pinolite, and gave on analysis:—

FeO.	MnO.	MgO.
11.88	1.36	37.68

Bloedite of a yellow colour is met with in the rock salt, and gave on analysis:—

SO ₃ .	MgO.	Na ₂ O.	Cl.	H ₂ O.	Total.
46.35	12.59	17.20	0.99	23.78	100.91

B. H. B.

Melanophlogite. By G. FRIEDEL (*Jahrb. f. Min.*, 1891, i, Ref. 201—205; from *Bull. Soc. Fran. Min.*, 13, 356).—The author collected a series of good specimens of melanophlogite in the Solfara Giona, in Sicily, and has subjected them to careful investigation. The mineral occurs in a bed of limestone, occurring in cavities with sulphur, calcite, and celestine. The crystals are in the form of cubes or small globes composed of a large number of cubes. From the optical examination, the author concludes that melanophlogite is formed of six quadratic pyramids, the mineral affording an example of a peculiar kind of quadratic pseudo-cube and not, as Mallard suggests, of a pseudomorph. The mineral has a sp. gr. of 2.030, and gave on analysis the following results:—

SO ₃ .	SiO ₂ .
6.19	93.18

The formula is SO₃.20SiO₂. There is also a variable percentage of carbon, which the author regards as unessential, as the limestone in which the mineral occurs is highly bituminous. The crust, on which the melanophlogite is planted, consists of opal, and the author is of opinion that the melanophlogite has been formed by the action of sulphuric anhydride on this mineral at a temperature not exceeding 100°. On a specimen of sulphur, the author found spheroidal groups of melanophlogite crystals, the crystals being hexagonal and exhibit-

ing the form of. *tridymite*. This variety he terms hexagonal melanophlogite in contradistinction to the quadratic variety crystallising in pseudo-cubes.

B. H. B.

Ferronatrite. By AL. ANDERONI and A. FRENZEL (*Zeit. Kryst. Min.*, 18, 595—598).—Under the name of ferronatrite, Mackintosh (Abstr., 1890, 455) described an iron sodium sulphate occurring with other iron sulphates in Chili. As the description of this mineral did not accord with that of a similar mineral from Camacoles, Chili, Frenzel suggested for the latter the name of *gordaites*. The mineral ferronatrite was subsequently described by Genth and Penfield (this vol., 274), and from this description the authors conclude that *gordaites* and ferronatrite are identical. A new analysis gave:—

SO ₃ .	Fe ₂ O ₃ .	Na ₂ O.	H ₂ O.	Total.
50·85	17·69	20·22	11·90	100·66

Formula: $3\text{Na}_2\text{SO}_4\cdot\text{Fe}_2\text{S}_3\text{O}_{13} + 6\text{H}_2\text{O}$.

B. H. B.

Eutaxitic Glasses of the Liparites. By P. WENJUKOFF (*Jahrb. f. Min.*, 1891, i., Ref. 281—282; from *Trav. soc. natur. St. Pétersbourg*, 21, 1—19).—In the island of Unga, east of Kamtschatka and in the River Marekanka, massive rocks of banded structure occur. Light and dark bands alternate. In polarised light, under the microscope, it is seen that both rocks consist essentially of spherulites of finely fibrous, radiated structure. Analysis gave the following results:—

	SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	CaO.	K ₂ O.	Na ₂ O.	H ₂ O.	Total.
I.	75·36	14·21	0·13	0·84	2·72	4·78	1·09	99·13
II.	76·19	13·42	0·41	1·35	2·63	4·57	1·15	97·72
III.	72·78	14·15	0·17	0·82	2·48	4·51	4·35	99·26

I. Banded rock from the Marekanka; II. banded rock from Unga; III. perlite from the Marekanka. These analyses show that these rocks are chemically identical with various liparite glasses. They therefore belong undoubtedly to the liparites, and are distinguished from obsidian and similar rocks merely by their banded structure and by the fact that devitrification has advanced further. The author proposes to include all such banded rocks in a separate group of "eutaxitic glasses." Such rocks are widely distributed, occurring, as they do, in Hungary, Lipari, the Yellowstone Park, Teneriffe, Mexico, New Zealand, Ecuador, Japan, Shropshire, and Snowdon.

B. H. B.

Basaltic Hornblendes. By C. SCHNEIDER (*Zeit. Kryst. Min.*, 18, 579—584).—The author gives the results of analyses of various basaltic hornblendes, and notes the connection existing between the percentage of ferrous oxide and the direction of extinction observed in the specimens examined. The hornblendes analysed were from the following localities: I. From the basalt-tuff of the Goldkante, Vogelsberge (sp. gr. 3·240); II. From Bohemia; III. From Hirtling, in the Westerwald (sp. gr. 3·247); IV. From Hoheberg, near Giessen (sp. gr. 3·247); V. From Wolkenburg, in the Siebengebirge;

VI. From the Laacher See (sp. gr. 3.245). The analytical results were as follows:—

	SiO ₂ .	TiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	FeO.	MgO.	CaO.	Na ₂ O.	K ₂ O.	Total.
I.	40.66	4.99	14.89	10.84	0.57	12.38	12.80	1.59	1.77	100.49
II.	39.75	5.40	15.00	7.86	2.89	14.16	12.97	1.92	1.61	101.56
III.	40.15	5.21	14.34	7.80	4.53	13.14	11.75	2.31	1.14	100.37
IV.	40.14	4.26	14.30	7.07	6.48	11.62	12.00	2.22	1.35	99.44
V.	39.29	4.36	16.57	9.13	3.19	10.40	12.90	?	?	—
VI.	39.05	4.68	15.45	6.39	7.34	11.28	13.75	1.34	0.94	100.22

For comparison, the author also gives four published analyses of hornblende (1) from a hornblende-andesite dyke in the Kaiserstuhl, (2) from the hornblende-diorite of Gräveneck, with 4.97 per cent. of titanium anhydride, (3) from Jan Mayen, and (4) from Bohemia, with 0.89 per cent. of titanium anhydride. The results of the author's analyses show that there is a great uniformity in the composition of the basaltic hornblendes, if the proportion of ferrous and ferric oxides is neglected. Many lavas, such as the leucite basalt of Ulrichstein and the basalt of Härtlingen, are very similar in composition. From the external characters of the basaltic hornblendes, the author was led to believe that they had been subjected to alteration. In order to obtain evidence on this point, he submitted specimens to the action of superheated steam at a red heat. Before ignition, the proportion of ferrous oxide and the angle of extinction of the various hornblendes were as follows:—

Laacher See	7.03 per cent.	8½°
Altenbusch	6.27 „	6 to 8
Härtlingen	4.53 „	2 to 4
Wolkenburg	3.19 „	1 to 3
Bohemia	2.89 „	1
Ortenberg	0.57 „	0

After long ignition of all these varieties, the direction of extinction became straight, and all the ferrous oxide was converted into ferric oxide. The hornblendes became dichroic and acquired the characters of the varieties from Bohemia and Ortenberg. B. H. B.

Undetermined Silicates from the Kaiserstuhl. By A. KNOR (*Zeit. Kryst. Min.*, 18, 668).—A secondary mineral, probably identical with the “sideroklept” of Saussure, occurring in the limburgite of Sasbach, gave on analysis the following results:—

SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	MgO.	MnO.	H ₂ O.	Total.
51.20	8.29	19.62	4.04	0.25	18.80	100.20

Protonotromite is the name given by the author to a dark-grey mineral which gave on analysis—

SiO ₂ .	Al ₂ O ₃ .	FeO.	MgO.	MnO.	CaO.	H ₂ O.	Total.
48.52	5.94	6.00	24.72	0.59	2.79	10.70	99.26

B. H. B.

Melanite from the Kaiserstuhl. By R. SOLTSMANN (*Zeit. Kryst. Min.*, 18, 628—629).—The author gives the results of an analysis of melanite from Oberrothweil, in the Kaiserstuhl:—

SiO ₂ .	TiO ₂ .	ZrO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	Mn ₂ O ₃ .	FeO.	CaO.
30.48	11.01	1.28	3.13	15.21	0.28	3.84	30.19
		MgO.	Na ₂ O + K ₂ O.	Ignition.	Total.		
		2.28	1.65	0.19	99.54		

The titanium may occur partly in the form of Ti₂O₃. The presence of zirconia is of interest, as it has not hitherto been detected in a mineral of the garnet group. B. H. B.

Composition of Idocrase. By A. KERNIGOTT (*Jahrb. f. Min.*, 1891, i., Mem. 200—207).—The composition of idocrase (vesuvian), a mineral of which more than fifty analyses are known, has not yet been definitely formularised. The author has consequently recalculated the analyses available, and finds that the idocrases from the various localities consist essentially of the silicate

Besides this, however, and independent of it, there is a small proportion, as yet undetermined, which cannot be included in the silicate formula. This constituent is suggestive of the potassium fluoride in apophyllite, or of the calcium fluoride in apatite. It is, however, always an essential constituent of the idocrase. In idocrase, this portion is made up of water, possibly hydroxyl, potassium and sodium, and fluorine. As these substance occur in variable quantities, it has not been found possible to group them as a formula. (Compare Abstr., 1890, 221, 718.) B. H. B.

Composition of Slags. By J. H. L. VOGT (*Zeit. Kryst. Min.*, 18, 669—678).—The author endeavours to determine the state of combination in which alumina is present in slags. He makes use of the following analyses:—

	SiO ₂ .	Al ₂ O ₃ .	CaO.	MgO.	MnO.	FeO.	K ₂ O.	Na ₂ O.	Total.
I.	55.60	5.86	24.90	11.07	1.09	1.30	—	—	99.82
II.	56.73	7.04	18.80	16.43	0.10	0.48	—	—	99.58
III.	54.00	5.37	27.75	8.67	0.91	2.06	0.51	0.53	99.80
IV.	54.68	4.79	24.70	13.87	0.97	1.85	—	—	99.86
V.	50.64	2.52	16.79	7.27	20.11	2.38	—	—	99.71

I. Coarsely crystalline blast-furnace slag from Sunnemo containing augite crystals; II. The same from Karlsdal; III. From Idöfjåoen; IV. From Sunnemo; V. Blast furnace slag with augite and rhodonite from Hofors. On calculating these analyses, it is seen that aluminium is not, as in many natural augites, present as basic silicate, but as a so-called bisilicate. Analysis I, for example, gives the formula

or expressed in detail,

In each case the ratio Si: (R'' + $\frac{1}{3}\text{Al}_2$) is so nearly equal to 1:1 that the entire mass could solidify as augite. In slags containing less silica, examined by the author, augite does not separate out, but olivine or a silicate resembling melilite. In this way the proportion of silica in the residue is increased, so that it becomes possible for augite to separate out provided the mass does not rapidly solidify in the form of a glass. B. H. B.

Lithionite-granites. By F. v. SANDBERGER (*Zeit. Kryst. Min.*, 18, 663—667).—In the lithionite-granites of the Fichtelgebirge, of the Erzgebirge, and of Northern Bohemia, there occurs an almost black mica, an analysis of which is given by the author. Analyses are also given of the orthoclase and other minerals met with in these rocks. The minerals met with in the cavities may be regarded as having been washed out of the surrounding rock. They differ from the tin ore veins chiefly in the predominance of tourmaline and albite, whilst tin ore and wolfram occur but sparsely. At Epprechtstein the minerals have been deposited in the following order: 1. Mica (sp. gr. 2.825). 2. Albite. 3. Fluorspar. 4. Tourmaline, and 5. gilbertite, appear to have been formed simultaneously with the fluorspar. The gilbertite of Cornwall closely resembles this variety in its mode of occurrence. 6. Apatite. 7. Hyalite, in transparent crusts, frequently covers all the other minerals; 8. Lithophorite; 9. Lime uranium mica and copper uranium mica. The order in the case of the principal minerals is the same with the filling of the tin veins at Zinnwald, in the Erzgebirge. B. H. B.

Rocks of the Eruptive Mass of Jablonica. By Ü. v. JONN (*Zeit. Kryst. Min.*, 18, 661; from *Jahrb. k. k. Geol. Reichsanst.*, 38, 343).—In the course of a geological investigation of the rocks of Jablonica, on the Narenta, the following analyses are given:

	SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	CaO.	MgO.	K ₂ O.	Na ₂ O.	Ignition.	Total.
I.	46.80	33.50	0.90	15.85	0.56	0.21	2.23	0.67	100.72
II.	53.50	29.65	0.20	11.55	0.28	0.77	4.67	0.75	101.37
III.	57.50	25.45	1.40	9.15	0.55	0.89	4.65	0.45	100.04

I. Plagioclase from a gabbro in the midst of the mass; II. Plagioclase from an augite-diorite on the southern edge; III. Plagioclase from an augite diorite from Schemnitz. B. H. B.

The Lautenthal Brine-Spring. By G. LATTERMANN (*Jahrb. f. Min.*, 1891, i., Ref. 248—249; from *Jahrb. preuss. geol. Landesanst.*, 1889, 259—283).—In the "Güte des Herrn" mine, at Lautenthal, in the Harz, a brine-spring has been known for 30 years, and is interesting on account of its abnormal constitution. The salt has the following composition, in grams per litre:—

	BaCl ₂ .	SiCl ₂ .	CaCl ₂ .	MgCl ₂ .	NaCl.	KCl.
I.	0.314	0.854	10.509	3.219	67.555	0.359
II.	0.318	0.899	10.120	4.360	68.168	0.458
III.	0.219	0.859	10.490	3.275	61.076	0.387

I. From the main spring; II. From the same, taken a year later; III. From a point 70 metres from the shaft. Assuming that the flow amounts to 40 litres per minute, the amount deposited by the spring, deduced from Analysis I, would be as follows:—

	Per day.	Per year.
Barium chloride	18 kilos.	6,570 kilos.
Strontium chloride	49 „	17,885 „

It is highly probable that this spring is connected with the system of fissures of the Lautenthal ore-veins, and is derived from the rock-salt bed situated to the north of the Harz. B. H. B.

Organic Chemistry.

Tertiary Nitro-hydrocarbons of the Aliphatic Series. By J. BEVAN (*Ber.*, 24, 973—976).—Hitherto no tertiary nitro-compound of the aliphatic series has been prepared in a pure condition; Tscherniak obtained a liquid boiling at 90—100° from the product of the action of silver nitrite on tertiary butyl iodide, but gives no sufficient reason for regarding it as tertiary nitrobutane (this Journ., 1876, i, 902). In view of the close relations which would probably exist between such tertiary nitro-compounds and the aromatic nitro-compounds, the author has endeavoured to obtain the former by a reaction different from that employed by Tscherniak; and finds that tertiary nitrobutane is formed by acting with zinc methyl on bromonitropropane, $\text{CMe}_2\text{Br}\cdot\text{NO}_2$, and on dibromonitroethane, $\text{CMeBr}_2\cdot\text{NO}_2$, the first-named compound giving the better yield. To carry out the reaction, ethereal solutions of bromonitropropane are mixed and allowed to remain until the mixture no longer fumes on shaking, which takes several weeks. The mixture is then poured in small portions on to ice, and the precipitated zinc hydroxide dissolved in dilute sulphuric acid. The acid aqueous solution is extracted with ether, and the combined extracts evaporated and fractionated. By repeated distillation, a liquid is obtained boiling at 127—127.5°, and is further purified by cooling to -10° and separating the portions which remain liquid. Tertiary nitrobutane, CMe_2NO_2 , is thus obtained as a crystalline mass which melts at 24°, boils at 126—126.5° under 748 mm. pressure, is miscible with alcohol, ether, and benzene, but insoluble in water, and has a specific gravity less than that of water. It has a caustic taste and peculiar acid odour, and gives off vapours which attack the eyes; it is insoluble in aqueous soda, and is not

acted on by bromine or nitrous acid, and therefore corresponds in these respects with the aromatic nitro-compounds.

When reduced with tin and hydrochloric acid, it is converted into *tertiary butylamine*, the *hydrochloride* of which crystallises in characteristic plates, and melts at 270° .

If zinc ethide is substituted for zinc methide, the corresponding tertiary nitropentane and nitrohexane are obtained; nitroheptane is formed by the action of zinc ethide on chloropicrin, $\text{CCl}_3\cdot\text{NO}_2$. Those all resemble the nitrobutane in their properties, but the yield is very small.

H. G. C.

The Supposed Isomeride of Acetylene Diiodide. By E. PATERNO and A. PERATONER (*Gazzetta*, 20, 670—687).—In a previous paper (Abstr., 1890, 1219), the authors showed that whilst both the so-called diiodides of acetylene behave as though the two iodine atoms were symmetrically disposed, the percentage composition and molecular weight of the liquid iodide pointed to the formula $\text{C}_2\text{H}_2\text{I}_2 + \text{C}_2\text{H}_2$ as the most probable; this, however, does not satisfactorily explain the reactions of the liquid iodide described below, and the authors have therefore been led to reconsider their views.

When the solid iodide is treated with alcohol and zinc powder, it is decomposed, and an approximately theoretical quantity of acetylene is evolved; the liquid iodide, however, whilst giving up the whole of its iodine to the zinc, only evolves from 13 to 17 per cent. of the acetylene corresponding with the formula $\text{C}_2\text{H}_2\text{I}_2 + \text{C}_2\text{H}_2$. It was previously stated (*loc. cit.*) that the liquid iodide is converted into the solid compound by heating with water or by steam-distillation, and it is now found that the yield of solid iodide is generally about 20 per cent. The numerical results of the experiments seem to indicate that the liquid iodide only yields a quantity of acetylene theoretically corresponding with the amount of solid iodide it is capable of yielding. By passing acetylene first through glacial acetic acid and then into a mixture of iodic acid and alcohol, the authors have succeeded in obtaining a purer form of the liquid diiodide, which yields less solid iodide on heating with water (about 5 per cent.), and very little acetylene when treated with zinc.

The analyses of this product approximately agree with the formula $\text{C}_2\text{H}_2\text{IO}$, but the molecular weight determinations by Raoult's method point to a double molecule $\text{C}_4\text{H}_4\text{I}_2\text{O}_2$. It does not contain an OH group, as neither acetic nor benzoic chloride has any action on the pure product, nor has hydriodic acid until the temperature rises to 120° , when the mass is resinified. On distilling it with phosphorus pentachloride, acetic chloride, and iodine pass over; on reducing it with sodium amalgam, acetic acid is formed, together with traces of alcohol. Oxidation of the impure iodide with chromic acid also results in the formation of acetic acid. When heated with water in a reflux apparatus for several days, it is decomposed with the formation of acetic and oxalic acids. The acetyl group, which thus seems to be present in the liquid iodide of acetylene, contains neither of the iodine atoms, as on treatment with sodium and methyl iodide, the product consists of acetic acid, acetylene, ethane, an olefine, and

traces of a heavy oil, but contains no derivative of either propionic or isobutyric acids.

Although the extreme solubility of the solid iodide in the liquid compound renders it impossible to isolate the latter in a state of purity, the authors hold the reactions of the latter compound can only be accounted for by regarding it as the acetate of a symmetrical di-iodovinyl, $\text{CHI}:\text{CIAc}$, and consider it as proved that the so-called isomeric diiodoethylenes have in reality completely different compositions. S. B. A. A.

Anhydrogeraniol, Olefinic Terpenes, and the Formation of Closed Carbon Chains. By F. W. SÄMMLER (*Ber.*, 24, 682—685).—The author has already shown (this vol., p. 540) that gerun-aldehyde, by loss of the elements of water, is converted into cymene, formation of a closed chain thus taking place. When geraniol is heated with potassium hydrogen sulphate, and the product distilled in a current of steam, a peculiar smelling oil is obtained, which after purification by repeated distillation over sodium boils at $172\text{--}176^\circ$ (uncorr.), and has a sp. gr. of 0.8232 at 20° and $n_D = 1.4835$ at 20° . From the analysis and determination of the vapour density, it was found to have the formula $\text{C}_{10}\text{H}_{16}$, and therefore belongs to the class of terpenes. In its physical properties, it differs, however, from the known members of that group, the sp. gr. being lower, and the molecular refraction much higher. It also yields a hydrocarbon $\text{C}_{10}\text{H}_{12}$, on reduction, and forms the compound $\text{C}_{10}\text{H}_{18}\text{Br}_2$ on treatment with bromine. The hydrocarbon must therefore contain an open chain of carbon atoms, and is the first representative of a new class of terpenes, for which the author proposes the name *olefinic terpenes*. Similar hydrocarbons have been obtained from coriandrol, linalool, and other olefinic camphors, and are being further investigated.

The results obtained in the author's various researches on this subject lead to the conclusion that the benzene derivatives occurring in plants are formed from compounds containing an open chain of carbon atoms. In order, however, that formation of a closed chain may take place, the parent substance must contain an aldehyde group, and a methylene group in the α -position to it. Further, a methylene group must not occupy the α -position to the aldehyde group, as in that case also an unsaturated compound is formed.

If the benzene derivatives occurring in plants are really formed in this manner, no compound can occur in which the hydrogen atoms in the positions 1 : 2 : 6 are all displaced, or in which displacement has ever taken place in the position 6, the carbon atoms being numbered from the one in combination with an aliphatic radicle, usually allyl. All the benzene compounds hitherto examined by the author obey this rule. H. G. C.

Ammoniacal Derivatives of Mercuric Cyanide. By R. VARET (*Compt. rend.*, 112, 535—536).—Gaseous ammonia, when passed into a solution of cupric bromide, forms a green precipitate, which redissolves and is followed by a blue, crystalline precipitate of cuprammonium bromide. The crystals and the mother liquor are added to an ammoniacal

solution of mercuric cyanide, heated at 30° , and agitated until completely dissolved. The filtrate, on cooling, deposits hard, brilliant, blue crystals, of the composition $2\text{HgCy}_2, \text{CuBr}_2, 4\text{NH}_3$. This compound alters but slightly when exposed to air, is almost insoluble in ammonia, and is decomposed by water. It can be heated at 100° for several hours without undergoing any appreciable change. The mutual action of cupric bromide and mercuric cyanide in presence of ammonia is quite different from their action in presence of water. Ammoniacal derivatives of the compound $\text{HgCy}_2, \text{CuBr}_2$ could not be obtained.

The compound $2\text{HgCy}_2, \text{CdBr}_2 + 3\text{H}_2\text{O}$ dissolved in aqueous ammonia at 40° yields small, white crystals of the compound $2\text{HgCy}_2, \text{CdBr}_2, 4\text{NH}_3, 2\text{H}_2\text{O}$, only slightly soluble in ammonia, and decomposed by water. At 100° , it becomes anhydrous without any loss of ammonia.

Cadmium iodide, when mixed with aqueous ammonia in quantity insufficient to dissolve it, and added in small quantities to an ammoniacal solution of mercuric cyanide, heated at about 40° , until it no longer dissolves, yields small, white crystals of the compound $\text{HgCy}_2, \text{CdCy}_2, \text{HgI}_2, 4\text{NH}_3$. It is very unstable when exposed to air, and when treated with hydrochloric acid, is decomposed with precipitation of mercuric iodide and liberation of hydrogen cyanide. Heated in a small tube at a temperature insufficient to decompose mercuric cyanide, it evolves ammonia and yields a sublimate of mercuric iodide.

Ammoniacal compounds of mercuric cyanide and cadmium chloride seem to exist, but the author has not determined the conditions under which the compounds are formed in a pure state.

No evidence was obtained of the existence of ammoniacal compounds of mercuric cyanide with nickel chloride. C. H. B.

Action of Iodine on the Alcohols of the Fatty Series, $\text{C}_n\text{H}_{2n+2}\text{O}$. By J. TRAUBE and O. NEUBERG (*Ber.*, 24, 520-521). When equal weights of ethyl alcohol and iodine are heated at 80° in a sealed tube for half an hour, an oily product is obtained which consists of ethyl ether and ethyl iodide, together with a small quantity of higher boiling products and unabsorbed iodine. Isobutyl alcohol and isoamyl alcohol, when heated at $100-110^\circ$ with iodine, yield theoretical quantities of isobutyl iodide and isoamyl iodide respectively. A complete reaction takes place between iodine and ethyl ether at 200° . When small quantities of iodine are heated with ether above its critical temperature, the mixture of dark non-transparent gas gradually changes to a beautiful dark-red, then to bright-red, and finally becomes colourless. Bromine (1 vol.) acts readily on ethyl alcohol or ethyl ether (4-5 vols.) at 80° , and hydrogen bromide and ethyl bromide, together with higher brominated products, are formed. E. C. R.

Metallic Derivatives of Alcohols. By J. W. BRÜHL and H. BILTZ (*Ber.*, 24, 649-650).—When borneol or menthol is dissolved in dry toluene or xylene and treated at the boiling point with sodium or potassium, a very violent action at first takes place,

hydrogen is evolved, and a portion of the metal is dissolved. The action then becomes less violent, and continued heating is required for a considerable period of time before the alcohol takes up the theoretical quantity of the metal. It may be assumed from this that at first a molecular compound of the alcohol and the metallic derivative is formed, which is then gradually resolved into its components.

A similar reaction takes place with the simplest alcohols, and may be utilised for the preparation of alkyl oxides free from alcohol. Methyl and ethyl alcohols dissolved in xylene, treated with sodium, behave just like borneol and menthol. A longer period of time is required, however, in these cases to complete the reaction, the sodium compounds being insoluble in the xylene, and forming a protecting layer on the surface of the sodium. Eventually, the whole of the alcohol is converted into alkyl oxide, the latter remaining as a white, gelatinous mass suspended in the xylene. H. C.

Alkaline Derivatives of Erythritol. By DE FORCRAND (*Compt. rend.*, 112, 484—487 and 532—535).—Cold concentrated solutions of erythritol and sodium hydroxide were mixed in the proportion of 1 mol. of the former to 1 to 2 mols. of the latter, and the solution was allowed to evaporate over phosphoric anhydride. The nature of the product is not affected by variations in the proportion of alkali between the limits stated. After some days, crystals separate which have the composition $C_4H_8NaO_4 + 2H_2O$. They alter rapidly in moist air, deliquesce like the alkaline alkyl oxides, and are not dehydrated at 100° . In a current of hydrogen at 110 — 115° , however, the hydrate $2C_4H_8NaO_4 + H_2O$ is obtained, as a white, crystalline, deliquescent solid. After heating in hydrogen at 135° for about 12 hours, the total loss rises to 19.65 per cent., and the residue has the composition $C_4H_8NaO_4$.

Potassium hydroxide under similar conditions yields a crystalline hydrate, $2C_4H_8KO_4 + H_2O$, which must be heated at 140 — 150° for about 20 hours in a current of carefully dried hydrogen in order to expel all the water; the residue has the composition $C_4H_8KO_4$.

The heats of dissolution of these products are as follows :—

$C_4H_8NaO_4 \cdot 2H_2O$	—6.57
$C_4H_8NaO_4 \cdot \frac{1}{2}H_2O$	—1.06
$C_4H_8KO_4 \cdot \frac{1}{2}H_2O$	—4.35
$C_4H_8NaO_4$	+0.53
$C_4H_8KO_4$	—1.23

The heat of neutralisation of erythritol by sodium hydroxide (equal equivalents) is +0.69 Cal., and by potassium hydroxide +0.708 Cal.

The calculated thermal disturbances corresponding with the formation of the various hydrates under various conditions are given. The heats of formation from carbon (diamond), gaseous hydrogen and oxygen, and solid metal are +257.67 Cal. in the case of the sodium compound and +264.22 Cal. in the case of the potassium salt.

The heat developed by the action of solid sodium oxide on solid

erythritol (+24.13 Cal.) is far greater than would correspond with a mere molecular combination of erythritol with sodium oxide. Moreover, the heats of formation of the various hydrates are of the same order of magnitude as the corresponding values for hydrated salts, and the relation between the different hydrates is also similar in the two cases. It follows that the products have the formulae already given, and are not molecular compounds of the type $2C_4H_{10}O_4.K_2O$.

The heats of formation of the alkaline alkyl oxides increase with the hydricity of the alcohol from which they are formed, thus: sodium methoxide +95.22 Cal., mono-sodium glycol oxide +150.82, mono-sodium glycer oxide +209.41, mono-sodium erythrit oxide +257.67 Cal.

C. H. B.

Formation of Sorbose from the Juice of Mountain Ash Berries.

By A. FREUND (*Monatsh.*, **11**, 560—578; compare Abstr., 1889, 180).— Since Pelouze first obtained sorbose (sorbin) in 1852, several investigators have attempted to prepare the sugar, but with varying results. Byschl and Boussingault were not successful in obtaining it, the latter having found the hexhydric alcohol sorbitol in the juice of the ripe mountain-ash berries (*Sorbus aucuparia*). According to Delffs, sorbose does not exist as such in the fresh juice of the berries, but is formed from the malic acid contained in it by the action of the ethyl alcohol derived from fermentation of the glucose present. The author confirms the view that sorbose is only formed after fermentation of the juice; but finds that its origin is not to be traced to the interaction of malic acid and alcohol. The most favourable conditions for the formation of the sugar are obtained when the juice is diluted to a sp. gr. of 1.09—1.06, and allowed to remain in open vessels for 10—12 months. If, after this time, a small quantity of the fermented liquid on evaporation yields an insignificant quantity of sorbose, the exposure to air is continued.

The formation of sorbose is really due to an oxidation of some substance present in the juice. The author thought that this substance would probably prove to be sorbitol, but on attempting to isolate that compound from the fresh juice, he obtained only a non-crystalline jelly, which gave a crystalline acetyl derivative melting at 100.2°, and an amorphous dibenzoic acetal (compare Meunier, Abstr., 1889, 223 and 479) melting at 190—191°. Sorbitol, on the other hand, gives a liquid acetyl derivative and a dibenzoic acetal melting at 160°. The non-crystalline jelly can be obtained from sorbose by reduction with sodium amalgam, thus proving that the formation of sorbose in the juice of the mountain ash berries is really due to its oxidation. That the jelly is very closely related to sorbitol, however, is shown by its conversion into that substance either by boiling its solution with very dilute nitric acid or more simply, by placing a crystal of sorbitol in a concentrated aqueous solution, which determines the formation of much crystalline sorbitol, the production of which may perhaps be explained by the assumption that an absorption of the elements of water takes place.

G. T. M.

Wood-sugar (Xylose) and Wood-gum (Xylan). By E. W. ALLEN and B. TOLLENS (*Annalen*, **260**, 289—306; compare Abstr., 1890, 472).—The quantity of wood-gum (xylan) which can be obtained from wheat straw by extracting it three times with 4—5 per cent. soda as described in its preparation from beech-wood (Abstr., 1889, 847) is 16·2 per cent. of the straw employed; the gum obtained in this way contains 3·76 per cent. of water and 28·27 per cent. of ash, consisting principally of silica, but it seems to be free from lignin, starch, cellulose, and hexoses; on distillation with acids, it yields from 9·17 to 19·19 per cent. of furfuraldehyde. A solution obtained by dissolving the gum (0·9794 gram = 0·6993 gram free from ash) and sodium hydroxide (1 gram) in water (50 cc.) has a rotatory power of $[\alpha]_D = -84\cdot1^\circ$; on hydrolysis with 5 per cent. sulphuric acid (8 parts) at 100° , it yields 7·4 per cent. of pure crystalline xylose.

The yield of wood-gum from cherry-wood is 12·4 per cent.; the product contains 7·03 per cent. of water and 6 per cent. of ash, and on hydrolysis it gives 19·4 per cent. of crystalline xylose.

Loofah, free from seeds, yields 5·73 per cent. of wood-gum, dried over sulphuric acid; this product contains 3·26 per cent. of ash.

The gum obtained by extracting beet-root with boiling 5 per cent. soda gives arabinose on hydrolysis with 5 per cent. sulphuric acid, and is probably identical with Scheibler's metapectic acid.

When the cherry-red liquid prepared by warming xylose or arabinose with a solution of phloroglucinol in hydrochloric acid (Abstr., 1889, 847) is examined with the spectroscope, a very distinct and characteristic absorption band, situated almost exactly between the D- and E-lines, is observed; this behaviour distinguishes xylose and arabinose from substances, such as wood, which give a red coloration with phloroglucinol and hydrochloric acid in the cold (lignin reaction), no absorption band being observed in such cases. The bluish or yellowish-green solution obtained by treating xylose or arabinose with orcinol and hydrochloric acid and then dissolving the precipitate in alcohol also shows a very characteristic absorption band, situated between the C- and D-lines, but close to and partially overlapping the latter.

F. S. K.

Conversion of Starch into Dextrin by the Butyric Ferment. By A. VILLIERS (*Compt. rend.*, **112**, 435—437).—Finely divided potato starch was suspended in water in the proportion of 50 grams per litre, and steam was blown into the mixture until the temperature rose to 100° . The original liquid and the condensed water almost completely filled the flask, and whilst still at 100° the liquid was mixed with a few cubic centimetres of a cultivation of *Bacillus amylobacter* and the flask plugged with sterilised cotton wool. The vessels were kept at 40° , and, as a rule, the starch was completely liquefied in 24 hours. Fermentation was allowed to continue until the liquid no longer gave a blue coloration with starch, the time required varying with the homogeneity of the starch paste. The bacillus forms very mobile rectilinear rods, but towards the end of the change they thicken at one end and become perfectly motionless. Beyond this point the

products of fermentation undergo no change. A very small quantity of gas is evolved, and the liquid has a distinct odour of butyric acid, but the quantity of this substance present does not exceed 0.3 per cent. of the original starch.

The products of the change are almost exclusively dextrins, which can be obtained by precipitation with alcohol, and may be partially separated by fractional precipitation. When dried, they form white, friable, very hygroscopic solids which combine with water with development of heat. The rotatory power of different fractions varies from $+156^\circ$ to $+207.5^\circ$. Iodine gives a red colour with the most optically active products, the intensity of the colour decreasing with the rotatory power. The reducing power, however, varies inversely with the optical activity.

'Rotatory power	' 156°	175.4°	207.5°
Reducing power	23.9	11.3	5.0

These dextrins are converted into sugars with very great difficulty; with water at 100° , the change is scarcely perceptible even after 48 hours, and with dilute sulphuric acid at 100° , the complete change requires about a day.

The absence of glucose and maltose from the products of fermentation indicates that the ferment converts the starch directly into dextrin without the intervention of any diastase secreted by the organism.

C. H. B.

Fermentation of Starch by the Butyric Ferment. By A. VILLIERS (*Compt. rend.*, 112, 536—538).—The alcoholic liquid from which the dextrins have been precipitated (preceding abstract) after some weeks deposits long, radiating crystals in amount equal to about 0.3 per cent. of the original starch. The crystals contain water and about 4 per cent. of alcohol; when exposed to air, they lose alcohol, absorb water, and become opaque, without any noteworthy alteration in weight. When recrystallised from warm water, the compound $2C_6H_{10}O_5 + 3H_2O$ is obtained in small, brilliant crystals which do not alter on exposure to air. The dried substance rapidly absorbs water from the air, but as soon as the quantity of water present corresponds with the formula, no further change takes place. The crystals which separate from the alcoholic solution have the composition $6C_6H_{10}O_5, C_2H_5O, 5H_2O$.

The new compound *cellulosin* has a very slight sweet taste; 100 c.c. of water at 15° dissolve 1.3 grams, and at 70° , 15 to 16 grams. It has a high rotatory power; for the anhydrous compound $[\alpha]_D = +159.42^\circ$. It does not melt, but bursts with intumescence when heated, is not fermentable, and does not reduce alkaline copper solution. Dilute acids convert it completely into glucose, but the boiling must be continued for about 24 hours. It has no action on phenylhydrazine. Cellulosin does not preexist in the starch, but is a true secondary product of the action of the butyric ferment.

After the starch has been completely fermented, there remains an insoluble, bulky, white, flocculent residue which agglutinates on dry-

ing. It has the composition of cellulose, and is very slowly converted into glucose when boiled with dilute inorganic acids. C. H. B.

Levosin, a New Carbohydrate from Cereals. By C. TANRET (*Compt. rend.*, 112, 293—295). Ground rye is extracted with alcohol of 50°, and the solution is mixed with twice its volume of alcohol of 94°, which precipitates a quantity of gum. The alcohol is partially distilled off, and the residue mixed with baryta-water until the addition of more merely produces a precipitate which redissolves immediately. It is then filtered, and mixed with a large quantity of hot, concentrated baryta solution, until a permanent precipitate is obtained; this precipitate is washed with baryta-water, decomposed by carbonic anhydride, and the solution concentrated, when levosin separates. To remove the small quantity of barium which it contains, it is dissolved in the smallest possible quantity of alcohol of 60°, mixed with just sufficient dilute sulphuric acid, and after removal of the barium sulphate, is precipitated with excess of alcohol of 95°.

Levosin, dried at 110°, has the composition $C_6H_{10}O_5$, and determinations of the molecular weight by Raoult's method show that the value of n is 4. When the anhydrous compound is exposed to air, it increases in weight by 11 per cent., and forms a hydrate $C_{24}H_{40}O_{20} + 4H_2O$.

Levosin is a white, almost tasteless compound, which dissolves in water in all proportions, and is very soluble in dilute alcohol, but is almost insoluble in alcohol of 95°. It softens at 145°, and melts at 160°; sp. gr. = 1.62; rotatory power $[\alpha]_D = -36^\circ$, which is not affected by the age of the solution or by temperature. It does not reduce Fehling's solution, is not affected by diastase, and does not ferment with beer-yeast. In presence of very dilute acid, it becomes hydrated with the same rapidity as cane-sugar, and the change is complete if the levosin is heated with water alone in sealed tubes at 100° for 24 hours. The rotatory power of the product is $[\alpha]_D = -76^\circ$, and it consists of a mixture of 75 per cent. of levulose and 25 per cent. of a dextrose with a very feeble dextro-rotatory power.

Levosin is not attacked by boiling alkaline solutions, but with some bases it forms definite compounds. The barium compound, $Ba_2C_{24}H_{40}O_{20}$, is obtained by adding a solution of the carbohydrate to baryta-water; it is insoluble in baryta-water, and when treated with pure water yields the compound $BaC_{12}H_{20}O_{10}$. The latter is obtained by adding baryta-water to a solution of levosin until a slight, permanent precipitate is formed. The calcium compound, $C_{24}H_{40}CaO_{20}$, is obtained in a similar manner, and is precipitated by the addition of dilute alcohol. Levosin gives no precipitate with normal or basic lead acetate in aqueous solution, but in presence of alcohol it gives with the basic acetate a precipitate of the compound $C_{24}H_{40}Pb_2O_{20}$. With ammoniacal lead acetate, the compound $C_{24}H_{40}Pb_3O_{20}$ is precipitated. With acetic anhydride and sodium acetate, levosin yields a triacetate, and with acetic anhydride and zinc chloride, a tetracetate. When dissolved in cold fuming nitric acid, and precipitated by sulphuric acid, it yields a somewhat explosive mixture of dinitrates and trinitrates. It gives no coloration

with iodine, and is oxidised by nitric acid to oxalic acid without the intermediate formation of mucic acid.

Levosin exists in rye to the extent of 0·8 per cent. of the dried grain; in green wheat it is present in the same proportion, but in ripe wheat only to the extent of 0·2 per cent. In the case of barley the variations are greater, the proportion in the green grains in July being 2·0 per cent. of the dried matter, whilst in the ripe grains there was only 0·1 per cent. Oats, whether green or ripe, and ripe maize, contain no levosin. C. H. B.

Cotton Dyeing. By L. VIGNON (*Compt. rend.*, 112, 487—489).—Thermochemical measurements have shown (Abstr., 1890, 553 and 939) that when cotton is placed in solutions of dyes, &c., it exerts a much smaller chemical effect than animal fibres under the same conditions.

Cotton, when heated in sealed tubes at 100° to 200° with 4 parts of ammoniacal calcium chloride or 4 parts of aqueous ammonia of 22°, undergoes very little physical change, but combines with 1·05 to 2·86 per cent. of nitrogen, which cannot be removed by washing with dilute acids or with water. When this product is placed in dilute sulphuric acid, it produces a much greater thermal disturbance (0·90 Cal. for 100 grams) than natural cotton under the same conditions (0·37 Cal. for 100 grams). The increased basic power of the cotton is also shown by the fact that when placed in solutions of dyes with an acid function, it acquires a somewhat deep colour, whilst ordinary cotton is but slightly tinted. C. H. B.

Normal Butylamines. By A. BERG (*Compt. rend.*, 112, 487—489).—Normal butyl chloride was heated in sealed tubes at 120° for about 10 hours with an equivalent quantity of aqueous ammonia mixed with sufficient alcohol for complete solution. The reaction is complete, and from the residue which remains after distilling off the alcohol, the hydrochloride of the secondary base can easily be crystallised. If the mother liquors from this salt are treated with dilute sodium hydroxide solution, an insoluble mixture of the secondary and tertiary bases separates, and the liquid on distillation yields an almost pure solution of the monamine. No quaternary base is formed, and the proportion of the primary, secondary, and tertiary bases are 4, 7, and 1 respectively.

When the dilute aqueous solution of the monamine is mixed with ethyl oxalate in proper proportion, normal dibutylloxamide separates as a bulky precipitate almost insoluble in boiling water, but crystallising in silky needles from hot alcohol. The mother liquor contains butylamine, butyl oxamate, and normal butylamine oxalate. Calcium butylloxamate crystallises from hot water in very slender needles. Ethyl oxalate behaves in a similar manner with amylamine and with isobutylamine, hence the formation of the three terms of dehydration seems to be general.

Dibutylamine hydrochloride is somewhat soluble in water, and crystallises in beautiful scales; the aurochloride crystallises in beautiful, slender, golden-yellow needles which are only slightly soluble in cold water, and melt under water below 100°, but when dry melt

at 170° to a reddish oil. The stannochloride is very soluble, and separates from a boiling solution as a colourless oil which solidifies on cooling, but can be obtained in long needles by slow evaporation. The acid oxalate resembles the hydrochloride, and is not very soluble in water. It is, however, much more soluble than the corresponding salt of diisobutylamine. C. H. B.

Additive Products of Hexamethylenamine. By H. MOSCHATOS and B. TOLLENS (*Ber.*, 24, 695—696).—With many metallic salts, solutions of hexamethylenamine give precipitates, which in some cases are additive products. The compound

is formed with mercuric nitrate; auric chloride also gives a precipitate containing hexamethylenamine, whilst the precipitates produced by copper sulphate or lead nitrate are simply basic salts, and do not contain hexamethylenamine.

The crystalline dinitrate, described by Wohl, is precipitated from concentrated solutions of hexamethylenamine on the addition of concentrated nitric acid. Crystalline compounds are also obtained with aromatic hydroxy-derivatives. The subject is being further investigated by the authors. A. R. L.

The Simplest Normal Oxime, $\text{CH}_2\text{:NOH}$, and its Polymerides. By R. SCHOLL (*Ber.*, 24, 573—581).—Formoxime is obtained when a solution of formaldehyde is treated with hydroxylamine. It cannot, however, be isolated, as, like formaldehyde, it exists only in solution and in the form of vapour, and on evaporation of the solution it polymerises and yields a solid, which the author considers to be trioximidomethylene.

Trioximidomethylene is best prepared as follows:—A cold saturated solution of hydroxylamine hydrochloride (20 grams) is mixed in a mortar with finely-powdered soda (41 grams) and filtered. The solution, which must be used at once, is slowly poured into a well-cooled 40 per cent. solution of formaldehyde (20 grams). The mixture soon becomes semi-solid, and to complete the action is allowed to remain all night, the product is then collected, washed with warm water (at 50°), alcohol (at 50°), and ether. It is a white, amorphous substance, insoluble in water and all ordinary organic solvents, but dissolves easily in dilute mineral acids and caustic alkalis; it is not precipitated from the latter on neutralisation. It does not melt, but at 132—134° is converted directly into vapour, and it commences to vaporise at 100°. The molecular weight of the solid cannot be determined. If hydrogen chloride is passed through the compound suspended in ether, a soluble hydrochloride is formed, and the percentage of chlorine indicates this to be a mixture.

Formoxime, $\text{CH}_2\text{:NOH}$, is slowly evolved in the gaseous state on heating the above compound at 100°, and quickly at 132—134°. A vapour density determination agreed with the formula $\text{CH}_2\text{:NOH}$. On cooling the gas, it condenses to trioximidomethylene.

Trioximidomethylene, when heated suddenly in a test-tube at the

temperature of a Bunsen burner, decomposes with a more or less violent detonation into water and hydrocyanic acid.

When boiled for a short time with water, alcohol, or ether, it does not dissolve. On prolonged boiling with water or alcohol, or on heating with an indifferent solvent in a sealed tube at 100° , it forms a solution which is neutral, has a faint, characteristic odour, and is stable at the ordinary temperature if not stronger than 10–20 per cent. A molecular weight determination by Raoult's method gave 42.3; the theory for CH_2NOH is 45. By heating the solution with dilute sulphuric acid, formaldehyde and hydroxylamine are formed; by reduction with sodium amalgam, methylamine is produced. A characteristic property of formoxime in aqueous solution is its strong reducing power; silver nitrate is reduced at once, as also is mercuric oxide in presence of alkali. If mercuric chloride is added to the aqueous solution, a yellow mercury salt is precipitated which on warming yields mercurous chloride and then metallic mercury. Mercury nitrate also forms a yellow precipitate, which quickly changes to metallic mercury. Bromine-water is at once decolorised. With Fehling's solution in the cold, it gives an intense green coloration, changing to a blue-green, and on warming, cuprous oxide is deposited. Copper sulphate gives a brownish-green; ferric chloride gives an intense red, changing to brownish-red. E. C. R.

Oximes of Sugars. By H. JACOBI (*Ber.*, 24, 696–699).—The fact that dextrose and galactose, like the simple aldehydes, yield oximes was first pointed out by E. Fischer, whilst the oxime of galactose was first obtained in the crystalline form by Rischbieth (*Abstr.*, 1888, 40), and the corresponding derivative of mannose soon afterwards by E. Fischer and Hirschberger (*Abstr.*, 1889, 687). In studying the oximes of dextrose and rhamnose, the author found that, when these were prepared from a mixture of hydroxylamine hydrochloride and sodium hydroxide, they could not, on account of their great solubility in water, be separated from the inorganic salts; this difficulty is, however, obviated by employing free hydroxylamine.

Dextrose oxime, $\text{C}_6\text{H}_{13}\text{O}_5\text{N}$, is prepared by exactly precipitating a not too dilute solution of hydroxylamine sulphate (20 grams) with a warm solution of barium hydroxide, and, after cooling, dissolving pure dextrose (20 grams) in the filtrate, the mixture being allowed to remain for three days. The solution is next decolorised by gently warming with animal charcoal, and is then evaporated to a syrup under diminished pressure at 40 – 50° . By allowing the latter to remain over concentrated sulphuric acid for 2–3 days, it solidifies to a crystalline mass, which is then freed from adhering mother liquor by spreading on a porous plate. The yield is 15 grams. It is purified by crystallisation from 80 per cent. methyl alcohol, and forms colourless, microscopic prisms, melts at 136 – 137° , and is very soluble in water, very sparingly in alcohol, and insoluble in ether. It has a faintly sweet taste, reduces Fehling's solution strongly on heating, and is lævo-rotatory, exhibiting bi-rotation. Its specific rotatory power in a 9 per cent. solution is $[\alpha]_{\text{D}_{20}} = -2.2^{\circ}$.

Rhamnose oxime, $\text{C}_6\text{H}_{13}\text{O}_5\text{N}$, is prepared in a similar manner to dextrose

oxime, but crystallises more readily; the syrup which remains on evaporating its aqueous solution solidifies on triturating for a few minutes with a little methyl alcohol. The yield is 80 per cent. of the theoretical. It forms colourless tables, melts at $127-128^{\circ}$, and is very easily soluble in water, only sparingly in hot absolute alcohol, and insoluble in ether. It is dextro-rotatory, and exhibits bi-rotation; its specific rotatory power in a 9 per cent. solution is $[\alpha]_{D_{20}} = 13.6$.

The author has also determined the specific rotatory powers of the oximes of galactose and mannose, both of which, on account of their sparing solubility in cold water, could only be examined in 5 per cent. solutions. They are both dextro-rotatory and exhibit bi-rotation. The mean values of two determinations with each are as follows:—galactose oxime, $[\alpha]_{D_{20}} = 14.75$, and mannose oxime, $[\alpha]_{D_{20}} = 3.15$.

Ethylsulphonacetone and Diethylsulphonacetone. By R. OTTO and J. TRÖGER (*Ber.*, 24, 868—870).—*Ethylsulphonacetone*, $\text{SO}_2\text{Et}\cdot\text{CH}_2\cdot\text{COMe}$, is obtained by the action of sodium ethylsulphinate on chloroacetone at the ordinary temperature; it is a yellow, viscid liquid, miscible with water, dilute alcohol, or benzene, but does not volatilise with steam. A crystalline compound is formed with hydrogen sodium sulphite. The *oxime* is deposited in colourless crystals melting at 101° . On treatment with potash, the sulphone is hydrolysed to acetic acid and ethyl methyl sulphone. Carbonic anhydride, acetic acid, and ethylsulphonic acid are formed on oxidation with potassium permanganate. The *bromo-derivative*, $\text{SO}_2\text{Et}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{CH}_2\text{Br}$, is prepared by the action of bromine on an aqueous solution of the sulphone, and melts at 80° . *Diethylsulphonacetone*, $\text{CO}(\text{CH}_2\text{SO}_2\text{Et})_2$, is obtained by the action of sodium ethylsulphinate on the preceding compound, and crystallises in small plates melting at 119° ; it is readily soluble in water and dilute alcohol, but only sparingly in ether or benzene; the constitution of the compound is proved by the formation of ethyl methyl sulphone and ethylsulphonacetic acid on treatment with potash; the latter compound, on further hydrolysis, also yields ethyl methyl sulphone.

Phenylsulphonacetone has no physiological action.

J. B. T.

Turkey Red Oil. By SCHNEURER-KESTNER (*Compt. rend.*, 112, 395—397).—The sulphonic acid in Turkey red oil can be separated from the free acid, or acid desulphonised during washing, by agitating the oil with a mixture of ether and water. The non-sulphonised acids dissolve in the ether, and the sulphonic acids dissolve in the water, from which they can be precipitated by a solution of sodium sulphate of 10°B . The proportion of sulphonic acid varies in oils prepared under seemingly identical conditions, and the solubility of the oil is determined by the proportion of the sulphonic acids. The degree of polymerisation is greater in the portion soluble in ether (mol. wt. = 472) than in the portion soluble in water (mol. wt. = 402).

The ricinoleosulphonic acid precipitated by sodium sulphate forms a hydrated, non-fluorescent syrup, which constitutes 40 to 50 per cent. of the most soluble Turkey red oil. Its composition agrees with that

of diricinoleosulphonic acid, $\text{COOH}\cdot\text{C}_{17}\text{H}_{33}\cdot\text{COO}\cdot\text{C}_{17}\text{H}_{33}\cdot\text{O}\cdot\text{SO}_3\text{H}$. After heating at 60° , it seems to contain 8 mols. H_2O .

The sulphonic and non-sulphonised acids in Turkey red oil can be estimated by making titrations with phenolphthaleïn and litmus respectively as indicators. Litmus becomes blue when all the sulphonic acid has been neutralised, but phenolphthaleïn does not change until all the non-sulphonised acid has also been neutralised.

Normal ricinoleïc acid, when treated with sulphuric acid, yields a product containing practically the same proportion of sulphonic and non-sulphonised acid as the product from resin oil.

C. H. B.

A New Optically Active Modification of Lactic Acid, obtained by Bacterial Decomposition of Cane Sugar. By F. SCHARDINGER (*Monatsh.*, 11, 545—559).—According to Le Bol's hypothesis, optically inactive ethylidenelactic acid, $\text{OH}\cdot\text{CHMe}\cdot\text{COOH}$, since it contains an asymmetric carbon atom, should be separable into two active constituents, one dextrorotatory, the other levorotatory. Until now only the former of these has been prepared (compare Lowkowitzsch, *Abstr.*, 1884, 296). The author has succeeded in obtaining the levorotatory variety by fermenting cane sugar with a micro-organism which he has named *Bacillus acidi levolactici*. The organism was obtained from a streamlet running through a Hungarian military station, the water having been examined owing to several cases of splenic gangrene occurring amongst the horses. The bacillus forms short rods of about the same size as Heuppe's *Bacillus acidi lactici*. Under different conditions of growth, however, it assumes different forms; sometimes the individuals are joined in twos, sometimes they unite, producing long, thread-like masses. It appears to be without toxicological action on the smaller animals, is readily coloured by "carbolfuchsin," has a maximum activity at a temperature of 36° , is inert below 10° and above 40° , and is of anaërobic growth.

In order to study the products of fermentation, 30 grams of cane sugar was dissolved in 1 litre of water, to which 10 grams of ammonium chloride, 1 gram of disodium phosphate, 0.20 gram of magnesium sulphate, and 15—20 grams of calcium carbonate were added. The solution thus formed was sterilised and then inoculated with a pure culture obtained by Koch's method. In 1—1½ days, fermentation commenced, which attained its maximum in 4—5 days and ceased in 7—8 days. On distilling the product, a minute quantity of ethyl alcohol and much water passed over, and the residue (25 grams) consisted of a granular calcium salt, from which a zinc salt, $(\text{C}_2\text{H}_3\text{O}_2)_2\text{Zn} + 2\text{H}_2\text{O}$, crystallising in microscopic prisms, was obtained. In order to prepare the free acid, the zinc salt was dissolved in hot water, the metal precipitated with hydrogen sulphide, and the solution filtered and evaporated at a temperature of about 60° . The acid was further purified by treatment with ether, which left sulphur and some undecomposed zinc salt undissolved. On evaporating the ethereal solution, the acid was obtained in the form of a viscid, bright-yellow liquid, soluble in alcohol, ether, and water. The silver salt, $\text{C}_2\text{H}_3\text{O}_2\text{Ag} + \frac{1}{2}\text{H}_2\text{O}$, crystallises in long prisms, is very soluble in water, and rapidly turns yellow on exposure to light. The

calcium salt, $(C_3H_5O_2)_2Ca + 4\frac{1}{2}H_2O$, is precipitated from its aqueous solution by absolute alcohol in the form of a felted mass of microscopic needles. The specific rotatory power of the acid is -4.8° ; and, like paralactic acid, it has the property of forming an anhydride at ordinary temperatures, which anhydride has an opposite rotatory power to that of the acid from which it is obtained (compare Wislicenus, *Annalen*, 167, 323, *et seq.*). The salts of the new acid are dextrorotatory, as those of dextrorotatory paralactic acid are levorotatory.

When a mixture of equal parts of the zinc salts of dextrorotatory and levorotatory ethylenelactic acids was allowed to crystallise from a warm, saturated solution, the zinc salt of the ordinary fermentation lactic acid, $(C_3H_5O_2)_2Zn + 3H_2O$, was obtained, thus placing beyond doubt the complex nature of the last-named acid.

G. T. M.

Xylose. By E. FISCHER and R. STAHEL (*Ber.*, 24, 528—538).—Xylose, as stated in a former communication (*Abstr.*, 1890, 1399), combines easily with hydrogen cyanide to form a hexonic acid, whose lactone has the formula $C_6H_{10}O_6$. The latter is the optical antipode of d-gulonolactone (see p. 677); it is l-gulonolactone, and the sugar obtained from it l-gulose. By oxidation, l-gulonic acid is converted into l-saccharic acid.

L-Gulonic acid (xylosecarboxylic acid) is prepared by mixing xylose (100 grams) dissolved in twice its weight of water with the calculated quantity of hydrocyanic acid and a few drops of ammonia. The mixture turns bright brown in a few hours, and the action is complete in two days. The liquid is mixed with a solution of pure barium hydroxide (200 grams) in water (1200 grams), and boiled until all the ammonia is expelled. The baryta is precipitated quantitatively with sulphuric acid, the solution decolorised with animal charcoal, and evaporated to a syrup. Crystals of *gulonolactone* separate after a time. The mother liquors contain an acid which is probably an isomeride of gulonic acid. The yield of gulonolactone amounts to 60 per cent. of the xylose employed. It is purified by crystallisation from warm water or alcohol (60 per cent.), sinters at 179° , melts at 181° (corr. 185°), is easily soluble in hot water, but only sparingly so in cold water and absolute alcohol; it has a faintly sweet taste, and a neutral reaction; an aqueous solution, however, after a time becomes faintly acid. For a 9.15 per cent. aqueous solution, the specific rotation $[\alpha]_D = -55.3$ at 20° . The *basic barium salt* dissolves in a large quantity of hot water and crystallises in spherical aggregates of very slender needles. The *normal barium salt* is very soluble in water, and was not obtained crystalline. The *normal calcium salt* is obtained as a syrup, and crystallises after remaining a week or so. The *phenylhydrazide* is much more soluble in water than the corresponding compound of gluconic and mannonic acids, and cannot, in consequence, be used to precipitate gulonic acid. It melts at $147-149^\circ$ (uncorr.), and decomposes at 195° .

L-Gulose is obtained by reducing a well-cooled solution (10 per cent.) of the lactone in the usual way with sodium amalgam. It is a colourless syrup, tastes sweet, is slightly dextrorotatory, and is not fermentable. The *phenylhydrazone* is obtained by adding a mixture of phenyl

hydrazine (1 part) and acetic acid (50 per cent., 1 part) to a cold solution of the syrup (1 part) in water (2·5 parts). It crystallises from hot, absolute alcohol in slender, white needles, melts at 143° without decomposition, and is easily soluble in warm water, not so soluble in cold water and absolute alcohol. The *osazone* is obtained by heating the hydrazone or the sugar with excess of phenylhydrazine acetate for one hour on the water-bath; it crystallises from hot water in yellow, flocky masses, and turns reddish-brown on drying; when crystallised from dilute alcohol, it retains its yellow colour, melts at 156° without decomposition, and is remarkably soluble in hot water, differing in this respect from all known osazones of the natural hexoses. It resembles in this respect the osazones of xylose and arabinose, and has properties similar to those of β -acrosazone; it is probable that the latter is the inactive form of gulosazone.

i-Gulonolactone is obtained in well-formed crystals by crystallising a mixture of equal quantities of the l- and d-compound from water, and melts at 160°.

When l-gulonic acid is oxidised with nitric acid (sp. gr. = 1·2), l-saccharic acid is obtained, and is purified by means of its calcium salt.

The alcohol corresponding with dextrose and ordinary saccharic acid is sorbitol. Since l-gulose is a derivative of l-saccharic acid, it is to be expected that, on reduction, it would yield the unknown l-sorbitol; the product obtained is very like sorbitol, but does not crystallise so readily. It is obtained from alcohol as a colourless, gelatinous mass, which, when dried in a vacuum, forms a white powder, and melts at 70—75°. The benzal derivative is very like the derivative from ordinary sorbitol. Sorbitol in borax solution shows a faint dextrorotation; the new compound gives a lævorotation. The authors conclude that it is l-sorbitol.

From a consideration of the above results, the authors conclude that gluconic and gulonic acids have the same structure and similar configuration, and differ only in the position of the carboxyl group, as is shown in the (stereometric) formulæ (?)

Xylose, from the ease with which it is converted into furfuraldehyde, probably contains, like arabinose, a normal carbon chain; this is confirmed by the preceding results. Arabinose and xylose do not, however, bear the same relation to each other as gluconic and gulonic acids. For then they should both give the same alcohol on reduction. Arabinose, however, yields arabitol.

Xylose yields a new compound, *xybitol*, which forms a non-crystallisable syrup, and on treatment with benzaldehyde and sulphuric acid forms a crystalline benzal derivative. In borax solution it is optically inactive. Arabitol in borax solution is lævorotatory.

E. C. R.

Xylonic Acid. By E. W. ALLEN and B. TOLLENS (*Annalen*, 260, 306—313).—*Xylonic acid*, an isomeride of arabonic acid, is formed when xylose (6 grams) is dissolved in water (30 grams), the solution treated with bromine (7 grams), and kept at the ordinary tempera-

ture until the halogen has dissolved; after removing the hydrobromic acid with lead and silver carbonate, and freeing the solution from metals with hydrogen sulphide, the filtrate is boiled with calcium carbonate, filtered, and evaporated, when the calcium salt remains as a syrup. The zinc and silver salts were prepared in like manner, but they could not be obtained in crystals. The *strontium* salt, $(C_7H_5O_6)_2Sr$, prepared by decomposing the calcium salt with oxalic acid and then treating the solution of the acid with strontium hydroxide, separates from dilute alcohol in efflorescent crystals containing about $8\frac{1}{2}$ mols. H_2O ; the rotatory power of the salt, dried at 100° , is $[\alpha]_D = 12.14^\circ$, whilst that of the strontium salt of arabonic acid is $[\alpha]_D = 1.96$. The rotatory power of a solution of xylonic acid, obtained by decomposing the strontium salt with the theoretical quantity of hydrochloric acid, was found to be $[\alpha]_D = 17.48^\circ$; the rotatory power of a solution of arabonic acid, prepared in like manner, is $[\alpha]_D = -45.86^\circ$. F. S. K.

Relative Properties of Dimethylglutaric and Trimethylsuccinic Acids; Stereo-isomeric Trimethylsuccinic Acids. By N. ZELINSKY and A. BENRUKA (*Ber.*, 24, 459—478).—In their various attempts to synthesise trimethylsuccinic acid, Auwers and Jackson (*Abstr.*, 1890, 1098), and Bischoff and Mintz (*Abstr.*, 1890, 743; this vol., p. 290), have obtained substances which they believe to be the isomeric dimethylglutaric acid, identical with the symmetrical dimethylglutaric acid described by Zelinsky (*Abstr.*, 1890, 132), as it has the same melting point of $102-104^\circ$, the same conductivity constant, and also yields a dibromo-compound, which would scarcely be expected were the product really a trimethylsuccinic acid.

The authors, however, believe that, notwithstanding this similarity, the compounds are not identical, for the "dibromodimethylglutaric acid" of Auwers and Jackson may be readily converted into the corresponding dihydroxy-compound, a stable substance which does not pass into a lactone, whereas Zelinsky's symmetrical dihydroxy-dimethylglutaric acid yields a monolactone with great ease. The explanation given by Auwers and Jackson of the formation of dimethylglutaric acid from ethyl α -bromoisobutyrate and ethyl sodio-methylmalonate, is regarded by the authors as very probable, but they believe that this is only a subsidiary action, and that the chief portion of the product is in reality trimethylsuccinic acid, which in its physical properties closely resembles the lower melting dimethylglutaric acid. In favour of the glutaric constitution, Bischoff adduces the fact that the acid, when heated in a sealed tube, is converted into the higher melting dimethylglutaric acid; this fact, however, is really against that view, for Zelinsky's lower melting glutaric acid does not behave in the same manner, but, on the contrary, the higher melting acid is completely converted by hydrochloric acid at 200° into the lower melting acid; the symmetrical diethylglutaric acids behave in the same manner. Further, the lower melting dimethylglutaric acid forms an anhydride melting at $84-86^\circ$, which, on treatment with water, yields the higher melting acid.

Led by these considerations, the authors have attempted to synthesise trimethylsuccinic acid by a new method, namely, by acting on ethyl sodiocyanopropionate with ethyl α -bromisobutyrate, and hydrolysing the product with sulphuric acid. The following equations represent the reactions which take place :—

The product of the hydrolysis is a mixture of acids all having the composition $\text{C}_7\text{H}_{12}\text{O}_4$. By repeated fractional precipitation with light petroleum from benzene solution, three acids were obtained; the first of these crystallises in rhombohedra and melts at $140\text{--}141^\circ$ when quickly heated; the second forms granules melting at $100\text{--}101^\circ$, and the third melts at $68\text{--}74^\circ$. The latter is probably a mixture, but requires further investigation; whilst the other two the authors regard as stereo-isomeric trimethylsuccinic acids, this substance containing an asymmetrical carbon atom. The second acid has almost the same melting point as symmetrical dimethylglutaric acid, but is more readily soluble in benzene; its conductivity constant k was found to be 0.0063, against 0.0055 for dimethylglutaric acid, whilst the constant for the acid melting at $140\text{--}141^\circ$ was 0.0322. The conductivity of the two stereo-isomerides, as in the case of other stereo-isomeric succinic acids, is very different, whereas in the glutaric and adipic series this remains almost constant.

The isomeride melting at $100\text{--}101^\circ$ is not identical with isopimelic or amylenepimelic acid (Abstr., 1878, 294), which melts at $100\text{--}106^\circ$. The supposed syrupy trimethylsuccinic acid recently described by Hell and Wildermann (this vol. p. 164) has not really the composition assigned to it, an error having been made in calculating the results of the analysis.

The authors have also observed that the conductivity of solutions of mixtures of stereo-isomerides remains constant in dilutions of 10—400 or more litres, but that on still further dilution, the constant decreases. To avoid errors, it is therefore necessary to examine the conductivity of extremely dilute solutions. H. G. C.

Acetonedicarboxylic Acid. By H. v. PFEHMANN (*Annalen*, 261, 151—162; compare Abstr., 1885, 138).—Acetonedicarboxylic acid, $\text{CO}(\text{CH}_2\cdot\text{COOH})_2$, is best prepared in the following manner :—Finely divided, anhydrous citric acid (500 grams), obtained by heating the commercial acid at $145\text{--}150^\circ$ for 1—2 hours, is placed in a flask of 4—6 litres capacity and a mixture of concentrated sulphuric acid (500 grams) and fuming sulphuric acid (500 grams), containing about 12 per cent. of anhydride, added; the flask is then fitted with a cork, through which passes a short piece of glass tubing. After 15 minutes time, the flask is placed on a water-bath, which has been previously heated to boiling, and the escaping gas is ignited, the heating being continued until the evolution of carbonic oxide

ceases, which is usually the case in 30—45 minutes; the contents of the flask are then cooled to 0—5° and ice (600 grams) is gradually added, care being taken that no considerable rise of temperature occurs. On cooling again to 0—5°, the acetonedicarboxylic acid is deposited in crystals and is freed from the mother liquors by pressing it in flannel bags; the crude product, which is a grey or colourless powder, must be kept in an open vessel over sulphuric acid as, if placed in a closed vessel, it soon changes into a brown syrup and then decomposes into acetone and carbonic anhydride. The yield of crude acid, which contains about 5.0 per cent. of sulphuric acid and 36 per cent. of water, is 500—600 grams from 1 kilo. of commercial citric acid. The pure compound can be obtained by recrystallising the crude product from warm water, or ethyl acetate, or better, by shaking it with ether and evaporating the dried ethereal solution. It crystallises in colourless needles and melts at 135°, being decomposed into acetone and carbonic anhydride; the same decomposition takes place on boiling solutions of the acid. It is readily soluble in water and alcohol, but more sparingly in ethyl acetate, very sparingly in ether, and almost insoluble in chloroform, benzene, and light petroleum; in its aqueous solutions, ferric chloride produces an intense violet coloration and sodium nitrite a crystalline precipitate of dinitrosoacetone; on adding phenylhydrazine hydrochloride to a neutral solution of the acid in sodium carbonate, a colourless, crystalline precipitate is produced and carbonic anhydride is evolved. The salts of acetonedicarboxylic acid are rather unstable, and undergo decomposition into acetone and a carbonate even in the cold. The barium salt is precipitated in colourless crystals when a cold, concentrated solution of the acid is saturated with barium carbonate, and the filtrate mixed with alcohol; in aqueous solutions of the barium salt, most of the heavy metals produce a precipitate, silver nitrate and lead acetate giving a colourless, ferric chloride a brownish-red, and copper acetate a green precipitate which contains both barium and copper and is insoluble in hot water.

Ethyl acetonedicarboxylate, $C_6H_{14}O_6$, is prepared by passing a rapid stream of hydrogen chloride into a solution of the crude acid (200 grams) in absolute alcohol (200—250 grams), until the mixture becomes warm and begins to froth; the stream of gas is then moderated and the solution is saturated in the cold, otherwise decomposition sets in and carbonic anhydride is evolved. After keeping over night, the mixture is poured into ice-cold water containing a little sodium chloride, the solution repeatedly extracted with ether, the concentrated ethereal extract washed with small quantities of sodium carbonate until the washings give a turbidity on the addition of hydrochloric acid, then once with dilute sulphuric acid, and finally three times with water, dried over calcium chloride, and evaporated. The ethyl salt, prepared in this way, still contains alcohol and, as a rule, ethyl acetate, but is otherwise tolerably pure; it can be obtained in a state of purity by dissolving it in sodium carbonate, or by converting it into the potassium or copper derivative (compare this vol., p. 673). Ethyl acetonedicarboxylate is a colourless oil of sp. gr. 1.1130 at 17°; it boils at 169–174° under a

pressure of 50 mm. with only very slight decomposition, and under the ordinary atmospheric pressure its boiling point is about 250° ; it is only sparingly soluble in water, but it dissolves freely in other neutral solvents and is also soluble in alkalis and alkaline carbonates; its dilute alcoholic solution gives a deep red coloration with ferric chloride and a dirty green precipitate with a solution of copper acetate. It dissolves sodium with evolution of hydrogen, and on adding anhydrous potassium carbonate to an ethereal solution of the oil, a colourless, crystalline potassium derivative is formed.

F. S. K.

Synthesis of Citric Acid from Acetonedicarboxylic Acid.

By M. DÜNSCHMANN and H. v. PECHMANN (*Annalen*, 261, 162—166).

—Citric acid can be obtained synthetically by treating ethyl acetonedicarboxylate with hydrogen cyanide in well-cooled ethereal solution and boiling the product, first with concentrated hydrochloric acid, and then with soda to ensure complete hydrolysis; the citric acid is isolated by means of its calcium salt, which is then decomposed with oxalic acid.

When ethyl acetonedicarboxylate is converted into the potassium derivative (compare next page), and the latter is boiled with water, ethyl acetoacetate separates from the solution as an oil.

Acetonedicarboxylic acid readily undergoes decomposition into acetone and carbonic anhydride when it is heated alone or boiled with acids or dilute alkalis; when boiled with concentrated alcoholic potash, it yields malonic acid.

F. S. K.

Condensation of Acetonedicarboxylic Acid with Phenols.

By B. S. BURTON and H. v. PECHMANN (*Annalen*, 261, 166—172).—

β -Methylumbelliferonecarboxylic acid (β -umbelliferoneacetic acid),

$\text{O} < \begin{array}{c} \text{CO} - \text{CH} \\ \text{C}_6\text{H}_3(\text{OH}) \end{array} > \text{C} \cdot \text{CH}_2 \cdot \text{COOH}$, is formed when an intimate mixture

of resorcinol (25 grams) and crude acetonedicarboxylic acid (45 grams) (compare preceding page) is added to concentrated sulphuric acid (250 grams); the solution is kept over night, then poured into water, and the precipitated product purified by recrystallisation from alcohol or water. It crystallises in slender, lustrous needles, melts at 201 — 202° with decomposition, and is moderately easily soluble in boiling water and alcohol, but insoluble in cold water, ether, chloroform, and benzene; it separates from water in crystals containing 1 mol. H_2O , which is expelled at 110° , and its solutions in alkali and alkaline carbonates show a blue fluorescence. The silver salt, $\text{C}_{11}\text{H}_7\text{O}_5\text{Ag}$, is a yellow compound, which turns black on boiling with water. The ethyl salt, prepared from ethyl acetonedicarboxylate and resorcinol, melts at 134° .

β -Methylumbelliferonecarboxylic acid is isomeric with the acid prepared by Michael from resorcinol, ethyl malonate, and sodium ethoxide (Abstr., 1888, 956); when heated above its melting point, it is converted into β -methylumbelliferone (m. p. 185 — 186°), a fact which shows that acetonedicarboxylic acid is an intermediate product in the formation of β -methylumbelliferone from citric acid, resorcinol, and sulphuric acid (compare Pechmann and Duisberg, Abstr., 1884, 66).

Ethyl methylphenylpyrazolonecarboxylate, $\begin{array}{c} \text{CO}\cdot\text{CH}_2 \\ \text{NPh}-\text{N} \end{array} \text{C}\cdot\text{CH}_2\cdot\text{COOEt}$,

is obtained when ethyl acetonedicarboxylate is heated with phenylhydrazine at 100° ; it crystallises from dilute alcohol in lustrous prisms melting at 85° , and is insoluble in water, but soluble in ether, benzene, and chloroform; it combines both with bases and with acids, and gives the reactions of the pyrazolones. The free acid, $\text{C}_{11}\text{H}_{10}\text{N}_2\text{O}_3$, crystallises from boiling water in flat needles, melts at 134° , and is soluble in alcohol, but insoluble in ether, chloroform, and benzene; it combines with acids and with bases, and in its aqueous solution, ferric chloride produces a brownish-red coloration. On adding sodium nitrite to a sulphuric acid solution of the acid, a yellow, crystalline compound is precipitated, and when the acid is heated above its melting point it is decomposed into carbonic anhydride and methylphenylpyrazolone (m. p. 127°), identical with the compound obtained from ethyl acetoacetate.

When ethyl acetonedicarboxylate is boiled for a long time with an alcoholic solution of phenylhydrazine, yellow crystals are deposited; this substance is insoluble in acids, behaves in some respects like a hydrazone, and differs from the pyrazolone derivative described above.

F. S. K.

Alkyl Derivatives of Acetonedicarboxylic Acid. By M. DÜNSCHMANN and H. v. PECHMANN (*Annalen*, 261, 173—190).—Ethyl acetonedicarboxylate yields metallic derivatives analogous to those of ethyl acetoacetate, but it contains four hydrogen atoms which are replaceable by alkyl radicles; of the two theoretically possible disubstitution products, only those of symmetrical structure can be obtained.

Ethyl potassioacetonedicarboxylate, $\text{COOEt}\cdot\text{CHK}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{COOEt}$, is obtained in crystals when ethyl acetonedicarboxylate is treated with the theoretical quantity of alcoholic potash, and the solution then mixed with a little ether; it crystallises from hot dilute alcohol in concentrically grouped needles, does not decompose at 100° , and is soluble in water, to which it imparts an alkaline reaction. The *dipotassium* derivative, $\text{CO}(\text{CHK}\cdot\text{COOEt})_2$, prepared in like manner, forms small, lustrous crystals and absorbs carbonic anhydride from the air; its aqueous solution has a strongly alkaline reaction, and, when boiled, gives off an odour of acetone. The *copper* derivative, $(\text{C}_6\text{H}_{11}\text{O}_5)_2\text{Cu}$, separates from alcohol in green crystals, melts at $142\text{--}143^\circ$, and is insoluble in water, and only sparingly soluble in ether, but readily in hot benzene and cold chloroform.

Ethyl ethylacetonedicarboxylate, $\text{COOEt}\cdot\text{CHEt}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{COOEt}$, can be prepared by treating ethyl acetonedicarboxylate with sodium ethoxide and ethyl iodide in alcoholic solution. It boils at 207° under a pressure of 120—130 mm., and, in its alcoholic solution, ferric chloride produces a red coloration.

*Ethyl *ac'*-diethylacetonedicarboxylate*, $\text{CO}(\text{CHEt}\cdot\text{COOEt})_2$, prepared in like manner, boils at about 216° under a pressure of 130 mm.; its alcoholic solution is coloured violet by ferric chloride, but only after

some time. The *triethyl* derivative, $\text{COOEt} \cdot \text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{CHEt} \cdot \text{COONt}$, prepared from the preceding compound, boils at $223\text{--}224^\circ$ under a pressure of 130 mm.; the *tetreehyl* derivative, $\text{C}_{17}\text{H}_{30}\text{O}_5$, boils at $231\text{--}232^\circ$ under the same pressure.

When the ethyl salts of the homologues of ethyl acetonedicarboxylate are treated with excess of concentrated alcoholic potash at the ordinary temperature, the corresponding potassium salts are formed; a remarkable difference of behaviour is observed on decomposing these potassium salts with acids, for whereas the acids of symmetrical constitution can be easily prepared from the potassium salts and isolated in a crystalline condition, those of a symmetrical structure so readily undergo decomposition into carbonic anhydride and syrupy, ketone-like compounds that they cannot be obtained in a free state.

aa'-Diethylacetonedicarboxylic acid, $\text{C}_9\text{H}_{14}\text{O}_5$, crystallises from ether in colourless needles, melts at 112° , and is readily soluble in water, alcohol, and ether; when heated alone, or with water, it is decomposed with evolution of carbonic anhydride.

Tetreehylacetonedicarboxylic acid, $\text{C}_{13}\text{H}_{22}\text{O}_6$, crystallises from ether in small needles, melts at 70° , and is soluble in water and alcohol, but more sparingly in ether and benzene; it is decomposed either when heated alone or with water.

Ethyl methylacetonedicarboxylate is a liquid boiling at $195\text{--}200^\circ$ under a pressure of 120—130 mm., and at 255° under the ordinary atmospheric pressure; its alcoholic solution gives a violet coloration with ferric chloride.

Ethyl aa'-dimethylacetonedicarboxylate, $\text{C}_{11}\text{H}_{18}\text{O}_6$, boils at $199\text{--}200^\circ$ under a pressure of 130 mm., and at about $255\text{--}266^\circ$ under the ordinary atmospheric pressure; it gives a violet coloration with ferric chloride, and when boiled with dilute sulphuric acid, it yields diethyl ketone.

Ethyl aa'-dibenzylacetonedicarboxylate, $\text{C}_{23}\text{H}_{26}\text{O}_6$, can be obtained by treating ethyl acetonedicarboxylate with benzyl chloride and sodium ethoxide; it separates from hot alcohol in crystals melting at 92° . The *mono*-, *tri*-, and *tetra*-*benzyl* derivatives are thick, yellow oils, and, as in the case of the corresponding ethyl derivatives, only the symmetrical compounds yield crystalline acids.

aa'-Dibenzylacetonedicarboxylic acid, $\text{C}_{19}\text{H}_{18}\text{O}_5$, prepared by hydrolysing the ethereal salt with alcoholic potash at the ordinary temperature, crystallises from a mixture of chloroform and ether in lustrous needles, and melts at $115\text{--}116^\circ$. The *silver* salt, $\text{C}_{19}\text{H}_{16}\text{O}_5\text{Ag}$, is colourless.

Tetrabenzylacetonedicarboxylic acid, $\text{C}_{33}\text{H}_{30}\text{O}_6$, crystallises from dilute alcohol in plates, and melts at 95° ; the *silver* salt, $\text{C}_{33}\text{H}_{28}\text{O}_6\text{Ag}$, and most of the other metallic salts, are only sparingly soluble in water.

Dibenzylacetone, $\text{CO}(\text{CH}_2\text{CH}_2\text{Ph})_2$, is obtained when the dibenzyl derivative of acetonedicarboxylic acid is boiled with acids or alkalis; this ketone is also produced by the dry distillation of calcium hydrocinnamate. It is a colourless oil boiling at $280\text{--}285^\circ$ under a pressure of 130 mm. The *oxime*, $\text{C}_{17}\text{H}_{19}\text{NO}$, prepared by boiling the

ketone with a dilute alcoholic solution of hydroxylamine hydrochloride, crystallises in colourless, lustrous needles, melts at 92° , and is insoluble in water, but readily soluble in alcohol, ether, and chloroform.

Ethyl diphenylpyronedicarboxylate, $\text{CO} \left\langle \begin{smallmatrix} \text{C}(\text{COOEt})\text{:CPh} \\ \text{C}(\text{COOEt})\text{:CPh} \end{smallmatrix} \right\rangle \text{O}$, is formed when ethyl sodacetonedicarboxylate is treated with benzoic chloride in ethereal solution; it crystallises from dilute alcohol in colourless plates, and is readily soluble in most ordinary solvents except water. It behaves towards alkalis like the corresponding dimethyl derivative (compare Conrad and Guthzeit, *Abstr.*, 1888, 502), being decomposed into benzoic acid and acetophenone.

F. S. K.

Citracumalic Acid, a Condensation Product of Acetonedicarboxylic Acid. By A. NIEME and H. V. PECHMANN (*Annalen*, 261, 190—208).—*Citracumalic acid*,

is formed by the condensation of acetonedicarboxylic acid, just as isodehydracetic acid is formed from acetoacetic acid, and cumalinic acid from formylacetic acid (compare Pechmann, *Abstr.*, 1884, 1124). These three condensation products must all be regarded as 1:2:3-derivatives of a compound of the constitution

which the author names *cumalone*; it seems probable that all β -ketonic acids can be converted into carboxy-derivatives of cumalone by treatment with concentrated sulphuric acid.

Citracumalic acid is prepared by dissolving acetonedicarboxylic acid in concentrated sulphuric acid, and keeping the mixture for a long time at the ordinary temperature; the solution is then poured into ice-cold water; the precipitated acid separated by filtration, washed with a little water, and dried on porous plates. The crude product is a greenish-yellow powder, from which the pure acid is best obtained by recrystallising once from hot water, and then repeatedly extracting the dried crystals with boiling ether, when the pure compound remains as a colourless, crystalline powder. It begins to turn brown at 150° , and melts at 185° with decomposition, but it has no well-defined melting point; it is readily soluble in hot water and alcohol, but only sparingly in ether and glacial acetic acid, and is insoluble in chloroform, and benzene. No metallic or alkyl salts were obtained in a pure condition. Citracumalic acid is very stable towards acids, but is decomposed when boiled with water or heated alone at 190 — 200° , yielding carbonic anhydride and isodehydracetic acid (m. p. 153°); when heated with soda-lime, it gives off an odour of mesityl oxide.

Lutidonecarboxylic acid (pseudolutidostyryldicarboxylic acid),

is obtained in the form of its ammonium salt, when citracumalic acid is repeatedly evaporated with concentrated ammonia, and, on adding dilute sulphuric acid, the acid is precipitated as a dirty-grey powder. It crystallises from hot water in small, colourless needles, melts at 200–201° with evolution of carbonic anhydride, and is only very sparingly soluble in cold water, alcohol, and ether. The *silver* salt, $\text{C}_8\text{H}_7\text{NO}_5\text{Ag}_2$, is colourless. Lutidonedicarboxylic acid is partially decomposed by boiling water with evolution of carbonic anhydride, and, when heated above its melting point, it is completely converted into lutidone (m. p. 176°).

Lutidonecarboxylic acid (pseudolutidostyrylcarboxylic acid),

is formed when the original condensation product of ethyl acetoacetate (compare Anschütz, Bendix, and Kerp, this vol., p. 172) is treated with concentrated ammonia at the ordinary temperature, the solution kept for 48 hours, and then evaporated. It separates from dilute acetic acid in crystals melting at 256–258° with evolution of carbonic anhydride, being converted into pseudolutidostyryl; it is probably identical with the acid obtained by Collie from ethyl amidoacetoacetate (Abstr., 1885, 374). F. S. K.

Preparation of Pyromucic Acid. By H. SCHIFF (*Annalen*, 261, 254–256).—The author again describes his improved method for the preparation of pyromucic acid from furfuraldehyde (*Annalen*, 239, 374), as it has been tried by Bieler and Tollens with unsatisfactory results; when the operation is properly carried out, 28 grams of the pure acid and 25 grams of crude furfuralcohol are obtained from 56 grams of furfuraldehyde. F. S. K.

Solubility of Potassium Hydrogen Tartrate. By C. BLARENZ (*Compt. rend.*, 112, 434–435).—The author has redetermined the solubility of potassium hydrogen tartrate in water, with results agreeing with those obtained by previous observers, although showing some differences at temperatures near 100°. The quantity of the salt, Q , contained in 100 parts of the solution at the temperature t , is given by the equation $Q_t = 0.351 + 0.00151t + 0.00055t^2$, which for practical purposes may be replaced by the simpler formula $Q_t = 0.369 + 0.000569t$.

In presence of potassium chloride, the solubility of the potassium hydrogen tartrate is a function of the temperature and the quantity of chloride present, but is not continuous. With small quantities of potassium chloride, the quantity of tartrate precipitated is equivalent to that of the chloride added, but this ceases to hold good when the quantities of tartrate and chloride in solution are nearly equal.

When the quantity of chloride present is greater than the quantity

of tartrate that the pure water could dissolve at the same temperature, the law of solubility is represented by a formula, which is a direct function of the temperature, but an inverse function of the square root of the potassium contained in the chloride added.

$$Q_s = (0.0489 + 0.00005216t) / \sqrt{K}$$

Potassium hydrogen tartrate is completely insoluble in a mixture of alcohol of 90° 100 parts, water 900 parts, normal potassium sulphate 4 parts, tartaric acid 2 parts, but dissolves if the hydrogen sulphate is substituted for all or part of the normal sulphate.

C. H. B.

Reduction of Saccharic Acid. By E. FISCHER and O. PILLOY (*Ber.*, 24, 521—528).—The lactone of saccharic acid, as already stated (*Abstr.* 1890, 599), is easily reduced in acid solution by sodium amalgam. The aldehyde-acid which is formed the authors have now obtained in a crystalline condition, and shown it to be identical with glycuronic acid. By the further reduction of the acid they obtained a well-crystallised lactone, $C_6H_{10}O_8$, of a monobasic acid; this is identical with the product obtained by Thierfelder by the reduction of glycuronic acid. The authors, in agreement with Thierfelder, call the new acid gulonic acid, and the corresponding sugar gulose. On reduction of saccharic acid, evidently the carbonyl which is contained in gluconic acid is attacked, and the carbonyl of the new monobasic acid is at the other end of the carbon chain. The relation of these compounds is shown by the following formulæ:—

Glucose, $OH \cdot CH_2 \cdot [CH \cdot OH]_4 \cdot COH$.

Gluconic acid, $OH \cdot CH_2 \cdot [CH \cdot OH]_4 \cdot COOH$.

Saccharic acid, $COOH \cdot [CH \cdot OH]_4 \cdot COOH$.

Glycuronic acid, $COOH \cdot [CH \cdot OH]_4 \cdot COH$.

Gulonic acid, $COOH \cdot [CH \cdot OH]_4 \cdot CH_2 \cdot OH$.

Gulose, $COH \cdot [CH \cdot OH]_4 \cdot CH_2 \cdot OH$.

Synthesis of glycuronic acid.—A solution of saccharic acid, obtained by decomposing the cadmium salt with hydrogen sulphide, is concentrated to a syrup, and heated for 5—6 hours on the water-bath to convert as much as possible into the lactone. 20 grams of this product is dissolved in 150 grams of water, well cooled, and mixed with 3 c.c. of sulphuric acid (20 per cent.), and 100 grams of sodium amalgam (2.5 per cent.). The mixture is constantly shaken, well cooled, and kept acid by constant additions of dilute sulphuric acid. When the first lot of amalgam is used up, a second lot of 100 grams is added, and then 50 grams. The solution is neutralised with soda, evaporated on the water-bath until a large quantity of sodium sulphate separates, 10 grams of concentrated sulphuric acid mixed with double the weight of water is added, and the mixture poured into eight times the quantity of hot absolute alcohol. The hot, filtered alcoholic solution is evaporated to one-tenth its bulk, diluted with water, neutralised with barium hydroxide, excess of baryta precipitated with carbonic anhydride, the baryta precipitated from the filtrate with sulphuric acid, and the liquid concentrated and neutralised while hot with white lead; the lead is precipitated with sulphuric acid, and the filtrate evaporated to a syrup. The lactone of glycuronic

acid separates after a time, is filtered, dried on porous plates, and on recrystallisation from warm water is obtained in good, colourless crystals. It sinters when rapidly heated to 170° , and melts at $175-178^{\circ}$. For a 4 per cent. aqueous solution, the specific rotation $[\alpha]_D = +19.1^{\circ}$ at 20° . The yield of crystallised glycuronolactone amounts to only a few per cents. of the saccharic acid employed, but more is formed in reality, as is shown by the reducing power of the solution obtained by reduction of saccharic acid, and also by the greater yield of gulonolactone.

d.-Gulonic acid is prepared as follows:—20 grams of syrupy saccharic acid is mixed with 300 grams of sodium amalgam, and the liquid allowed to become faintly alkaline; after a time more amalgam is added, and the solution constantly neutralised with sulphuric acid. 400 grams of amalgam were added, with continuous shaking, in the course of four hours. When the hydrogen is no longer taken up, and the solution does not reduce Fehling's solution, all the glycuronic acid is converted to gulonic acid. The liquid is treated in a manner similar to that described above for glycuronic acid. Gulonolactone crystallises from warm water or 60 per cent. alcohol, and melts at $180-181^{\circ}$. For an aqueous solution of sp. gr. 1.0373, the specific rotation $[\alpha]_D = +55.1$ at 20° . The yield of pure gulonolactone amounts to 10–12 per cent. of the syrupy saccharic acid employed. The *phenylhydrazide* is obtained by heating the lactone (1 part) with phenylhydrazine (1 part) and water (3 parts) for one hour on the water-bath; it melts at $147-149^{\circ}$, and is easily soluble in hot water and hot alcohol.

d.-Gulose is obtained from gulonolactone by reduction with sodium amalgam and sulphuric acid. It is a colourless syrup, and is easily soluble in water, but only very sparingly in absolute alcohol. With phenylhydrazine, it behaves like l.-gulose (see this vol., p. 667). When evaporated with nitric acid (sp. gr. = 1.15), it is converted into saccharic acid. A 10 per cent. aqueous solution at 30° showed no perceptible fermentation with yeast after remaining 24 hours.

The synthesis of d.-gulonic acid gives a general method for the production of new sugars, as the reduction of other bibasic acids of this group (mannosaccharic, mucic, and isosaccharic acids) will probably yield isomerides of the hexoses. H. C. R.

d.- and l.-Mannosaccharic Acids. By E. FISCHER (*Ber.*, 24, 539–546).—By the oxidation of arabinosecarboxylic acid, Kiliani obtained a compound isomeric with saccharic acid, to which he gave the name metasaccharic acid (*Abstr.*, 1887, 465). The optical isomerides of this acid are obtained from d.- and l.-mannonic acid. The author considers that arabinosecarboxylic acid in consequence of its relation to mannose would be better designated as l.-mannonic acid, and metasaccharic acid as mannosaccharic acid.

d.-Mannosaccharic acid is obtained by heating the lactone of d.-mannonic acid with one and a-half times the quantity of nitric acid (sp. gr. = 1.2) for 24 hours at 50° . The mixture is diluted with water, and evaporated to a syrup. The acid is then converted into the calcium salt, the latter decomposed with oxalic acid, and the

filtrate evaporated to a syrup, which, on the addition of a little alcohol, crystallises. The product, which is the double lactone of d.-mannosaccharic acid, is purified by recrystallisation from hot alcohol. The yield amounts to 30–35 per cent. of the mannonolactone employed. It crystallises from hot alcohol or a small quantity of warm water in long, colourless needles of the formula $C_8H_{10}O_8$, sinters at 170° , melts at 180 – 190° with evolution of gas when heated quickly, reduces Fehling's solution rapidly when warmed, and is easily soluble in warm water, but somewhat sparingly in cold water. The aqueous solution is neutral when freshly prepared, but if left for 12 hours becomes strongly acid. For a 3.932 per cent. aqueous solution, the specific rotation $[\alpha]_D = +201.8$ at 23° . The isomeric compound prepared by Kiliani gives an equal and opposite rotation. The compound is more easily prepared from mannose, as in this case the solution obtained by treating ivory-nuts with acid can be directly employed. The lactone dissolves easily in dilute alkali, and the solution turns yellow when boiled. The *calcium salt*, $C_8H_{10}O_8Ca$, is obtained as a crystalline powder by heating the lactone dissolved in water (100 parts) for half-an-hour with excess of calcium carbonate, decolorising the solution with animal charcoal, and evaporating in a vacuum. The *barium salt* is more soluble than the calcium salt, and crystallises in microscopic, elongated tablets. The *strontium salt* forms a crystalline powder. The *cadmium salt* is very insoluble in water, and is obtained in microscopic tablets on adding cadmium acetate to a solution prepared by adding acetic acid to the sodium salt.

d.-Mannosaccharodiamide is obtained in colourless, rhombohedral crystals by shaking the dilactone with excess of ammonia. It darkens when quickly heated to 180° , melts about 189° with decomposition, and is decomposed with evolution of ammonia on boiling with alkalis.

The *monophenylhydrazide* is prepared by adding the finely-powdered dilactone (1 gram) to a cold solution of phenylhydrazine (1 gram) in acetic acid (50 per cent.). It crystallises from hot water in colourless needles, is easily soluble in hot water, but only sparingly in cold water or alcohol, dissolves in alkalis with precipitation of phenylhydrazine, turns yellow when heated rapidly to 185° , and melts at 190 – 191° with decomposition. The *dihydrazide*, $C_8H_{12}O_8(N_2H_5Ph)_2$, is obtained in pale-yellow plates by heating an aqueous solution of the lactone with excess of phenylhydrazine acetate. It turns yellow at about 200° , melts at about 212° with evolution of gas, and is quite insoluble even in hot water.

i.-Mannosaccharic acid is obtained by crystallising a mixture of equal parts of the d.- and l.-compounds, and also by the oxidation of i.-mannonolactone. It darkens about 170° , melts at 190° with decomposition, and is easily soluble in warm water, somewhat sparingly so in alcohol. Its aqueous solution is inactive, and when freshly prepared is neutral. The salts are very like those of the above d.-compound. The *diamide* crystallises in tablets, darkens at 170° , and melts at 183 – 185° with decomposition. The *hydrazide* is somewhat easily soluble in hot water, and melts at 190 – 195° with decom-

position. The *dihydrazide* crystallises in colourless plates, melts at 220—225° with decomposition, and is quite insoluble in water.

Of the 10 bibasic acids with normal carbon chains indicated by theory, six are now known, namely, two active saccharic acids, two active mannosaccharic acids, mucic acid, and isosaccharic acid. The seventh acid which probably belongs to this group is obtained by heating galactonic acid with quinoline at 145°, and treating the product with nitric acid. It is optically active, and is distinguished from mucic acid by its greater solubility in water and alcohol. A similar acid is obtained by heating mucic acid with quinoline or pyridine at 140°, and is optically inactive. The author is engaged in working on these compounds. E. C. R.

Tricarballic Acid. By W. O. EMERY (*Ber.*, 24, 596—602; compare Abstr., 1890, 133).—*Anhydrotricarballic acid*, $C_6H_4O_4$, is prepared by heating tricarballic acid with acetic chloride until solution takes place; after removal of the excess of acetic chloride, the residue crystallises from a mixture of chloroform and glacial acetic acid in slender needles; it melts at 132°, and is readily soluble in water or alcohol, but more sparingly in ether or chloroform. The same compound is also obtained by heating the acid in portions of 10 grams at 240—250° under reduced pressure; the anhydro-acid distils over at 233—235°; for this and similar operations, the author recommends a form of apparatus consisting of an ordinary Anschütz flask with the receiver ground to fit the narrow side tube of the distillation flask. The anhydro-acid is represented by one or other of the following formulæ,

of which the first appears to be the more probable.

When the anhydro-acid is treated in ethereal solution with anhydrous ammonia, *hydrogen ammonium tricarballicamate*, $C_6H_{16}N_3O_5$, is formed as a white, hygroscopic powder; with silver nitrate, it yields the normal silver salt of tricarballic acid.

With phenylhydrazine, *tricarballicphenylhydrazidic acid* is obtained; its calcium salt, $C_{12}H_{13}N_3O_5Ca$, is crystalline.

Anilidotricarballic acid is prepared by the action of aniline on the anhydro-acid at the ordinary temperature, and is a viscid liquid; the silver salt, $C_{12}H_{11}NO_5Ag_2$, is crystalline. At higher temperatures, tricarballicanilic acid is formed.

Orthotoluidotricarballic acid, $C_{13}H_{15}NO_5$, prepared from the anhydro-acid and orthotoluidine at the ordinary temperature, crystallises in colourless, nodular aggregates, and melts at 143°. By the action of acetic chloride, *tricarballicorthotoluidic acid* is obtained, and is deposited from water in colourless crystals melting at 152°.

Tricarballicamidimide, $NH < \begin{array}{c} \text{CO} \cdot \text{CH}_2 \\ \text{CO} \cdot \text{CH} \cdot \text{CH}_2 \cdot \text{CONH}_2 \end{array}$, may be prepared by heating tricarballicamide at 220°, until ammonia ceases to be evolved.

1-2-3-*Tribenzoylpropane*, $CH_2Bz \cdot CHBz \cdot CH_2Bz$, is formed by heating

tricarballic chloride with benzene and aluminium chloride; it crystallises from alcohol in straw-coloured needles and melts at 137° . On warming with phenylhydrazine, a *monophenylhydrazone* is obtained; it is precipitated from glacial acetic acid, on the addition of water, in pale-yellow flocks, and melts at $57-60^{\circ}$. J. B. T.

Constitution of Leucine. By E. SCHULZE and A. LUKWERNIK (*Ber.*, 24, 669—673).— α -Amidoisobutylacetic acid (amidocaproic acid), prepared from isovaleraldehyde, as described by Hüfner (*J. pr. Chem.* [2], 1, 6), is identical with inactive leucine, which has been obtained from the active vegetable product by heating the latter with water and barium hydroxide at 160° . When the synthetical inactive amido-acid is fermented with *Penicillium glaucum*, a solution of an active acid is obtained; this active acid has the same rotatory power ($[\alpha]_D = -17.4^{\circ}$) as the lævo-rotatory acid obtained by fermenting a solution of inactive leucine prepared from the natural amido-acid; the two compounds have, moreover, the same solubility in water, and they yield the same hydroxycaproic acid (m. p. $50-52^{\circ}$) on treatment with nitrous acid.

These results show that natural leucine is optically active α -amido-isobutylacetic acid. The leucine employed in the above experiments was obtained from a vegetable protoid (conglutin); it is possible that leucine from other natural sources may have a different constitution.

F. S. K.

Isopurpurates. By R. VARET (*Compt. rend.*, 112, 339—341).—When zinc cyanide is added in small quantities to a boiling aqueous solution of picric acid, hydrogen cyanide is evolved and zinc picrate is formed, and the latter reacts with the excess of zinc cyanide. The liquid is heated for 36 hours with occasional addition of water, and the liquid gradually becomes redder and redder. It is then filtered and evaporated slowly on the water-bath, when crystals of zinc isopurpurate and ammonium isopurpurate separate. Sometimes the two salts combine, but this compound could not be obtained at will. The formation of ammonium isopurpurate is due to the substitution of ammonia during the action of the zinc oxide on the picric acid, and the quantity of the ammonium salt is greater the longer the period of ebullition. Zinc cyanide and ammonium picrate yield only ammonium isopurpurate, and no zinc isopurpurate.

Mercuric cyanide and picric acid yield no hydrogen cyanide and no isopurpurate, and this is true also with ammonium, potassium, barium, and strontium picrates, although in the last two cases compounds of mercuric cyanide and picric acid with barium or strontium picrate are precipitated.

Silver cyanide gives no isopurpurate when acted on with picric acid or potassium picrate. Copper cyanide yields no isopurpurate if heated with picric acid; it becomes bright-green, but the colour disappears on washing with water.

The displacement of hydrogen cyanide by picric acid from certain metals, and not from others, is in agreement with thermo-chemical data.

C. H. B.

Alkyl Compounds of Cadmium and Magnesium. By P. LÖHE (*Annalen*, 261, 48—87).—When finely-divided cadmium is heated with pure methyl iodide in exhausted sealed tubes at 100° for 40 to 50 hours, or at 110° for 20 to 25 hours, the methyl iodide is completely decomposed, a large quantity of gas is produced, and the metal is converted into a yellowish, crystalline mass, which consists principally of cadmium iodide, but contains small quantities, at the most about 12 per cent., of cadmium methyl iodide; analyses of the gaseous mixture showed that it consisted of ethane and small quantities of hydrogen or methane. On heating the yellowish, crystalline compound at about 110° in an atmosphere of carbonic anhydride, a mixture of cadmium dimethyl and methyl iodide collects on the cooler portions of the tube, but the quantity of this liquid is so small that the crystalline residues from 10 tubes only yield 90 to 100 drops. By careful fractional distillation in an atmosphere of carbonic anhydride, a considerable quantity (but not the whole) of the methyl iodide can be separated; analyses of the crude cadmium dimethyl, obtained in this way, showed that it contains about 76·37 per cent. of the pure organo-metallic compound, and about 23·97 per cent. of methyl iodide.

Cadmium dimethyl, CdMe_2 , is a heavy, transparent, highly-refractive liquid, the vapours of which have an intensely repulsive odour, and a disagreeable metallic taste, producing nausea and vomiting. A mixture of cadmium dimethyl and methyl iodide, in the proportions given above, is not spontaneously inflammable at the ordinary temperature, but when gently warmed, it takes fire and burns with a luminous, smoky flame, giving off brownish-red fumes of cadmium oxide; it rapidly oxidises on exposure to the air, being converted into cadmium methoxide, $\text{Cd}(\text{OMe})_2$, a solid, colourless compound, and it is quickly decomposed by water and dilute acids with development of heat and evolution of methane. It is completely decomposed by concentrated nitric acid, and, like the zinc alkyl derivatives, it destroys caoutchouc. It boils at 104—105° under a pressure of 738 mm., and solidifies to a mass of colourless crystals when cooled with ice and salt; zinc dimethyl solidifies almost immediately when cooled by the evaporation of liquid carbonic anhydride; zinc diethyl and mercury dimethyl also solidify under these conditions, but not so quickly, whereas mercury diethyl simply becomes viscous. Vapour-density determinations, made with crude cadmium dimethyl, gave results in agreement with those required by the molecular formula CdMe_2 .

Attempts to prepare cadmium dimethyl by heating mercury or zinc dimethyl with cadmium or cadmium iodide were unsuccessful, the organo-metallic compound employed being simply decomposed into ethane and metal.

When finely-divided cadmium is heated with ethyl iodide, under the same conditions as those employed in the preparation of cadmium dimethyl, a reaction commences at 90°; the gas produced consists of about equal volumes of ethane and ethylene, but contains also small quantities of higher hydrocarbons, principally olefines, hydrogen, and probably also normal butane. The solid contents of the tube consist

of a mixture of about equal parts of cadmium iodide and cadmium ethyl iodide and a little unchanged ethyl iodide; after exhausting and heating the tubes at 75–80° to expel the ethyl iodide, the residual colourless solid was heated in an atmosphere of carbonic anhydride; when the temperature had risen to 194–197°, a trace of a liquid showing all the properties of an organo-metallic compound distilled over, but practically the whole of the cadmium ethyl iodide was decomposed into cadmium, ethane, and unsaturated hydrocarbons. Other attempts to prepare cadmium diethyl were equally unsuccessful.

Finely-divided cadmium and propyl iodide react at about 70°, yielding a crystalline mixture of cadmium iodide and cadmium propyl iodide, and gaseous products; on heating the crystalline mixture at 185–187°, it is decomposed into cadmium, propane, and propylene, and only the least trace of cadmium dipropyl is formed.

In direct contradiction to the statement of Cahours (*Annalen*, 114, 240), magnesium, either in the form of filings or ribbon, has no action whatever on methyl iodide at the ordinary temperature, and even at 200° the reaction is not complete; magnesium amalgam is also without action on the halogen iodide at the ordinary temperature. When, however, magnesium or magnesium amalgam is treated with methyl iodide in presence of ethyl acetate, an energetic reaction sets in, and a considerable development of heat occurs, but the mixture must be heated in sealed tubes at 110° for 40 to 50 hours before complete decomposition ensues. On opening the tubes, a gaseous mixture of ethane, ethyl acetate, and methyl iodide escapes, and there remains a dirty-grey, solid compound, which is probably either magnesium methyl iodide or a mixture of magnesium dimethyl and magnesium iodide; this grey substance is decomposed by water with great violence, yielding a very disagreeably-smelling, inflammable gas, and it retains this property even after it has been heated at 330° in an atmosphere of hydrogen.

When mercury dimethyl is heated in exhausted sealed tubes at 130° for 36 hours with a slight excess of the theoretical quantity of magnesium, in the form of filings, a dirty-yellow, solid compound is obtained, but no gaseous products are formed. Various analyses, and a careful examination of this yellow solid, showed that it is a mixture of metallic mercury and *magnesium dimethyl*. It takes fire spontaneously in an atmosphere of carbonic anhydride, burning with a brilliant display of sparks, and leaving a residue of magnesium, mercury, and carbon; it also takes fire when brought into contact with water, the gas evolved burning with a pale, slightly luminous flame; it is not decomposed when heated at 200° in an atmosphere of hydrogen, but at about 250°, a gas (in all probability ethane) is evolved. The above experiments show beyond doubt that magnesium dimethyl is a solid, non-volatile compound.

Magnesium, in the form of filings or ribbon, is without action on ethyl iodide at the ordinary temperature, but on prolonged heating at 100° in sealed tubes, the halogen iodide is decomposed, with liberation of ethane and other hydrocarbons, and a yellowish solid, consisting of a mixture of magnesium iodide and magnesium ethyl iodide, is formed; this solid product undergoes no change when heated at 280° in an in-

different atmosphere, and behaves, in other respects, like the mixture obtained from methyl iodide in like manner. In presence of a small quantity of ethyl acetate, a very violent reaction takes place between magnesium and ethyl iodide; after heating the mixture at 80° for several hours to complete the decomposition, the same products are obtained as when ethyl acetate is not added. On heating magnesium with mercury diethyl (or zinc diethyl) at 130° , small quantities of gaseous products and a voluminous, dirty-yellow substance are obtained; the solid product has the same properties as that formed from mercury dimethyl in like manner, and, doubtless, consists of a mixture of metallic mercury and solid magnesium diethyl.

Propyl iodide is decomposed by magnesium at a temperature of $75-80^{\circ}$. The principal gaseous product is propane, but considerable quantities of propylene and a little hydrogen are also formed. The solid product is a mixture of magnesium iodide and magnesium propyl iodide, which, in general behaviour, resembles the corresponding products obtained in like manner from the other halogen iodides.

Purity of Benzene. By C. LIEBERMANN and A. SCHWILZ (*Ber.*, 24, 788-790).—The authors have observed that when commercially pure benzene (b. p. $80-82^{\circ}$) is mixed with phenylhydrazine, a compound is precipitated after a time in white plates of silvery lustre. On examination, it proved to be the compound

and is formed by the action of carbon bisulphide on phenylhydrazine. The authors state that by means of this compound the carbon bisulphide is easily estimated. Crystallised benzene was found to contain no carbon bisulphide.

E. C. R.

Acetylation of Aromatic Halogen Substitution Products.

By R. SCHWETZER (*Ber.*, 24, 550-552).—*Acetyl bromobenzene*, $\text{C}_6\text{H}_4\text{BrAc}$, is obtained by gently warming a solution of bromobenzene in carbon bisulphide with acetic chloride in the presence of aluminium chloride. The viscous product is treated with water, extracted with carbon bisulphide, and the crystalline mass so obtained purified by boiling with animal charcoal in alcoholic solution. It crystallises in shining plates, melts at 51° (uncorr.), and has an agreeable odour resembling that of dried flowers; it is fairly easily soluble in alcohol, and very easily in ether, carbon bisulphide, light petroleum, acetic acid, and benzene.

Acetyl iodobenzene, $\text{C}_6\text{H}_4\text{IAc}$, prepared in a similar way to the brominated derivative, crystallises from a mixture of light petroleum and ether in tablets, melts at 85° (uncorr.), has an agreeable odour, and is easily soluble in carbon bisulphide, alcohol, acetic acid, and benzene, less so in ether, and only sparingly in light petroleum.

Acetyl- α -bromonaphthalene is obtained by the action of acetic chloride on α -bromonaphthalene, in the presence of aluminium chloride in the cold. The product is treated with water and purified by fractional distillation. It is a pale-yellow oil, and boils at $345-347^{\circ}$ (uncorr.) without decomposition.

Acetyl- β -bromonaphthalene.—The β -bromonaphthalene was obtained from β -naphthylamine by Sandmeier's reaction. The condensation with acetic chloride takes place in the cold; it is, however, better to heat the mixture. It crystallises well from petroleum, melts at 102° (uncorr.), and is very soluble in carbon bisulphide, acetic acid, and benzene, less so in alcohol and ether, and still more sparingly in light petroleum.

Paradiiodobenzene and 1:4-dibromonaphthalene gave no acetylation product when treated with acetic chloride and aluminium chloride in carbon bisulphide solution. E. C. R.

A New Reaction for Dinitro-compounds. By J. V. JANOVSKY (*Ber.*, 24, 971—972).—The author has previously observed (*Ber.*, 19, 2158) that the nitro-derivatives of azobenzene give a characteristic coloration with acetone and potash. This reaction is a general one for dinitro-compounds, but is not given by mononitro-compounds, and may, therefore, be used for determining the presence of the former. The reaction is carried out by dissolving a few milligrams of the compound in acetone, and adding aqueous potash drop by drop. A characteristic coloration is formed, the intensity of which is increased by the further addition of potash. Dinitrobenzene gives a reddish-violet coloration, which, after a time, becomes as dark as potassium permanganate, and is changed by acetic acid to dark-red, and by hydrochloric acid to yellow. 1:2:4-Dinitrotoluene gives a blue coloration, which is changed by acetic acid to violet-red; and α -dinitronaphthalene a bluish-red tint, which becomes eosin-red on addition of acetic acid. H. G. C.

Synthesis of Hydrocarbons. By R. HEISE (*Ber.*, 24, 768—772).—Gustavson has shown that by the action of propyl bromide on benzene in the presence of aluminium chloride, isopropylbenzene is produced, and the author, after confirming this, has studied the reaction at a lower temperature.

Propylbenzene (b. p. 154 — 160° ; 16 grams) is obtained, together with higher boiling products (4 grams) and unaltered benzene, when aluminium chloride (10 grams) is dropped into a mixture of propyl bromide and benzene (50 grams), cooled to -2° , and maintained at this temperature, with frequent shaking, for five hours. The propylbenzene was identified by means of its strontium and barium sulphonates, as well as by the melting point of its sulphonamide.

When propylbenzene (50 grams) is heated with aluminium chloride, and dry hydrogen chloride for six hours at 100° , a mixture of meta- and para-dipropylbenzene (18 grams), benzene (6 grams), and unaltered or regenerated propylbenzene is obtained. To separate the dipropylbenzenes, the mixture is sulphonated by heating on the water-bath with fuming sulphuric acid (2 parts), and converted into the lead salts, from the aqueous solution of which, after concentration, needles and plates separate, the former in the smaller quantity. The needles, which prove to be the para-salt, are separated from the plates by treating the mixture with cold water, in which the former are sparingly soluble. *Metadiisopropylbenzenesulphonic acid* forms

elongated tables, which easily deliquesce; the *lead salt* crystallises in very thin, glistening, rectangular, truncated tables, containing $1\frac{1}{2}$ mol. H_2O , easily soluble in cold water; the *barium salt* forms small, elongated plates, contains $1\frac{1}{2}$ mol. H_2O , and is readily soluble in water; whilst the *potassium salt* crystallises in well-formed tables, and is easily soluble in water. The *sulphonamide* separates from aqueous solutions in very long, delicate needles, and melts at 195° .

Parapropylisopropylbenzene is conveniently prepared from parabromocumene; the *sulphonic acid* crystallises in concentric tufts of needles, does not deliquesce in the air, and melts at $59-60^\circ$; the *lead salt* forms microscopic aggregates of needles, containing 1 mol. H_2O , and is somewhat sparingly soluble in water; the *calcium salt* crystallises in tufts of very long, flat, silky needles, belonging to the oblique system, which contain 8 mols. H_2O , and slowly effloresce in the air; whilst the *barium salt* forms delicate bunches of needles, somewhat sparingly soluble in water. The *sulphonamide* separates from water or dilute alcohol in long, delicate needles, and melts at $95-96^\circ$.

When propylbenzene is treated with isopropyl bromide and aluminium chloride at -2° , a mixture of para- and meta-propylisopropylbenzene is obtained, which is under investigation. A. R. L.

The Constitution of Cymene. By O. WIDMAN (*Ber.*, 24, 439-456).—The researches of Fittig, Fittica, and others on cymene have led to the conclusion that this hydrocarbon is paramethylpropylbenzene, whilst the hydrocarbon cumene, with which it is closely related, is isopropylbenzene. This has been confirmed by Jacobsen (*Abstr.*, 1879, 228), who again prepared a paramethylpropylbenzene synthetically and found it to be identical with the cymene obtained from camphor; he also prepared paramethylisopropylbenzene and found its properties to be quite distinct from those of cymene. There appeared, therefore, to be no doubt as to the existence of the normal propyl group in cymene, but from the case with which the latter passes into compounds containing the isopropyl group, such as cumic acid, it was supposed that the propyl group in this compound readily undergoes an intramolecular change, passing into the isopropyl group. The author's experiments on thymol led him to the conclusion that this change depends on the nature of the group in the para-position, a methyl group causing a predisposition to the formation of propyl, and a carboxyl group to the formation of isopropyl (*Abstr.*, 1886, 464). His further investigation has, however, shown that, whilst this conclusion holds when a methyl group is oxidised to carboxyl, no such conversion of propyl into isopropyl takes place when ethyl, acetyl, propyl, or isopropyl is converted into carboxyl. This result was so inexplicable from a theoretical point of view that the author undertook a thorough revision of the whole question of the constitution of the propyl group in cymene, and has obtained results in direct contradiction with those of most of the previous work.

The investigation consists in the preparation of paramethylpropylbenzene and paramethylisopropylbenzene, and a comparison of their derivatives with those of the cymene obtained from camphor. *Paramethylpropylbenzene* is readily obtained by the action of sodium

on a mixture of parabromotoluene and propyl bromide. On distillation, by far the greater portion is obtained in the fraction 182—184°; and on redistillation, it boils for the most part at 183—184° (774 mm.), and has then a sp. gr. of 0.8682 at 15°. Under similar conditions, cymene boils at 175—177°, and has a sp. gr. of 0.8602 at 15°, and the odour of the two hydrocarbons is quite distinct. On sulphonation, the synthetical paramethylpropylbenzene yields a mixture of two sulphonic acids, which are separated by the different solubility of their barium salts. *Barium methylpropylbenzene- α -sulphonate* ($C_6H_5MePr^{\alpha}SO_3$)₂Ba + H₂O is formed in much the larger quantity, and is sparingly soluble in cold water; it crystallises in lustrous, six-sided tablets, which are unaltered at 100°, and only lose their water of crystallisation slowly at 140—160°. Previous investigators have found this salt to contain 3 mols. H₂O. The *potassium* salt, $C_{10}H_{13}SO_3K$ + H₂O, crystallises in large, four-sided tablets, which are dehydrated at 100°, whilst the *sodium* salt, which has the composition $4C_{10}H_{13}SO_3Na$ + 5H₂O, loses 2 mols. H₂O in the exsiccator and the remainder at 100°. The *α -sulphonamide*, $C_{10}H_{13}SO_2NH_2$, forms large, transparent, monosymmetric tablets ($a:b = 1.684:1$; $\alpha = 45^\circ 51'$), melts at 101—102°, and on oxidation yields the 1.2.4-sulphamidoparatolnic acid obtained by Hall and Remson (Abstr., 1880, 257). The sulphonic group therefore occupies the position 2. *Barium methylpropylbenzene- β -sulphonate* can only be obtained pure by repeated fractional crystallisation, and then forms short, prismatic needles having the composition

it remains unaltered in the exsiccator, but becomes anhydrous at 100°. The *β -sodium* salt crystallises in needles, and the *β -sulphonamide* separates from benzene in lustrous scales melting at 112—113°.

Fittica states that both cymene and paramethylpropylbenzene yield the same substances by the action of nitric acid, namely, a solid and a liquid nitro-derivative. It has been shown, however, by v. Gerichten and Holleman (Abstr., 1878, 672; 1888, 454), that the solid compound has quite a different composition, and Widman and Bladin have proved that the liquid portion is not a nitro-compound, but consists chiefly of paratolyl methyl ketone (Abstr., 1886, 541). The author has, therefore, also examined the action of nitric acid on the synthetical methylpropylbenzene, and obtained a product which is not paratolyl methyl ketone, but is in all probability a nitro-derivative.

Paramethylisopropylbenzene is readily obtained from the parabromio-derivative of cumene (isopropylbenzene), by treating it with sodium and methyl iodide. The isopropylbenzene was prepared by acting on benzene with isopropyl bromide in presence of aluminium chloride, and converted by bromination into parabromisopropylbenzene boiling at 215—217° (corr.). The product obtained by the action of sodium and methyl iodide was too small in amount to purify completely by fractional distillation, but the portion boiling at 173—176° had exactly the same odour as cymene; on sulphonation, it yields an acid, the *barium* salt of which has the composition $(C_{10}H_{13}SO_3)_2Ba$ + 3H₂O, and the characteristic appearance and properties of the salt obtained

in the same manner from cymene. The *sulphonamide* crystallises from dilute alcohol or benzene in lustrous plates and melts at 115—116°, as does also that prepared from cymene.

From these results, there can be no doubt that cymene contains the isopropyl and not the normal propyl group, as hitherto supposed. The frequent change of one group into the other, assumed in these compounds, does not therefore take place, as all are in reality isopropyl compounds. The supposition that thymol and carvacrol are propyl derivatives only rests on their relationship to cymene, and therefore these, and in all probability all naturally occurring terpenes and camphors, are also isopropyl derivatives. H. G. C.

Cymene. By R. MEYER (*Ber.*, 24, 970—971).—A reply to the communication of Widman (preceding abstract), in which the author points out that he did not, as might be assumed from Widman's paper, repeat and confirm Jacobsen's experiments, but simply analysed the barium salt of paraisopropyltoluenesulphonic acid, and found it in agreement with Jacobsen's result, to contain 1 mol. H_2O . H. G. C.

Ethylpropylbenzene. By O. WIDMAN (*Ber.*, 24, 456—459).—This paper consists chiefly of a criticism of the results obtained by v. der Becke (this vol., p. 183), which the author regards as very incomplete. The two compounds described by v. der Becke as meta- and para-ethylpropylbenzenes yield amorphous potassium salts and liquid sulphonamides, and must therefore, in reality, be mixtures. The evidence adduced in proof of the formation of diethylbenzene and diisopropylbenzene is quite insufficient, and it is hardly probable, from analogy with other researches, that aluminium chloride should cause an elimination of side chains from substituted benzenes at the ordinary temperature, as is assumed by v. d. Becke. The latter was unable to obtain the two sulphonic acids of paraethylpropylbenzene described by the author (this vol., p. 45), but prepared a single sulphonamide melting at 84°. This is probably a mixture of the author's α - and β -sulphonamides, which melt at 112—113° and 108° respectively. The latter compound belongs to the hexagonal system, and forms rhombohedral, hemihedral crystals ($a:c = 1:1.0365$). H. G. C.

Preparation of Nitroso-compounds. By C. WILLGFRODT (*Ber.*, 24, 592—595).—*Dinitrosodinitrophenol*, $NO_2 \cdot C_6H_3(NO)_2 \cdot OH$, is formed when an alcoholic solution of picryl chloride is boiled with two molecular proportions of potassium iodide; formic acid or glacial acetic acid may be advantageously substituted for the alcohol. It crystallises from water in pale-yellow needles, which readily form feathery aggregates and melts at 122°. The compound is readily soluble in acids and organic menstrua, it does not change blue litmus paper, gives a red colour with concentrated alkalis, and may be sublimed without decomposition. Its tinctorial properties are greatly inferior to those of picric acid; it dyes wool yellow, is slightly bitter to the taste, does not give the nitroso-reaction, and is extremely stable towards oxidising agents.

Dinitrosnitrophenol-anthracene, $\text{NO}_2 \cdot \text{C}_6\text{H}_2(\text{NO})_2 \cdot \text{OH} \cdot \text{C}_{14}\text{H}_{10}$, is prepared by boiling anthracene with an alcoholic solution of dinitrosnitrophenol, and crystallises in long, yellowish-red needles melting at 160° (uncorr.). The corresponding *acenaphthene derivative*, $\text{NO}_2 \cdot \text{C}_6\text{H}_2(\text{NO})_2 \cdot \text{OH} \cdot \text{C}_{12}\text{H}_{10}$, is deposited in yellow needles melting at 168° (uncorr.). The *naphthalene compound*, $\text{NO}_2 \cdot \text{C}_6\text{H}_2(\text{NO})_2 \cdot \text{OH} \cdot \text{C}_{10}\text{H}_8$, crystallises in pale-yellow needles, and melts at $150\text{--}151^\circ$ (uncorr.). *Dinitrosnitrophenolbenzene* is also crystalline, but decomposes on exposure to air.

Dinitrosnitrophenylazobenzene, $\text{NO}_2 \cdot \text{C}_6\text{H}_2(\text{NO})_2 \cdot \text{N}_2\text{Ph}$ (m. p. $215\text{--}218^\circ$), may be prepared by the action of glacial acetic acid and potassium iodide or bromide on picrylphenylhydrazine, or by heating trinitrophenylazobenzene with glacial acetic acid and potassium iodide. Trinitrosobenzene, when reduced with iodine in glacial acetic acid solution, yields the second dinitrosoazo-derivative (m. p. 225°).

Dinitrosnitrophenylparabromazobenzene may be obtained by the action of concentrated solution of hydrogen bromide in glacial acetic acid on picrylhydrazine or trinitrophenylazobenzene.

J. B. T.

Action of Chlorine on Resorcinol. By T. ZINCKE and S. RABINOWITSCH (*Ber.*, 23, 3766—3784; 24, 912—923).—By the action of chlorine on resorcinol in chloroform or acetic acid solution, the first product is *trichlororesorcinol*, $\text{C}_6\text{HCl}_3(\text{OH})_2$ ($\text{Cl} = 2 : 4 : 6$), which crystallises in white needles and melts at 83° . On further chlorination, the pentachlororesorcinol, $\text{C}_6\text{HCl}_5\text{O}_2$, obtained by Stenhouse by acting on resorcinol with potassium chlorate and hydrochloric acid, is formed, and the author states that it is much more readily prepared by the new method. As was to be expected from Zincke's researches on the action of chlorine on other phenols (*Abstr.*, 1888, 1277; 1889, 599, 967; 1890, 488, 1108), this is not a chloroxy-compound of the formula $\text{C}_6\text{HCl}_4(\text{OCl})_2$, but has the constitution $\begin{array}{c} \text{CCl} \cdot \text{CO} \cdot \text{CCl}_2 \\ | \\ \text{CH} \cdot \text{CCl}_2 \cdot \text{CO} \end{array}$ the group, $\text{C}(\text{OH}) : \text{C} \cdot \text{Cl}$, having

been converted into $\text{CO} \cdot \text{CCl}_2$. It is not so unstable as stated by Liebermann and Dittler (*this Journ.*, 1873, 62), the fact that the clear crystals became clouded being due to the absorption of water with formation of an unstable hydrate. It has all the properties described by Stenhouse, liberates iodine from potassium iodide solution, and yields trichlororesorcinol on reduction. The statement of Claassen (*Abstr.*, 1878, 867) that pentachlororesorcinol on reduction yields a trichlororesorcinol melting at 69° is incorrect. Pentachlororesorcinol boils at 160° under 25 mm. pressure without decomposition, and is converted into hexachlorobenzene by phosphorus pentachloride at 200° .

When the pentachloro-compound is triturated with water, the hydrate is first formed, and then gradually dissolves; this solution, after a time, deposits a voluminous precipitate consisting of microscopic needles of a new acid; after crystallisation from light petroleum, it melts at $122\text{--}123^\circ$, and is readily soluble in alcohol, ether, and benzene, but scarcely at all in water. In place of water, a solution of sodium

acetate may be employed and the solution precipitated with hydrochloric acid. The new compound is an acid of the composition $C_6H_3Cl_5O_2$, and does not yield trichlororesorcinol on reduction; it can, therefore, no longer contain a six-carbon ring, and does not contain a hydroxyl group, but on boiling with water loses carbonic anhydride forming a volatile oil, which, as will be shown later, is an orthodiketone, and has the constitution $CHCl_2 \cdot CO \cdot CO \cdot CH \cdot CHCl_2$. Hence it follows that the acid from which it is obtained must have the constitution $CHCl_2 \cdot CO \cdot CCl_2 \cdot CH \cdot CCl_2 \cdot COOH$, the formation of which from pentachlororesorcinol can be readily understood. It is, therefore, *dichloroacetyltrichlorocrotonic acid*. The *amide* of this acid,

is obtained by the action of dry ammonia on a cold benzene solution of pentachlororesorcinol, and forms slender, colourless needles, melts at 166° , and is soluble in hot water and hot dilute hydrochloric acid.

If the decomposition of the acid with water be carried out in a distillation flask, the product of the reaction distills over with the steam, as an oil, which, after fractionating in a vacuum and recrystallisation from light petroleum, forms broad, yellow needles or plates, melts at 94° , and boils at $90-92^\circ$ under 25 mm. pressure. It has an odour resembling that of quinone and chloropicrin and is readily soluble in alcohol, ether, benzene, and acetic acid. It has the composition $C_6H_3Cl_5O_2$, and is an orthodiketone, as it unites with orthotoluylenediamine forming a *quinoxaline* derivative, $C_{12}H_7Cl_4N_2$, which crystallises from light petroleum in yellowish, matted needles melting at 96° . With hydroxylamine, it yields a *monoxime*, $C_6H_3Cl_4NOH$, crystallising from benzene in transparent, prismatic crystals melting at 110° . The only formula which such an orthodiketone, obtained from pentachlororesorcinol, could have is $CHCl \cdot CH \cdot CO \cdot CO \cdot CHCl$, and it is therefore *dichloromethyl chlorovinyl orthodiketone*. By the action of alkalis, it is decomposed, monochloroacetylene being formed, a reaction for which no thoroughly satisfactory explanation can as yet be proposed. It is also acted on by phosphorus pentachloride with formation of a substance which appears to be $CCl_2 \cdot CCl_2 \cdot CCl_2 \cdot CH \cdot CHCl$, but has not been obtained pure.

When pentachlororesorcinol is subjected to further treatment with chlorine in chloroform or acetic acid solution, it takes up another two atoms of the halogen forming *heptachlororesorcinol* or *heptachloromustadiketo-hexamethylene*, $CCl_3 \cdot CO \cdot CO \cdot CCl_3$. It is most readily obtained

from the mother liquors of the pentachloro-compound, which already contain it in quantity, by the further action of chlorine, distilling off the chloroform, and fractionating the residual oil under 25-30 mm. pressure. It then boils at $170-175^\circ$, the fresh distillate forming a colourless oil which gradually solidifies to a hard, crystalline mass; it melts at 50° and is readily soluble in alcohol, ether, benzene, and chloroform. On reduction with stannous chloride, it also yields trichlororesorcinol, but could not be converted into a compound of the composition $C_6Cl_3O_2$.

On treatment with water, oily products are obtained, but well

characterised compounds containing an open chain of carbon atoms are formed by the simultaneous action of halogen and water.

Chlorine and water yield an acid of the composition $C_6H_2Cl_8O_8$, which crystallises from benzene in thick, lustrous, nodular aggregates of needles, melts at $139-140^\circ$, and is readily soluble in alcohol, ether, and hot benzene, sparingly in light petroleum. Its *methyl* salt, $C_7H_4Cl_8O_8$, obtained by the action of methyl alcohol and sulphuric acid, crystallises from dilute acetic acid in nacreous plates and melts at 68° . The acid readily undergoes decomposition, sets iodine free from potassium iodide, and on warming with water, loses carbonic anhydride and hydrogen chloride forming the compound $C_5Cl_4O_2$. The latter appears to contain a ring of five carbon atoms, for it behaves very like the compound $\begin{array}{c} \text{CCl}-\text{CCl}_2 \\ \text{CCl}-\text{CCl}_2 \end{array} > \text{CO}$, prepared by Zincke and Küster (Abstr., 1890, 754). For a substance of the composition $C_5Cl_4O_2$, containing a five-carbon ring, two formulæ are possible, namely:—

The compound does not react with orthodiamidotoluene, and on treatment with alkalis, yields a mixture of dichloracrylic acid, $\text{CHCl}:\text{CCl}-\text{COOH}$, and dichloracetic acid, $\text{CHCl}_2-\text{COOH}$, which proves that the second formula is correct.

For the acid $C_6H_2Cl_8O_8$, only two formulæ are possible, at whatever point the opening of the ring in heptachlororesorcinol takes place, namely:—

- I. $\text{CCl}_3-\text{CO}-\text{CCl}_2-\text{CHCl}-\text{CCl}_2-\text{COOH}$.
- II. $\text{CCl}_3-\text{CHCl}-\text{CCl}_2-\text{CO}-\text{CCl}_2-\text{COOH}$.

The formation of the above *tetrachlorodiketodihydropentene* does not decide between these two formulæ, but the authors regard the first as the more probable, according to which it is *trichloracetylheptachlorobutyric acid*. In favour of this view, is the fact that it is converted by alkalis into chloroform and a substance which behaves as a dicarboxylic acid.

The corresponding *dichlorobromopentachloracetylbutyric acid*, $\text{CCl}_2\text{Br}-\text{CO}-\text{CCl}_2-\text{CHCl}-\text{CCl}_2-\text{COOH}$, is obtained by treating heptachlororesorcinol with bromine and water, and crystallises from benzene in beautiful, lustrous prisms melting at 149° , and readily soluble in alcohol and ether, sparingly in light petroleum. It closely resembles the chlorine derivative, and on boiling with water yields a mixture of the compounds $C_6Cl_4O_2$ and $C_5Cl_3BrO_2$, whilst with alkalis it yields dichlorobromomethane and the above-mentioned dicarboxylic acid.

Tetrachlorodiketodihydropentene, $\begin{array}{c} \text{CCl}-\text{CO} \\ \text{CCl}-\text{CO} \end{array} > \text{CCl}_2$, the preparation of

which has already been described, crystallises from light petroleum in thick, transparent, rhombic tablets, melts at $75-76^\circ$, is volatile with steam, and has a peculiar, penetrating odour. It dissolves readily in alcohol, ether, benzene, and hot light petroleum, scarcely at all in

water, and is, as previously stated, converted by alkalis into dichloroacetic and α - β -dichloroacrylic acids. The identity of the latter with the α - β -compound described by Bennett and Hill (Abstr., 1879, 616), and by Ciamician (*Ber.*, 16, 2392), was proved by direct comparison, but the authors find the melting point to be 1° higher than previously given, namely, 87 – 88° , and have been unable to confirm Hill's statement that, on boiling with baryta-water, it yields carbonic anhydride, chloroacetylene, and malonic acid.

Ammonia acts on the diketone in benzene solution forming a compound which crystallises in transparent prisms, melts at 190° , and probably consists of the *amide*, $\text{CHCl}_2\cdot\text{CO}\cdot\text{CCl}_2\cdot\text{CCl}_2\cdot\text{CONH}_2$. The corresponding *anilide*, $\text{CHCl}_2\cdot\text{CO}\cdot\text{CCl}_2\cdot\text{CCl}_2\cdot\text{CO}\cdot\text{NHPh}$, is formed by the action of aniline in acetic acid solution, and forms slender, white needles melting at 162° . In alcoholic solution, aniline reacts in a different manner, forming a compound $\text{C}_{11}\text{H}_8\text{Cl}_2\text{O}_2\text{N}$, which crystallises in long, yellow needles, melts at 143° , and may possibly be a pyridone derivative.

By the action of phosphorus pentachloride on the ketone, a substance of the composition $\text{C}_6\text{Cl}_8\text{O}$ is obtained, which might have the constitution $\begin{array}{c} \text{CCl}_2\cdot\text{CCl}_2 \\ | \\ \text{CCl}_2\cdot\text{CCl}_2 \end{array} > \text{CO}$. Against this view is the fact that by the further action of phosphorus pentachloride at 300° it yields *perchloroethane*, C_2Cl_6 , and an oily compound having the approximate composition $\text{C}_6\text{Cl}_8\text{O}$. The oxygen can therefore hardly be present as ketonic oxygen. H. G. C.

Nitration of Aromatic Amines. By E. NOFLTING and L. STOECKLIN (*Ber.*, 24, 564–572).—The nitration is effected by dissolving the amine in sulphuric acid and adding to the well-cooled solution a mixture of concentrated nitric and sulphuric acids. After remaining half an hour or so, the mixture is poured on to ice and neutralised with soda. It is advisable to add a small quantity of carbamide to the solution before nitration, in order to destroy any nitrous acid which may be formed. The following results were obtained:—

Metatoluidine gives as the chief product paranitrotoluidine [$\text{NH}_2:\text{Me}:\text{NO}_2 = 1:3:4$], together with a small quantity of the two orthonitro-derivatives.

Orthoxylidine [$\text{NH}_2:\text{Me}_2 = 1:2:3$] yields a mixture of the paranitro-compound [$1:2:3:4$] (m. p. = 114°) and the orthonitro-compound [$1:2:3:6$] (m. p. = 64 – 65°).

Orthoxylidine [$\text{NH}_2:\text{Me}_2 = 1:3:4$] gives mainly the meta-compound [$1:3:4:5$] and a small quantity of the ortho-compound [$1:3:4:2$] or [$1:3:4:6$]. The former crystallises from alcohol in beautiful, reddish-yellow needles, and melts at 136 – 137° . The latter crystallises in brown needles, and melts about 80° .

Metaxylylidine [$\text{NH}_2:\text{Me}_2 = 1:2:6$] yields the *metanitro-compound* [$1:2:6:3$], which crystallises from alcohol in sulphur-coloured needles, and melts at 81 – 82° . The *acetyl* compound forms long, white needles, and melts at 170° . The same acetyl compound is obtained by nitrating acetometaxylylidine dissolved in 5 parts of sulphuric

acid with one molecular proportion of nitric acid (97—98 per cent.). If acetometaxylidine be nitrated in 10 parts of sulphuric acid with two molecular proportions of nitric acid, a *dinitro*-compound is obtained, which crystallises from alcohol in white needles, melts at 225—226°, and yields a *dinitroxylidine* melting at 177°. It has the constitution $[\text{NHAc} : \text{Me}_2 : (\text{NO}_2)_2 = 1 : 2 : 6 : 3 : 5]$, since the diamine obtained from it by reduction does not combine with phenantbraquinone. When treated with nitrous acid, it readily yields diazo-compounds.

The author concludes from the above results that on nitrating the xylidines in sulphuric acid solution, the amido-group has no influence on the position taken up by the nitro-group, and that the latter displaces the same hydrogen atom as it does in the case of the xylenes.

Mesidine $[\text{NH}_2 : \text{Me}_3 = 1 : 2 : 4 : 6]$, when treated under similar conditions to the above with one molecular proportion of nitric acid, yields mononitromesidine melting at 73—74° and identical with the product obtained by Maule, Knecht, and Ladenburg. With two molecular proportions of nitric acid, a dinitromesidine is obtained. It crystallises in beautiful needles, melts at 193°, and is identical with the product obtained by Fittig and Ladenburg.

Pseudocumidine $[\text{NH}_2 : \text{Me}_3 = 1 : 2 : 4 : 5]$ does not easily yield a nitro-compound unless special precautions are taken, and resinous products are formed under most conditions. The best method of nitration is the following:—Finely powdered cumidine nitrate (10 grams) is gradually added to sulphuric acid cooled to -17° to -10° , the mixture poured on to ice and fractionally neutralised with alkali, when the ortho-compound separates first; the temperature must be kept below 0° and an excess of alkali is to be avoided. The product consists of 80—85 per cent. of the ortho- and 18—20 per cent. of the meta-compound. If 20 parts of sulphuric acid be used instead of 10 parts, the yield of meta-compound is increased to 25 per cent. The two nitrocumidines are also obtained by nitrating acetopseudocumidine in sulphuric acid solution.

Isodurene $[\text{NH}_2 : \text{Me}_4 = 1 : 2 : 3 : 4 : 6]$ is also somewhat difficult to nitrate, and the same precautions must be taken as for pseudocumidine. *Nitroisodurene* crystallises from alcohol in yellowish-brown needles and melts at 87—88°. E. C. R.

Reactions of Oxyalkyl Derivatives of Dimethylaniline. By E. GRIMAUD (*Compt. rend.*, 112, 290—293).—Metethoxydimethylaniline (dimethylmetaphenotidine), when treated with carbonyl chloride in presence of aluminium chloride, yields a blue colouring matter; whilst dimethylaniline itself, under the same conditions, yields a violet product. The blue substance has great tinctorial power, and gives a very pure blue shade on silk, wool, and cotton mordanted with tannin. When heated with sulphuric acid at 100° , it yields a red, fluorescent substance resembling the product obtained by heating dimethylmetamidophenol with dehydrating agents. From its mode of formation, it is probable that this colouring matter is a hexamethyl- and triethoxy-derivative of magenta,

the introduction of the ethoxy-group having changed the colour from violet to blue.

Metethoxydimethylaniline yields a nitroso-compound, which resembles the corresponding derivative of dimethylaniline, but gives no compound similar to Meldola's blue with β -naphthol, and no derivative analogous to methylene-blue. With phthalic anhydride alone, the base undergoes no change, but in presence of zinc chloride or sulphuric acid, it forms a red, fluorescent compound which seems to be identical with rhodamine. When heated with arsonic acid at 175° , it yields a rose-coloured product which, seemingly, is not an oxidation product, but results from the formation and subsequent condensation of dimethylamidophenol. With phthalic chloride, a green colouring matter is formed similar to that obtained from dimethylaniline; with dimethylmetamidobenzoic chloride, a beautiful blue colouring matter is obtained; with chloroform and sodium hydroxide, a pink substance. When the base is gently heated with phenylsulphonic chloride, there is a violent reaction, and a blue compound is formed, which very rapidly changes to yellow. Benzaldehyde and zinc chloride, and "phenylchloroform," also produce colouring matters.

Dimethylorthoanisidine behaves in a very different manner. It yields no colouring matters with carbonyl chloride, phthalic anhydride, chloroform and sodium hydroxide, benzaldehyde, or "phenylchloroform." With sodium nitrite, it yields no nitroso-derivative analogous to nitrosodimethylaniline, and in this respect it resembles dimethylorthotoluidine. With arsenic acid at 175° , or with phenylsulphonic chloride, it yields a blue colouring matter, which, however, is formed when the hydrochloride is heated alone at 175 – 180° .

Neither the ortho- nor the meta-base yields colouring matters with cupric chloride.

The results show that the substitution of an oxyalkyl radicle for hydrogen greatly modifies the reaction aptitude, and also the tint of the colouring matters formed. The properties of the derivative are also largely dependent on the position of the substituted radicle.

C. H. B.

Action of Acid Chlorides on Orthodiamines. By A. BINTRZYCKI and G. CYBULSKI (*Ber.*, 24, 631–634).—When orthotoluylenediamine (1 mol.) is heated with benzoic chloride (1 mol.) in benzene solution, the principal product is the dibenzoyl derivative (m. p. 263 – 264°); but a considerable quantity of the monobenzoyl derivative (m. p. 193 – 194°) is also formed; even when the conditions of the experiment are varied, the dibenzoyl derivative is always produced in the larger quantity, and no anhydro-base is obtained.

Diphenylacetyltoluylenediamine, $C_6H_5Me(NH\cdot CO\cdot CH_2Ph)_2$, is formed, together with the mono-derivative, when orthotoluylenediamine is heated with phenylacetic chloride in benzene solution. It crystallises from alcohol in long, lustrous needles, melts at 174 – 176° , and is moderately easily soluble in hot benzene, but almost insoluble in ether and light petroleum.

Phenylacetyltoluylenediamine, $NH_2\cdot C_6H_5Me\cdot NH\cdot CO\cdot CH_2Ph$, crystallises from hot alcohol in small, slender needles, melts at 194 – 195° ,

and is readily soluble in boiling benzene, but insoluble in light petroleum.

Orthotoluylenediamine and benzenesulphonic chloride react in benzene solution yielding the hydrochloride of the base

and a very small quantity of a compound which is insoluble in dilute hydrochloric acid.

Acetic chloride converts orthotoluylenediamine into ethenyltoluyleneamidine when the reaction takes place at the ordinary temperature, but at 0° a considerable quantity of the diacetyl derivative of the diamine is also produced. F. S. K.

Paramidocarbinols. By O. FISCHER and G. FISCHER (*Ber.*, 24, 723—729).—The simplest paramidocarbinol, paramidobenzyl alcohol, $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{OH}$, has not hitherto been obtained. It is readily prepared by reducing the corresponding paranitrobenzyl acetate (*Annalen*, 147, 343) with stannous chloride. The acetyl group is eliminated at the same time, and, after removal of the tin, a solution of paramidobenzyl alcohol hydrochloride remains. On addition of sodium carbonate solution, the base is deposited as a microcrystalline powder, and, on recrystallisation from alcohol, forms beautiful, colourless, silvery plates, melting at 95° . It reduces silver from solutions of the nitrate. The *hydrochloride*, $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{OH} \cdot \text{HCl}$, crystallises in long, slender, colourless needles, and may be volatilised unchanged at 130° in a current of hydrogen. In air, however, it becomes yellow at 100 — 120° , and then colours silk yellow, but becomes colourless on redissolving in water. This change of colour is almost certainly due to elimination of water

and formation of the compound $\text{C}_6\text{H}_4 \begin{smallmatrix} \text{CH}_2 \\ \text{NH}_2\text{Cl} \end{smallmatrix}$, which, from analogy with the rosanilines, should be coloured; the elimination of water is, however, never complete. The *hydrobromide*,

resembles the hydrochloride, and also becomes yellow at 100° in the air; the *oxalate*, $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{OH} \cdot 2\text{C}_2\text{H}_2\text{O}_4$, crystallises in small, colourless needles, and melts with decomposition at 173° . The *acetyl* compound, $\text{NHAc} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{OH}$, crystallises in slender, colourless needles, melts at 188° , and is almost insoluble in water and ether, but dissolves readily in acetic acid. The *benzoyl* compound, $\text{NHBz} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{OH}$, is obtained by the action of benzoic chloride and aqueous soda, and crystallises from acetic acid in silvery plates melting at 223° . With benzaldehyde, amidobenzyl alcohol forms the *benzylidine* compound, $\text{CHPh} \cdot \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{OH}$, which crystallises in stellate aggregates of slender, greyish-white needles, and melts at 95° . The corresponding derivative obtained from salicylaldehyde forms yellowish-red, silky needles melting at 163° , and that from cinnamaldehyde crystallises in colourless plates, and melts at 155° .

The compound obtained by O. Fischer and Roser from benzhydrol and aniline, and further investigated by Fischer and Fränkel (*Abstr.*,

1881, 587; 1888, 56), is identical with the paramidotriphenylmethane obtained by Baeyer and Löhr from paranitrobenzaldehyde and benzene, and is not, therefore, as previously supposed, an ortho-derivative. The triphenylmethanecarboxylic acid obtained from it must also be a para-derivative.

H. G. U.

Sodium Compounds of Aromatic Anilides and Amines. By G. MINUNNI (*Gazzetta*, 20, 721—723).—The author mentions that his attempts to prepare compounds of the type $\text{COOEt}\cdot\text{CHAc}\cdot\text{NR}'\text{Ph}$ by the action of the sodium anilido-compounds on ethyl chloroacetoacetate were cut short by the publication of Paal and Otten's results (*Abstr.*, 1890, 1415), and that he is at present examining the constitution of the alkaline anilido-compounds, reserving the right of further investigation in that field.

S. B. A. A.

Action of Selenyl Chloride on Aromatic Tertiary Amines. By E. GODCHAUX (*Ber.*, 24, 765—767).—*Selenodimethylaniline*, $\text{Se}(\text{C}_6\text{H}_4\cdot\text{NMe}_2)_2$, is prepared by gradually adding 50 grams of selenyl chloride (1 mol.) dissolved in ether (30 c.c.) to a cooled solution of 10 grams of dimethylaniline (2 mols.) in ether (100 c.c.); a dark-brown mass separates which, after decanting the ether (see below), is dissolved in dilute hydrochloric acid, and an excess of sodium hydroxide added to the filtrate; the dimethylaniline is then removed by a current of steam, and the remaining oil washed successively with water, alcohol, and ether, when it solidifies; it is then pressed between filter-paper, dried, and crystallised from alcohol. The yield is small, and the compound is generally of a brown colour; it is obtained pure, however, by evaporating the above-mentioned ethereal solution, heating with water on the water-bath to remove the dimethylaniline, and crystallising from alcohol. It forms yellowish needles, melts at 124° , and is sparingly soluble in cold alcohol and ether. The sulphate, $\text{C}_{16}\text{H}_{20}\text{N}_2\text{Se}\cdot\text{H}_2\text{SO}_4$, crystallises in long, colourless needles, melts at 55° , and is very easily soluble in water; the *picrate*,

forms small, yellow plates, and melts at 135° .

Selenodiethylaniline, $\text{Se}(\text{C}_6\text{H}_4\cdot\text{NEt}_2)_2$, is obtained in a manner similar to the dimethyl derivative, but the yield is greater. It forms colourless, asbestos-like needles, melts at 83° , and is moderately soluble in cold alcohol or ether, and very easily in the boiling liquids. The *hydrochloride*, $\text{C}_{20}\text{H}_{28}\text{N}_2\text{Se}\cdot 2\text{HCl}$, melts at 73° ; the *picrate* crystallises from alcohol in small, yellow plates and needles, melts at 135° , and is easily soluble in hot alcohol.

A. R. L.

Triazobenzene. By G. ODDO (*Gazzetta*, 20, 798—802).—*Triazobenzene*, $\text{PhN} \begin{smallmatrix} \text{N} \\ \parallel \\ \text{N} \end{smallmatrix}$, may be prepared by the action of phenylhydrazine on diazobenzene tribromide. A mixture of diazobenzene chloride (0.1 mol.), bromine (20 grams), and concentrated hydrobromic acid (50 grams) is agitated in the cold, and phenylhydrazine (40 grams) added to the strongly-cooled product. The reaction takes place in

accordance with the equation $\text{PhN}_2\text{Br}_3 + 2\text{NHPH}\cdot\text{NH}_3 = \text{PhN}_3 + \text{C}_6\text{H}_5\cdot\text{NH}_2\cdot\text{HBr} + \text{PhN}_2\text{H}_3\cdot\text{HBr}$, and the yield is almost theoretical.

Triazobenzene is a pale-yellow liquid, having an odour of bitter almonds; it burns when lighted, with a slight explosion. It boils at $157.5-158^\circ$ with partial decomposition. It may be distilled unchanged under reduced pressure. It is partially decomposed on exposure to the sun's rays. Its sp. gr. = 1.12399 at $0^\circ/4^\circ$; its refractive index = 1.5597 for yellow light. It remains liquid at -33° .

S. B. A. A.

Constitution of the Amido-derivatives of Hydroxylamine. By G. MINUNNI (*Gazzetta*, 20, 657-670).—The author has previously obtained (Abstr., 1890, 256) a white compound, $\text{C}_{13}\text{H}_{11}\text{N}_2\text{O}$, melting at 166° , by heating a mixture of benzhydroxamic acid with phenylhydrazine at $130-140^\circ$. This substance is not a hydrazone, as was then supposed, but is identical with Fischer's benzoylphenylhydrazine, $\text{NHBz}\cdot\text{NHPh}$ (Abstr., 1878, 308), and yields Tafel's methylbenzoylphenylhydrazine, $\text{NHBz}\cdot\text{NMcPh}$, melting at $152-153^\circ$ (Abstr., 1885, 1060) on treatment with methyl iodide. When benzhydroxamic acid and phenylhydrazine are heated together below 100° , only benzoylphenylhydrazine and gaseous products are formed.

If a mixture of benzhydroxamic acid and aniline in molecular proportion is heated, benzanilide is obtained. After discussing at length Lossen's and Tiemann and Krüger's (Abstr., 1885, 790) arguments in favour of the formulæ $\text{OH}\cdot\text{CPh}\cdot\text{NOH}$ and $\text{NHBz}\cdot\text{OH}$ respectively, as representing the constitution of benzhydroxamic acid, the author concludes that the second formula is strongly confirmed by the formation of benzoylphenylhydrazine and benzanilide from that compound, since the reactions occur under conditions unfavourable to molecular change, and as other amides yield analogous compounds under similar conditions.

S. B. A. A.

Amidoximes. By F. TIEMANN (*Ber.*, 4, 801-803).—The compounds obtained from aromatic amines and cyanogen have previously been represented by one of the three following formulæ:—

the investigations of Vorländer (compare following abstract) show that these compounds exhibit a triple tautomerism. The paper concludes with some general remarks on the researches of A. Clemm (this vol., p. 699) and W. Krone (this vol., p. 700). J. B. T.

Constitution of Disubstituted Oxalenediamidines. By D. VORLÄNDER (*Ber.*, 24, 803-825).—The term *oxalenediamidine*, instead of oxamidine, is applied to the compound

obtained from oxaldiimidodiethyl ether. Oxalenediparatolyldiamidine (cyanoparatoluidine) is already known, and is best obtained by heating recently prepared oxalimidoethyl ether with excess of paratoluidine at 100° ; the product is dissolved in dilute sulphuric acid and

precipitated with ammonia. Oxalenedibenzylidiamidine (cyano-benzylamine) may also be obtained from oxalimidoethyl ether and benzylamine, by heating for 20 minutes at 100° , and then for 5 minutes at 110 — 120° . On heating oxalenediparatolyldiamidine at 150 — 160° in a current of hydrogen sulphide, ammonia and toluidine are eliminated, and a tarry residue is formed, from which no definite compound could be isolated. Oxalenediphenyldiamidine is decomposed by carbon bisulphide at 100° , hydrogen sulphide, phenylthiocarbimide, and resinous matters being produced; at lower temperatures, the amidine is scarcely attacked. Oxalenediparatolyldiamidine behaves in a similar manner.

Oxalenediparatolyldiamidodioxime, $\text{NOH}\cdot\text{C}(\text{NHC}_6\text{H}_7)\cdot\text{C}(\text{NH}_2)\cdot\text{NOH}$, is prepared by heating the tolyldiamidine with hydroxylamine hydrochloride or sulphate in alcoholic solution; it crystallises from water in small, white plates, melts at 175° , and is readily soluble in acids or alkalis; oxalenediamidoxime and paratoluidine are also formed during the reaction. Free hydroxylamine does not react with the amidine. The *dibenzoyl derivative*, $\text{NOBz}\cdot\text{C}(\text{NHC}_6\text{H}_7)\cdot\text{C}(\text{NH}_2)\cdot\text{NOBz}$, crystallises from alcohol in colourless needles, melts at 193 — 194° , and is readily soluble in alcohol or benzene.

Oxalenediparatolyldiamidineamidoxime, $\text{NH}\cdot\text{C}(\text{NHC}_6\text{H}_7)\cdot\text{C}(\text{NH}_2)\cdot\text{NOH}$, is obtained by treating the amidine with twice the theoretical quantity of hydroxylamine hydrochloride, sufficient soda being quickly added to liberate half the hydroxylamine; the product, after purification, crystallises from water in silvery, lustrous plates, melts at 147 — 148° , is insoluble in light petroleum, but readily dissolves in alcohol, chloroform, and benzene, and in alkalis and dilute acids. On further treatment with hydroxylamine, the compound yields toluidine and oxalenediamidoxime. The *hydrochloride*, $\text{C}_6\text{H}_7\text{N}_4\text{O}_2\cdot\text{HCl}$, crystallises in flocculent needles. The *ethyl ether*, $\text{NH}\cdot\text{C}(\text{NH}\cdot\text{C}_6\text{H}_7)\cdot\text{C}(\text{NH}_2)\cdot\text{NOEt}$, is deposited from alcohol, on the addition of water, in lustrous plates melting at 132 — 133° . The *benzyl ether*,

crystallises in needles and melts at 165° .

By the action of hydroxylamine hydrochloride on oxalenedibenzylidiamidine, oxalenediamidodioxime is formed. On warming this compound with acetic aldehyde, *oxalenedihydrazoxime-diethylidene*, $\text{CHMe}\cdot\text{C}(\text{NH}\cdot\text{N}\cdot\text{O})\cdot\text{C}(\text{NH}\cdot\text{N}\cdot\text{O})\cdot\text{CHMe}$, is obtained; it crystallises from benzene in colourless, slender needles, and melts at 198° . Diazoxime-diethenyl is produced on oxidation with potassium permanganate. *Chloraloxalenediamidoxime*, $\text{C}_6\text{H}_7\text{N}_4\text{O}_2\text{Cl}$, is prepared by gently heating the oxime with 7 parts of chloral, and crystallises from glacial acetic acid, on the addition of water, in lustrous plates melting at 196 — 197° . The compound is scarcely affected by concentrated sulphuric acid at the ordinary temperature; it does not react with alkaline copper solution or with ferric chloride; on treatment with alkalis, it yields ammonia and chloroform.

The formation of oxalenediamidines from oxalimido-ether appears to point to the first of the three possible formulæ (compare preceding

abstract); the reaction with carbon bisulphide is best represented by the second, whilst the analogy between oxalenediphenyldiamidine and aniline tells in favour of the third formula, as also does the action of hydroxylamine hydrochloride on di-substituted oxalenediamidines. The most probable explanation appears to be that these compounds afford the first observed example of triple tautomerism.

J. B. T.

Derivatives of Metahydroxybenzaldehyde. By A. CLUNN (*Ber.*, 24, 826—833).—On treating metahydroxybenzaldehyde with phenylhydrazine in alcoholic solution, *metahydroxybenzenyl-phenylhydrazone*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{N}_2\text{HPh}$, is formed, and is deposited from benzene, on the addition of light petroleum, as a white, crystalline powder melting at 130° . The *oxime*, $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{NOH}$, prepared by the action of hydroxylamine at ordinary temperatures, is obtained from benzene in colourless, silky, lustrous crystals melting at $87\cdot5^\circ$. *Acetylmetahydroxybenzonitrile*, $\text{OAc}\cdot\text{C}_6\text{H}_4\cdot\text{CN}$, is prepared by boiling the oxime with acetic anhydride for $2\frac{1}{2}$ hours; it crystallises from a mixture of benzene and light petroleum in long, transparent needles, melts at 60° , and is readily soluble in alcohol, ether, or hot water. On gently warming with dilute soda and acidifying, *metahydroxybenzonitrile*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{CN}$, is formed. *Metahydroxybenzenylamidoxime*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH}_2)\cdot\text{NOH}$, is prepared by heating the nitrile with hydroxylamine in alkaline solution at 60° for 6 to 8 hours, the solution is evaporated to dryness, extracted with alcohol, the alcohol removed, and the residue dissolved in water; it crystallises in aggregates of small, colourless needles, melts at 71° , and gives a dark-red coloration with ferric chloride. The *dibenzoyl derivative*, $\text{OBz}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH}_2)\cdot\text{NOBz}$, is deposited from benzene, on the addition of light petroleum, in small, bright crystals and melts at $152\cdot5^\circ$. On boiling the compound with water, *metahydroxybenzenylazoximebenzenyl*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{NO} \\ \text{N} \end{smallmatrix}\text{CPh}$, is produced; it has previously been prepared from metamidobenzenylazoximebenzyl and nitrous acid. The *benzoyl derivative*, $\text{OBz}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{NO} \\ \text{N} \end{smallmatrix}\text{CPh}$, crystallises from ether in microscopic needles and melts at 146° . *Methoxybenzenylamidoxime ethyl ether*, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH}_2)\cdot\text{NOEt}$, is obtained from the amidoxime by the action of ethyl iodide and sodium ethoxide, and crystallises from ether, on spontaneous evaporation, in colourless, well-developed needles melting at 109° . No monoethyl derivative could be isolated. On heating the amidoxime with succinic anhydride at 115° , water is eliminated and *metahydroxybenzenyl-azoximepropenyl- ω -carboxylic acid*,

is formed, crystallising from alcohol in colourless, transparent plates, and melting at 123° . The *silver salt* is crystalline. *Acetylmetahydroxybenzenylamidoxime*, $\text{OAc}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH}_2)\cdot\text{NOAc}$, is prepared by the action of acetic anhydride on the amidoxime at ordinary temperatures; it crystallises from ether in small plates and melts at 90° . On heating

this compound above its melting point, or by boiling the amidoxime with acetic anhydride, *meta*-hydroxybenzenylazoximethenyl,

is formed; this crystallises from alcohol, on the addition of water, in small plates, melts at 117°, and sublimes without decomposition.

J. B. T.

Parahydroxybenzenylamidoxime. By W. KRONH (*Ber.*, 24, 134—841).—*Parahydroxybenzenylamidoxime*,

is prepared by treating parahydroxybenzonitrile with hydroxylamine under pressure at 70°; it melts at 153° with decomposition, and gives a dark-red coloration with ferric chloride. The *hydrochloride* is crystalline and melts at 179°. The *benzoyl derivative*,

is formed by the action of sodium ethoxide and benzoic chloride on the amidoxime; it crystallises from alcohol, on dilution with water, in colourless, slender needles, melts at 166°, and becomes red on exposure to air. The constitution of the compound is shown by the fact that when heated with potash, it is converted into *parahydroxybenzenylazoximebenzenyl*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{NO} \\ \text{N} \end{smallmatrix} \text{CPh}$; this crystallises

from alcohol, on the addition of water, in colourless, lustrous plates, melts at 183°, and is readily soluble in alkalis. The *benzoyl derivative*,

is prepared by the action of benzoic chloride and potash on the preceding compound; it crystallises from alcohol in needles and melts at 140°. *Dibenzoylparahydroxybenzenylamidoxime*, $\text{OBz}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH}_2)\cdot\text{NOBz}$, is formed by treating the amidoxime dissolved in potash, with excess of benzoic chloride, and crystallises from benzene in slender needles melting at 185°.

Acetylparahydroxybenzenylamidoxime, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH}_2)\cdot\text{NOAc}$, obtained from the amidoxime and acetic anhydride at the ordinary temperature, crystallises from alcohol and melts at 122.5°. On heating the compound with water in a sealed tube at 100°, or by heating the amidoxime for a short time with a slight excess of acetic anhydride,

is formed; it crystallises from dilute alcohol in colourless, flat needles and melts at 185°.

Parethoxybenzenylamidoxime ethyl ether, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH}_2)\cdot\text{NOEt}$, prepared by the action of ethyl iodide and sodium ethoxide on the amidoxime, is deposited from alcohol in long, dark-yellow, rhombic crystals melting at 84°. No monethyl derivative could be isolated.

Parahydroxybenzenylazoximepropenyl- ω -carboxylic acid,

is formed on fusing the amidoxime with succinic anhydride at 115°; it melts at 176°, but is somewhat difficult to purify. The *silver salt* is colourless and crystalline.

J. B. T.

Action of Alkylene Bromides on Thiamides. By S. GABRIEL and P. HEYMANN (*Ber.*, 24, 783—788) —The authors have already (*Abstr.*, 1890, 524) described the formation of μ -phenylthiazoline, $C_6H_4<\begin{smallmatrix} N \\ S \end{smallmatrix}>CPh$, by the action of boiling ethylene bromide on thio-benzamide. They now find that a different reaction takes place when the conditions are altered.

Ethylene imidothiobenzoate hydrobromide, $C_6H_4(S \cdot CPh \cdot NH)_2 \cdot 2HBr$, is obtained as a white, granular mass by warming thiobenzamide (10 grams) with ethylene bromide (100 grams) on the water-bath and washing the product with absolute alcohol. It is easily soluble in water, melts at 233°, and, when boiled with water, is decomposed into ammonium bromide and *ethylene mercaptan dibenzoate*, $C_6H_4(SCOPh)_2$; this crystallises from alcohol in tablets and melts at 96°. The same salt is obtained by shaking ethylene mercaptan with excess of potash and benzoic chloride. A small quantity of the ethylene imidothiobenzoate is decomposed by water to yield ethylene mercaptan and benzamide.

μ -Phenylthiazoline, when warmed with bromine-water, is oxidised to benzoyltaurine; if, however, an alcoholic solution of the base is treated with a solution of bromine in alcohol, a bromo-additive compound, $C_6H_4NSBr_2$, is obtained which crystallises in large, yellow needles.

Methyl- μ -phenylthiazoline, $\begin{smallmatrix} CHMe \cdot S \\ CH - N \end{smallmatrix} > CPh$, is obtained as a yellow oil, on boiling a mixture of propylene bromide and thiobenzamide. The *picrate*, $C_{10}H_{11}NS, C_6H_5N_3O_7$, is sparingly soluble. When oxidised with bromine-water, it yields a crystalline compound which on account of its great solubility could not be purified, and is probably *benzoyl-methyltaurine*, $SO_3H \cdot C_6H_5 \cdot NH \cdot COPh$. The latter, on hydrolysis in a sealed tube with hydrochloric acid at 160°, yields benzoic acid and β -methyltaurine, $NH_2 \cdot CH_2 \cdot CHMe \cdot SO_3H$.

μ -Orthotolylthiazoline, $C_6H_4Me<\begin{smallmatrix} N \\ S \end{smallmatrix}>C_2H_5$, is obtained by the action of ethylene bromide on orthotolylthiamide. It is a yellow oil which decomposes when distilled at the ordinary pressure, but distils without decomposition between 200° and 203° under 90 mm. The *picrate* is obtained on adding picric acid to a solution of the hydrochloride. The *platinochloride* decomposes at 200° with frothing and a brown coloration. On oxidation with bromine-water and hydrolysis of the resulting compound, it yields taurine and orthotoluic acid.

Orthotolylthiamide is prepared by heating orthotolunitrile with ammonium sulphide under pressure; it crystallises from water and melts at 88°.

μ -Paratolylthiazoline is prepared in a similar way to the ortho-compound; it is a white, crystalline solid, insoluble in water, crystal-

lises from hot alcohol in beautiful, indented plates, melts at 81° , and is volatile with steam.

Paratolylthiamide is obtained from paracyanotoluene in the same way as the ortho-compound. It forms beautiful, yellow needles and melts at 168° .

No anhydro-base was obtained from ethylene bromide and thiacetamide. If a mixture of the two substances (10 : 1) is boiled, only a very small quantity of hydrogen bromide is evolved. When a mixture of equal weights is heated on the water-bath, *ethylene imidothioacetate hydrobromide*, $C_2H_4(SCMe.NH)_2.2HBr$, is formed. On boiling with water, it appears to give products similar to those obtained from the above aromatic compound. E. C. R.

Isomeric Ethyl Amidotolylcarbamates. By H. SCHIFF and A. VANNI (*Ber.*, 24, 687—689).—By the action of ethyl chloroformate on 1:2:4-diamidotoluene (*Abstr.*, 1890, 1124), the authors obtained an ethyl amidotolylcarbamate, $NH_2.C_6H_3Me.NH.COEt$, melting at $90-91^{\circ}$, which, on boiling with ethyl oxalate and alcohol, was converted into *ethyl oxamethanetolylcarbamate*,

melting at 128° . If amidotolylloxamethane is treated with ethyl chloroformate, an isomeric compound is obtained, which melts at 131° , but is otherwise very similar to the first compound. By the action of alcoholic ammonia, both are converted into monamides, having the formula $NH_2.C_2O_2.NH.C_6H_3Me.NH.COEt$. These crystallise in lustrous prisms; the one obtained from the isomeride of m. p. 128° melts at 223° , and that from the higher melting isomeride at 209° .

To ascertain the exact position of the groups in these isomerides, 1:2:4-nitrotoluidine was treated with ethyl chloroformate, and the resulting *ethyl nitrotolylcarbamate*, which crystallises in colourless needles and melts at 137° , reduced with stannous chloride and hydrochloric acid. The ethyl amidotolylcarbamate formed, crystallises in colourless prisms which become yellow in the air, and although it melts at 91° , is not identical with the ethyl amidotolylcarbamate obtained from 1:2:4-diamidotoluene. On treatment with ethyl oxalate, it forms the ethyl oxamethanetolylcarbamate melting at 131° . Hence, in the ethyl amidotolylcarbamate obtained from 1:2:4-ethyl nitrotolylcarbamate, the $NH.COEt$ group occupies the position 2, and the amido-group the position 4, whilst in the compound obtained from 1:2:4-diamidotoluene, these positions are reversed.

H. G. U.

Benzylidenebiuret and Chlorobenzylidenethiobiuret. By J. J. ABEL (*Amer. Chem. J.*, 13, 114—119).—*Benzylidenebiuret*, $C_6H_5N_2O_2$, is prepared by heating carbamide (3 mols.) with benzal chloride (1 mol.) in a flask on the sand-bath until the temperature reaches $198-200^{\circ}$, after which the reaction is allowed to proceed without further application of heat. When the product has cooled to 100° , it is treated with boiling water, collected, washed with hot alcohol, dissolved in much hot water, and allowed to crystallise.

Ammonium chloride and cyanic acid are formed at the same time as the benzylidenebiuret.

When slowly crystallised, benzylidenebiuret forms large, glistening, rhombic prisms; otherwise, clusters of fine needles are obtained. It melts at 258° (uncorr.) with decomposition; it dissolves sparingly in phenol, hot water, and alcohol, slightly in ether and chloroform, not at all in carbon bisulphide. Its aqueous solution is precipitated by most metallic salts. When boiled with alkalis, it is decomposed into benzaldehyde, carbamide, ammonia, and carbonic anhydride. Strong sulphuric acid dissolves it, and when the solution is diluted, a compound crystallises out in large clusters of rhombic prisms. The author favours the structural formula $\text{CHPh} \begin{smallmatrix} \text{NH} \cdot \text{CO} \\ \text{NH} \cdot \text{CO} \end{smallmatrix} \text{NH}$ for benzylidenebiuret, but evidence is yet lacking. Its *platinochloride* and some of its double salts with other metallic chlorides were obtained.

Chlorobenzylidenethiobiuret, $\text{C}_7\text{H}_9\text{ClS}_2\text{N}_3$, is obtained by heating dry thiocarbamide (40 grams) with benzal chloride (60 grams) until action begins, at which point the heating is discontinued. The product is recrystallised from hot water and purified by precipitation from hot alcohol by the addition of ether; the new compound is thus obtained in snow-white, crystalline flakes. Ammonium chloride is the only other product, Brodsky's benzylidenethiobiuret (Abstr., 1887, 580) not being obtainable by this method. When chlorobenzylidenethiobiuret is dissolved in strong sulphuric acid or glacial acetic acid, new chlorine-free products are obtained; these, as well as the parent substance are still being investigated. A. G. R.

Production of Orthochloranisaldehyde from Paranitrotoluene. By F. TIEMANN (*Ber.*, 24, 699—713).—Paranitrometamethoxybenzaldehyde was obtained by Ulrich (Abstr., 1886, 60) by the oxidation of paranitrometamethoxycinnamic acid, and is of importance, as it should yield vanillin on substituting hydroxyl for the nitro-group; this could not, however, be definitely established on account of the difficulty of obtaining a sufficiency of the compound by Ulrich's method, which is a very complicated one, involving great loss of material.

A simpler method of preparing the nitromethoxybenzaldehyde from paranitrometachlorotoluene was, however, described by Landsberg (Abstr., 1887, 483), and this has since been reinvestigated by Riecher (Abstr., 1889, 1170), who confirmed Landsberg's results, but pointed out (*Ber.*, 22, 2344 and 2363) that as the starting compound was in reality paranitrothochlorotoluene (compare Lellman, Abstr., 1884, 1133), the production of the metamethoxy-derivative, when the nitrochlorobenzaldehyde (Landsberg, *loc. cit.*) is heated with sodium methoxide, involved an isomeric change. In attempting to displace the nitro-group by hydrogen, by the usual method, in the supposed nitromethoxybenzoic acid, prepared by Landsberg's method, the author found that this was scarcely acted on by ferrous hydroxide; he then discovered that it contained chlorine but not nitrogen, and finally proved it to be paramethoxyortho-chlorobenzoic acid (ortho-chloroanisic acid). It was thus evident that when the nitrochloro-

benzaldehyde is heated with sodium methoxide, the nitro-group, and not the chlorine atom, is displaced by methoxyl. It is probable therefore that both Landsberg and Riecher dealt with a mixture of methoxychlorobenzaldehyde, containing unaltered nitrochloro-derivative. This is supported by the fact that the two compounds cling to each other with extreme tenacity (see below), the mixture having the same melting point as paranitrometamethoxybenzaldehyde, prepared by Ulrich's method.

Paranitrothochlorotoluene was prepared by Wachendorff's method (compare Lellmann, *loc. cit.*). It is converted into the *nitrochlorobenzyl bromide* melting at 49–50°, when heated with bromine (1 mol.) in a sealed tube for four hours at exactly 130–135°; the latter yields *nitrochlorobenzaldehyde*, when 25 grams of it is digested in a reflux apparatus for 48 hours with a solution of lead nitrate containing 90 grams in 1500 c.c. of water; this crystallises from light petroleum in delicate, white needles, and melts at 79°.

Paranitrothochlorobenzoic acid, melting at 138–139°, is formed when either of the three last-mentioned derivatives is oxidised with potassium permanganate. The corresponding amido-acid melts at 214.5°, and yields 1:2-chlorobenzoic acid, when an alcoholic solution is heated with ethyl nitrite.

Orthochloranisaldehyde is formed when paranitrothochlorobenzaldehyde (1 mol.) is heated on the water-bath in a reflux apparatus for three hours with sodium methoxide (1 mol.) in methyl alcoholic solution; after evaporating the methyl alcohol, the product is steam-distilled. It is best separated from the unaltered nitro-derivative by repeatedly dissolving in concentrated sodium hydrogen sulphite solution, adding sodium carbonate, and steam-distilling, but although no nitrogen could be detected by qualitative tests, the compound was not obtained quite pure after eight such treatments. The analytical results indicated that the product contained 2–3 per cent. of unaltered nitro-derivative. It forms long, white needles, melts at 62–63°, and is easily soluble in alcohol, ether, benzene, and light petroleum, sparingly in water. The *oxime*, $\text{OMe}\cdot\text{C}_6\text{H}_3\text{Cl}\cdot\text{OH}\cdot\text{NOH}$, crystallises from hot water in beautiful, white needles, melts at 93°, and is readily soluble in alcohol, ether, chloroform, and benzene; it is precipitated unaltered from its solutions in alkalis, on the addition of an acid. The *hydrazone*, $\text{OMe}\cdot\text{C}_6\text{H}_3\text{Cl}\cdot\text{CH}\cdot\text{N}_2\text{HPh}$, separates from dilute alcohol in yellowish-red needles, melts at 103°, and is easily soluble in alcohol, ether, and chloroform.

Orthochloranisic acid is prepared by oxidising the aldehyde with potassium permanganate. After repeated recrystallisations from dilute alcohol, it was obtained quite pure. It is almost insoluble in boiling water, but easily soluble in alcohol, ether, and benzene; it melts at 208°. By prolonged boiling with water and sodium amalgam, anisic acid is formed.

A. R. L.

Piperonal Derivatives. By F. HABER (*Ber.*, 24, 617–626; compare *Abstr.*, 1890, 1140).—*Dipiperonylacryl ketone*,

is prepared by the action of piperonal on acetone in presence of soda at the ordinary temperature; it crystallises from alcohol in slender, yellow needles, melts at 185° , and is readily soluble in chloroform or acetone; with concentrated sulphuric acid, an intense blue coloration is formed, changing gradually to violet-red. The *phenylhydrazone* is unstable.

Dinitrodipiperonylacryl ketone, $[\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_2(\text{NO}_2)\text{:CH:CH}]_2\text{CO}$, is obtained by the nitration of the ketone in glacial acetic acid solution; it crystallises from acetone in yellow needles, and melts at 218° with decomposition.

Piperonylacryl methyl ketone, $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_3\text{:CH:CH:COMe}$, is formed from piperonal and acetone by treatment with very dilute soda; it is readily soluble in alcohol, crystallises in long, yellow, prismatic needles, and melts at 107° . When the substance is heated in a current of steam, or when fractionally recrystallised from water, a compound is obtained which is regarded as a stereometric isomeride

of *isopiperonylacryl methyl ketone*, $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_3\text{:CH:CH:COMe}$; it is more soluble

than the previous modification, crystallises in small, white, slender needles, and melts at 111° ; when heated at 190° , it is converted into the isomeride of lower melting point. The normal *phenylhydrazone*, $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_3\text{:CH:CH:CMc:N}_2\text{HPh}$, is deposited from alcohol in yellow crystals melting at $158\text{--}160^{\circ}$ with decomposition. The corresponding *iso-derivative* crystallises in small, white needles, and melts at 163° . The *normal oxime*, $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_3\text{:CH:CH:CMc:NOH}$, is obtained in small, pale-yellow crystals melting at 186° ; it could not be converted into a β -modification, and is readily decomposed by the action of dehydrating agents. The *iso-oxime* is white, and melts at 183° .

Orthonitropiperonylacryl methyl ketone,

prepared by treatment of the ketone with nitric acid, crystallises from acetone in yellow needles, and melts at 153° . Attempts to convert the compound into an indigo derivative were unsuccessful.

The *phenylhydrazone*, $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_2(\text{NO}_2)\text{:CH:CH:CMc:N}_2\text{HPh}$, crystallises from alcohol in red needles, and melts at 197° ; on account of the colour of this substance, it is perhaps better represented by the tautomeric azo-formula

Dioxyethylenequinaldine, $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_2 < \begin{smallmatrix} \text{CH:CH} \\ \text{N=CMc} \end{smallmatrix}$, is formed by

the reduction of the nitro-ketone with tin and hydrochloric acid, or with ferrous sulphate and ammonia; it crystallises from water in colourless needles, and melts at 152° ; the yield is very small. The *chloride* and *sulphate* are readily soluble; the *picrate* melts at 175° ; the *platinochloride* is pale-grey; the *chromate* crystallises in small, yellow needles, and melts at 210° with decomposition.

By the nitration of piperonal below 6° , the *ortho-derivative* is obtained, but above this temperature a mixture of *ortho*- and *meta*-nitropiperonal is formed.

Orthonitropiperonalphenylhydrazone, $\text{CH}_3\text{O}_2\text{C}_6\text{H}_3(\text{NO}_2)\cdot\text{CH}\cdot\text{N}_2\text{HPh}$ crystallises in red needles melting at 212° . The *oxime*,

is deposited from alcohol in yellow needles, and melts at 203° . *Orthonitropiperonylnitrile*, $\text{CH}_3\text{O}_2\text{C}_6\text{H}_3(\text{NO}_2)\cdot\text{CN}$, is formed on heating the oxime with acetic anhydride, and melts at $138-139^\circ$.

Orthamidopiperonaloxime, $\text{CH}_3\text{O}_2\text{C}_6\text{H}_3(\text{NH}_2)\cdot\text{CH}\cdot\text{NOH}$, is prepared by the reduction of the nitro-derivative with hydrogen sulphide, and is deposited in yellow, crystalline scales melting at 175.5° ; a red coloration is produced with concentrated sulphuric acid. *Orthonitropiperonal* cannot be readily reduced.

Orthacetoamidopiperonylnitrile, $\text{CH}_3\text{O}_2\text{C}_6\text{H}_3(\text{ON})\cdot\text{NHAc}$, is formed when the amidoxime is boiled with acetic anhydride and sodium acetate; it crystallises from alcohol in yellow needles, and melts at 216° . By heating the oxime with acetic anhydride alone, *diacetylorthamidopiperonaloxime*, $\text{CH}_3\text{O}_2\text{C}_6\text{H}_3(\text{NHAc})\cdot\text{CH}\cdot\text{NOAc}$, is formed; it crystallises in yellow-grey aggregates, melts at 188° , and is not acted on by sodium acetate and acetic anhydride.

J. B. T.

Hydroxyketone Dyes. A New Dihydroxyxanthone. By C. GRAEBE and A. REICHENGRÜN (*Ber.*, 24, 967-970).—It has been found that the presence of a single carbonyl group is in many cases sufficient to cause an aromatic compound to show tinctorial properties, as, for example, the various hydroxybenzophenones. In order to compare the relationship of these compounds to the anthraquinone-derivatives, and to the xanthone group, the authors have examined the trihydroxybenzophenone obtained from benzoic acid and pyrogallol, known in commerce as alizarin-yellow, the tetrahydroxybenzophenone from salicylic acid and pyrogallol, and the tetrahydroxyphenylnaphthyl ketone from gallic acid and naphthol (alizarin W). They have been able to confirm the formulæ already given, and find that all readily yield oximes and hydrazones. The salts containing only one equivalent of metal are the most readily prepared, and it is very difficult to displace all the hydrogen of the hydroxyl groups by methyl or ethyl. Thus trihydroxybenzophenone yields, according to circumstances, either a mono- or a di-methoxy-derivative. The latter is only soluble with difficulty in soda solution, but yields a crystalline acetyl derivative, $\text{COPh}\cdot\text{C}_6\text{H}_3(\text{OMe})_2\cdot\text{OAc}$, conclusively showing the presence of three hydroxyl groups.

Another characteristic of these substances is their behaviour with sulphuric acid. Tri- and tetra-hydroxybenzophenone are converted into pyrogallolsulphonic acid and benzoic or salicylic acid. As regards the position of the hydroxyl groups in the trihydroxy-compound, two different formulæ, $[\text{Bz}:\text{OH}:\text{OH}:\text{OH} = 1:2:3:4; \text{ or } 1:3:4:5]$, are possible. The former supposition is regarded as more probable, inasmuch as in the tetrahydroxy-compound obtained from salicylic acid and pyrogallol, the hydroxyl groups, as will be shown below, must occupy the positions 2:3:4.

When tetrahydroxybenzophenone is heated with water at 180—220°, it is converted into a new dihydroxyxanthone (compare Abstr., 1890, 504). This reaction can only take place in the following manner:—

The hydroxyl groups must therefore occupy the positions 2 : 3 : 4.

3:4-Dihydroxyxanthone is obtained from its alkaline solution in pale-yellow, microscopic needles, and crystallises from alcohol likewise in pale-yellow needles containing 3 mols. H₂O. Like xanthone, it melts at 240°, and sublimes, although somewhat less readily, in pale-yellow needles. Its alkaline solutions are blood-red, and it dyes cotton mordanted with alumina a yellow colour. It is sparingly soluble in water, readily in alcohol, and yields a diacetyl compound, C₁₃H₆O₂(OAc)₂, melting at 161°. When heated with zinc-dust, it only yields small quantities of a reduction product, which appears to be diphenylenemethane oxide, C₆H₄< $\begin{smallmatrix} \text{CH}_2 \\ \text{O} \end{smallmatrix}\text{>$ C₆H₄. On treatment with bromine, it yields two derivatives having the composition C₁₄H₇O₄Br and C₁₁H₅O₄Br₃.
H. G. C.

Ethereal Salts of Chlorhydrins. By C. GOTTLIEB (*Ber.*, 24, 508—510).—Berthelot has shown (*Ann. Chim. Phys.* [3], 41, 216) that when hydrogen chloride is passed into heated mixtures of glycerol with acids, the corresponding glycerol ether may in certain cases be obtained. The author finds that at a higher temperature ethereal salts of the chlorhydrins may be obtained, and has prepared and examined the salicylate of dichlorhydrin, OH·C₆H₄·COO·C₂H₄Cl₂. It is formed by treating a saturated solution of salicylic acid in glycerol at 108° with hydrogen chloride for nine hours, the separated oil crystallising for the most part on cooling. Dichlorhydrin salicylate crystallises from alcohol in white, prismatic crystals, melts at 44°, has a sp. gr. of 1.331, and is readily soluble in alcohol, ether, chloroform, and benzene, scarcely in water. The empirical formula also agrees with the constitution C₆H₄Cl·CO·OC₂H₄Cl·OH, but the ether only yields salicylic acid on hydrolysis, and no trace of orthochlorobenzoic acid, and by the action of alkalis at 100° yields much epichlorhydrin. As the latter is only obtained from dichlorhydrins, and not from monochlorhydrins, the formula first given must be correct.
H. G. C.

Salts of Dichlorhydrin with Aromatic Acids. By P. FRIEDEMANN (*Ber.*, 24, 775—778).—Berthelot has shown that the product obtained by the action of hydrogen chloride on a mixture of glycerol and benzoic acid is benzo-chlorhydrin; and Maxwell Simpson obtained glycol-chloracetin by treating a mixture of glycol and glacial acetic acid with hydrogen chloride at 100°, and glycol-chlorobenzoic from glycol and

benzoic acid. On the other hand, Göttig obtained the monoglyceride of salicylic acid from glycerol and salicylic acid, under what appear to be similar conditions. The author obtains only the dichlorhydrin salt of the aromatic acid when hydrogen chloride is passed into a mixture of glycerol and an aromatic acid as long as it is absorbed. Benzoic, salicylic, paracresotic, or anisic acid is mixed with an equal weight to twice its weight of glycerol, and dry hydrogen chloride is passed into the mixture at the temperature of the water-bath. The dichlorhydrin salt is precipitated as an oil, and is washed with hot water and dilute soda.

Benzodichlorhydrin boils at 230—235° under 150 mm., has the specific gravity 1.28 at 15°, is a thick oil which does not crystallise, and is insoluble in water.

The dichlorhydrin salts of salicylic, paracresotic, and anisic acids are insoluble in water, solidify when cooled, and may be purified by crystallisation from alcohol, in which they are easily soluble. *Salicyldichlorhydrin* crystallises in long needles and melts at 45°. *Paracresotodichlorhydrin* crystallises in slender needles and melts at 45.5°. *Anisodichlorhydrin* crystallises in lustrous scales and melts at 81°.

The author assumes these compounds to have the constitution represented by the formula $OX \cdot CH(CH_2Cl)_2$ (X being an acid radicle, Bz, Ac). Reboul has shown that dichlorhydrin and acetodichlorhydrin are formed by the action of hydrogen chloride on a mixture of glycerol and glacial acetic acid, and Markovnikoff by the same method obtained the dichlorhydrin $(CH_2Cl \cdot CH(OH)CH_2Cl)$, its formation being due to the action of hydrogen chloride on the acetate $OAc \cdot CH(CH_2OH)_2$.
E. C. R.

Triglycerides of Aromatic Acids. By P. FRITSCH (*Ber.*, 24, 779—782).—The salts of dichlorhydrin with aromatic acids, described in the preceding abstract, are easily converted into simple and mixed triglycerides. The dichlorhydrin salt (1 mol.) is heated with somewhat more than 2 mols. of the sodium or potassium salt of the aromatic acid for some hours at 180—200°. After washing out the metallic chloride with water, the triglyceride is obtained as an oil. The triglycerides of aromatic acids can mostly be obtained crystalline from ethereal solution, and are best purified by washing the crystals so obtained with alcohol and recrystallising from ether or methyl alcohol. *Tribenzoin*, melting at 70.5°, crystallises in concentrically-grouped needles of silky lustre. *Trisulicylin* melts at 79° and crystallises in lustrous needles. *Trianisoin* melts at 103.5° and crystallises in needles. *Triparacresotin* melts at 118° and is a crystalline, friable mass. *Disulicylbenzoin* melts at 95° and crystallises in needles. *Dibenzosalicylin* is an oil. The triglycerides of the aromatic acids, like the natural fats, are insoluble in water, sparingly soluble in alcohol, and easily soluble in ether, chloroform, benzene, and carbon bisulphide.
E. C. R.

Action of Chlorine on Hydroxybenzoic Acids. By T. ZINCKM and H. WALBAUM (*Annalen*, 261, 208—254).—*Hexachlorometaketotetrahydrobenzoic acid*, $C_7H_2Cl_6O_3$, is gradually deposited in crystals when a

glacial acetic acid solution of metahydroxybenzoic acid is kept, saturated with chlorine, for six to seven days at the ordinary temperature. It crystallises from glacial acetic acid, and from a mixture of ether and light petroleum, in colourless, well-defined plates, turns yellow at 180° , and melts at about 190° with decomposition; it is readily soluble in alcohol, ether, and hot glacial acetic acid, but more sparingly in benzene and light petroleum, and almost insoluble in water and dilute hydrochloric acid; the salts of the acid could not be obtained. It is decomposed by boiling water, the solution giving off an odour of chlorophenols. When boiled with alcohol, it is converted into tetrachlorometahydroxybenzoic acid, and, when treated with potassium iodide or stannous chloride, it is converted into trichlorometahydroxybenzoic acid. It dissolves slowly in sodium carbonate, yielding a brownish-yellow solution, from which it is, for the most part, precipitated unchanged on acidifying immediately; if, however, the alkaline solution is kept for some time, no precipitate is produced on the addition of an acid. It is quickly decomposed by ice-cold, 50 per cent. potash, yielding a crystalline acid, which has not yet been obtained in a pure condition, and which, when boiled with water, is converted into a more stable acid, with evolution of carbonic anhydride.

Trichlorometahydroxybenzoic acid, $C_7H_3Cl_3O_3 + H_2O$ [$Cl_3 = 1:3:5$], can be prepared by passing chlorine into a solution of metahydroxybenzoic acid in glacial acetic acid until the solution smells of the gas, and then allowing it to evaporate; the product is deposited in colourless prisms, and can be purified by recrystallisation from hot hydrochloric acid. It forms colourless plates or needles, which contain 1 mol H_2O and melt at $104-105^{\circ}$; on further heating, the water of crystallisation is expelled, the anhydrous compound melting at $143-144^{\circ}$. It is very readily soluble in alcohol, ether, hot glacial acetic acid, and benzene, but only sparingly in water; it is not acted on by stannous chloride, even at 100° ; when treated with chlorine, it is converted into the hexachlorinated acid described above, and, on distillation with lime, it yields symmetrical trichlorophenol (m. p. $67-68^{\circ}$). The *silver salt*, $C_7H_2Cl_3O_3Ag$, is a colourless, crystalline powder. The *methyl salt*, $C_7H_2Cl_3O_3$, can be prepared by treating the silver salt with methyl iodide; it crystallises from hot light petroleum in colourless needles or prisms, melts at 90° , and is readily soluble in alcohol, ether, and benzene. The *acetyl derivative*, $OAc \cdot C_6HCl_3 \cdot COOMe$, prepared by heating the methyl salt with acetic chloride, crystallises in lustrous, well-defined plates, melts at 65° , and is readily soluble in benzene, alcohol, and light petroleum.

Tetrachlorometahydroxybenzoic acid, $C_7HCl_4O_3$, is deposited in crystals when a solution of the hexachlorinated acid in absolute alcohol (5 parts) is boiled for three to four hours, then mixed with dilute (1:10) hydrochloric acid (3 mols.), and allowed to evaporate. It crystallises from hot dilute hydrochloric acid in colourless needles or prisms, melts at $170-172^{\circ}$, distils with only slight decomposition, and is readily soluble in ether, alcohol, and glacial acetic acid, and moderately easily in hot benzene and dilute hydrochloric acid; it is not acted on by boiling concentrated nitric acid, but when treated

with chlorine in glacial acetic acid solution it yields a keto-chloride, C_6Cl_5O (m. p. $105-106^\circ$), identical with the compound obtained by Benedikt and Schmidt (*Monatsh.*, 4, 607), by treating pentachlorophenol with chlorine; on distillation with lime, it gives the tetrachlorophenol described below. The *barium* salt, $(C_6Cl_4O)_2Ba$, is a colourless, crystalline powder, very readily soluble in water. The *silver* salt, $OAg \cdot C_6Cl_4 \cdot COOAg$, is insoluble in water and alcohol. The *methyl* salt, $OMe \cdot C_6Cl_4 \cdot COOMe$, prepared from the silver salt, crystallises from light petroleum in colourless needles, melts at $37-38^\circ$, and is readily soluble in the ordinary solvents.

Acetyltetrachlorometahydroxybenzoic acid, $OAc \cdot C_6Cl_4 \cdot COOH$, is obtained when the acid is heated with acetic chloride at 100° ; it crystallises from a mixture of benzene and light petroleum in colourless needles, melts at $150-151^\circ$, and is readily soluble in alcohol and hot benzene, but almost insoluble in light petroleum. The *silver* salt, $OAc \cdot C_6Cl_4 \cdot COOAg$, prepared from the ammonium salt, is a colourless, granular compound. The *methyl* salt, $OAc \cdot C_6Cl_4 \cdot COOMe$, crystallises in small, colourless needles, melts at $68-69^\circ$, and is readily soluble in alcohol, ether, and benzene, but more sparingly in light petroleum.

Tetrachlorophenol, $[OH : Cl_4 = 1 : 2 : 3 : 4 : 6]$, is obtained in small quantities when the tetrachlorinated acid is carefully distilled with soda-lime in an atmosphere of hydrogen. It crystallises from light petroleum in small, colourless needles, melts at 67° , and is readily soluble in most ordinary solvents, except water. The *benzoyl* derivative, $C_6HCl_4 \cdot OBz$, is formed when the phenol is heated with benzoic anhydride; it separates from alcohol and light petroleum in small, colourless prisms melting at $113-115^\circ$.

Pentachloroparaketotetrahydrobenzoic acid,

is obtained by passing chlorine into a hot glacial acetic acid solution of parahydroxybenzoic acid until no separation of crystals of the dichloro-derivative occurs on cooling a portion of the solution; the liquid is then saturated at the ordinary temperature, kept for some days, and then allowed to evaporate, when the acid is obtained in colourless crystals. It melts at $180-181^\circ$, decomposes at about 200° , and is readily soluble in alcohol, ether, glacial acetic acid, and hot benzene, but almost insoluble in light petroleum; when treated with stannous chloride or potassium iodide, it is converted into dichloroparahydroxybenzoic acid. It is quickly decomposed by alkalis and by boiling water, but it undergoes no change on boiling with alcohol.

Dichloroparahydroxybenzoic acid, identical with the compound obtained by Lössner (*J. pr. Chem.* [2], 13, 434) by heating parahydroxybenzoic acid with antimony pentachloride, is deposited in crystals when chlorine is passed into a cold glacial acetic acid solution of parahydroxybenzoic acid; it melts at $259-260^\circ$, is not acted on by stannous chloride, and yields dichlorophenol $[OH : Cl_2 = 1 : 2 : 6]$, on distillation with lime. The *methyl* salt, $C_6H_2Cl_2O_3$, prepared by passing hydrogen chloride into a methyl alcoholic solution of the acid,

crystallises in colourless needles, melts at 121—122°, and dissolves freely in alcohol, ether, &c. The *acetyl* derivative, $\text{OAc} \cdot \text{C}_6\text{H}_2\text{Cl}_2 \cdot \text{COOMe}$, obtained by treating the methyl salt with acetic chloride, crystallises from methyl alcohol in colourless plates melting at 68—69°.

Dichlorosalicylic acid can be obtained by passing chlorine into a solution of salicylic acid in glacial acetic acid; it crystallises in colourless prisms, melts at 219°, and yields dichlorophenol $[\text{OH} : \text{Cl}_2 = 1 : 2 : 4]$, on distillation with lime. The methyl salt melts at 143—144°. The *acetyl* derivative, $\text{OAc} \cdot \text{C}_6\text{H}_2\text{Cl}_2 \cdot \text{COOMe}$, crystallises from alcohol in colourless needles, and melts at 57°. F. S. K.

Action of Phenylhydrazine and Hydroxylamine on some Ketonic Acids. By F. GARELLI (*Gazzetta*, 20, 692—701).—*Paramethoxyphenylglyoxylic acid*, $\text{OMe} \cdot \text{C}_6\text{H}_3 \cdot \text{CO} \cdot \text{COOH}$, is formed, together with anisic acid, when anethoil is oxidised with potassium permanganate, and is analogous to the ketonic acids obtained by Ciamician and Silber (Abstr., 1890, 965) from isosafrole, isomethyleugenol, and isocapile, forming the lowest member of this series of substituted hydroxyphenylglyoxylic acids. When pure, it crystallises from boiling benzene in needles melting at 89°, and from water in hydrated needles which melt at 60°; it dissolves in hot benzene, and very freely in alcohol, ether, and acetic acid. The yield is 40 per cent. The *hydrazone*, $\text{C}_{15}\text{H}_{14}\text{O}_3\text{N}_2$, obtained by treating the aqueous solution of the acid with phenylhydrazine hydrochloride, crystallises from benzene in minute prisms; it is insoluble in water, but freely soluble in alcohol, ether, and also in sodium carbonate; from the latter solution, it is reprecipitated unchanged on acidification.

The *hydrazone* of *dioxymethylenepherylglyoxylic acid* (from isosafrole), $\text{C}_{15}\text{H}_{12}\text{O}_4\text{N}_2$, is decomposed on repeated crystallisation from hot benzene. From its solution in sodium carbonate it is precipitated by hydrochloric acid as a yellow, amorphous powder which melts at 149°, and dissolves in all ordinary solvents except water.

The *hydrazone* of *dimethoxyphenylglyoxylic acid* (from isomethyleugenol), $\text{C}_{16}\text{H}_{16}\text{O}_4\text{N}_2$, is an unstable compound, obtained like the previous substance as a clear, yellow powder which melts at 179°, and is insoluble in water, but dissolves in alcohol, ether, and hot benzene.

The *hydrazone* of *apionylglyoxylic acid*, $\text{C}_{17}\text{H}_{16}\text{O}_6\text{N}_2$, is even more unstable than the preceding compounds, and is altered by exposure to light. It is obtained as a pale-yellow powder, melts at 169—170°, and dissolves in all ordinary solvents except water.

The above ketonic acids do not yield oximes on treatment with hydroxylamine hydrochloride, the products of the action of this reagent on the hot aqueous solution of the acids being more or less volatile compounds, insoluble in sodium carbonate and potash, and having a characteristic odour. They are regarded by the author as nitriles formed by the simultaneous elimination of water and carbonic anhydride from the oximes. *Piperonylnitrile*,

$\text{CH}_2 < \overset{\text{O}}{\text{C}} \cdot \text{C}_6\text{H}_3 \cdot \text{CN}$, crystallises from water in slender, white needles, melts at 94°, dissolves sparingly in water, freely in alcohol, ether, benzene, &c., and not at all in sodium carbonate and potash. It has

a pungent, but not disagreeable odour, and readily volatilises in steam. Anisonitrile, $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{CN}$, crystallises in white needles, melts at $57\text{--}58^\circ$, and has a sweet, penetrating odour; it readily dissolves in alcohol, ether, &c., but only very sparingly in water, and not at all in sodium carbonate and potash. It is thus identical with the anisonitrile described by Henry (*Ber.*, 2, 667), and by Miller (*Abstr.*, 1890, 144). Veratronitrile, $(\text{OMe})_2\text{C}_6\text{H}_3\cdot\text{CN}$, crystallises from water in small, shining needles. It is less volatile than the preceding compound, and has a less marked odour. It melts at $67\text{--}68^\circ$, dissolves readily in ordinary solvents, sparingly in water, and not at all in potash or sodium carbonate. Apionitrile, $\text{CH}_3\cdot\text{C}(\text{O})\cdot\text{C}_6\text{H}(\text{OMe})_2\cdot\text{CN}$, may be crystallised from dilute alcohol; it is very slightly volatile, and has only a feeble odour. It is quite insoluble in water, but dissolves in other solvents. It melts at $135\cdot5^\circ$. S. B. A. A.

Action of Sodium Phenylmercaptide on Ethyl Chloroacetate. By R. OTTO and A. RÖSSING (*Ber.*, 24, 685—687).—The action of sodium phenylmercaptide on ethyl chloroacetate has been examined by Autenrieth (this vol., p. 540), who obtained phenyl bisulphide as the sole product under very varying conditions. The authors have repeated the experiment, and find that when equivalent quantities of the two substances are mixed in alcoholic solution, boiled for an hour, the alcohol evaporated off at a low temperature, and the residue mixed with water, an oil is obtained, which, even on the addition of a crystal of phenyl bisulphide, does not solidify, and has only a feeble odour. It appears to be ethyl thiophenylacetate mixed with a little phenyl bisulphide. H. G. C.

Action of Ethyl Sodacetate on Ethyl Benzalmalonate. By J. BREDT (*Ber.*, 24, 603—605).—By the action of ethyl sodacetate and ethyl benzylmalonate in molecular proportion in alcoholic solution at 0° , a crystalline *sodium salt* is slowly deposited; it is not decomposed by carbonic anhydride, but on treatment with mineral acids, a compound of the formula $\text{C}_{18}\text{H}_{20}\text{O}_8$ is precipitated; this is very sparingly soluble in water, but dissolves in alcohol, and is deposited in crystalline aggregates; it melts at 155° with decomposition. The *silver salt* is also crystalline. J. B. T.

Ethyl Hydrogen Hemipinate. By R. WEGSCHNEIDER (*Monatsh.*, 11, 538—544).—This salt, $\text{COOH}\cdot\text{C}_6\text{H}_2(\text{OMe})_2\cdot\text{COOEt}$, has been prepared by the following methods:—(1.) From hemipinic acid (obtained from narcotine), by the action of hydrogen chloride on a solution in 10—15 times its weight of alcohol, and subsequent recrystallisation of the product from water, or treatment of it with dilute aqueous potash and reprecipitation by means of a dilute acid. (2.) From hemipinic acid, by first converting it into the corresponding anhydride and boiling this for several hours with absolute alcohol in a reflux apparatus. (3.) From diethyl hemipinate, $\text{C}_{10}\text{H}_8\text{O}_4\cdot\text{Et}_2$ (m. p. $70\text{--}72^\circ$), by heating with alcoholic potash in molecular proportion. The product, in every case, melted at 148° , that is, 6° higher than the melting point

previously attributed to it. The observation of Schmidt and Schilbach (*Arch. Pharm.* [3], 25, 176), that after long-continued drying at 100° , the melting point becomes lowered to 132.5° , was not confirmed; but when the salt had been once melted in a capillary tube, the melting point fell to about 125° , a behaviour probably dependent on the partial conversion of ethyl hydrogen hemipinate into hemipinic anhydride. Ethyl hydrogen hemipinate may be obtained crystallised in the anhydrous state, or with 1 mol. H_2O , as well as in the form of the previously-described hydrated salt containing $1\frac{1}{2}$ mols. H_2O .

G. T. M.

Oxidation of Gallic Acid. By C. BOETTINGER (*Annalen*, 260, 337—348; compare Abstr., 1890, 1130).—Various acids are obtained when gallic acid is oxidised with an alkaline solution of copper sulphate; the products are isolated in the following manner:—To a solution of copper sulphate (1.5 kilos.) and gallic acid (150 grams) in boiling water (4 litres), caustic soda, of sp. gr. 1.28 (1800 c.c.), is added, with constant stirring, and the mixture then boiled for half an hour; after filtering from the red precipitate which is produced, the residue is washed with water, the filtrate and washings concentrated by evaporation, acidified with sulphuric acid, and partially distilled. The distillate contains acetic acid and small quantities of an acid, probably pyruvic acid, which combines with phenylhydrazine; the residual solution is allowed to cool, separated from the crystals of sodium sulphate, the acid extracted with ethyl acetate, dissolved in water, and the diluted aqueous solution neutralised in the cold with calcium carbonate and calcium hydroxide, and filtered. The residue contains calcium oxalate and the calcium salt of an acid which the author names galic acid.

Gallic acid can be easily separated from oxalic acid, as it is insoluble in dilute hydrochloric acid and only very sparingly soluble in cold water, but it dissolves freely in hot water, yielding a brown solution; it is readily soluble in alcohol and acetic acid, but insoluble in ether and chloroform. It is decomposed on heating, is converted into an acetyl derivative by boiling acetic anhydride, and dissolves in concentrated nitric acid, yielding a reddish-brown solution, from which oxalic acid is deposited on keeping for several weeks. When dried over sulphuric acid, it seems to have the composition $\text{C}_{14}\text{H}_{12}\text{O}_{13}$ (or $\text{C}_{11}\text{H}_9\text{O}_{11}$), but when heated at 170° it loses 2 mols. H_2O , 1 mol. being driven off at 100° . The *lead* salt, prepared by precipitating a solution of the acid with lead acetate, has probably the composition $(\text{C}_{14}\text{H}_9\text{O}_{12})_2\text{Pb}_2 + 3\frac{1}{2}\text{H}_2\text{O}$. The *barium* salt, obtained by precipitating a solution of the ammonium salt with barium chloride, is insoluble in water, and seems to have the composition $(\text{C}_{11}\text{H}_9\text{O}_{12})_2\text{Ba}_2 + 2\text{H}_2\text{O}$.

When the acid is treated with bromine in well cooled, aqueous solution, it is converted into a brown substance, which decomposes at 95° , and seems to have the composition $\text{C}_{11}\text{H}_9\text{Br}_2\text{O}_{12} + 4\text{H}_2\text{O}$; when excess of bromine is employed, and the reaction is carried out at the ordinary temperature, a yellow substance, seemingly a tetrabromide, is obtained. Hydroxylamine converts gallic acid into a nitrogenous compound, which is decomposed by boiling alkali with evolution of

ammonia, and phenylhydrazine transforms it into a brown substance, which is insoluble in water.

When the filtrate containing the soluble calcium salts (see above) is evaporated to dryness, the residue decomposed with sulphuric acid, and the filtered solution extracted with ether, a deliquescent acid, having the composition $C_4H_4O_3$, is obtained; on distillation, it yields pyruvic acid and compounds which reduce ammoniacal silver nitrate solution. The *calcium* salt, $(C_4H_3O_3)_2Ca$, exists in two modifications; the one contains $2\frac{1}{2}$ mols. H_2O , and is insoluble in water, the other 2 mols. H_2O , and is readily soluble. The *barium* salt, $(C_4H_3O_3)_2Ba + 1\frac{1}{2}H_2O$, is soluble in water, but is precipitated from its aqueous solution on boiling. When a solution of the acid is warmed with phenylhydrazine, a reddish-yellow hydrazone is deposited; this compound is precipitated in crystals on adding water to its solution in boiling 10 per cent. acetic acid. F. S. K.

Aromatic Sulphines. By A. MICHAELIS and E. GODCHAUX (*Ber.*, 24, 757—764; compare *Abstr.*, 1890, 610; 1891, 74).—The authors have not succeeded in preparing thionyl dimethylaniline from dimethylaniline and thionyl chloride in the presence of aluminium chloride.

Hexamethyltriamidotriphenylsulphine chloride, $S(C_6H_4Me_2)_3Cl \cdot 6H_2O$, is prepared by dissolving mercury dimethylaniline (Schenk and Michaelis, *Abstr.*, 1888, 834) (10 grams) in benzene (200—250 c.c.), and adding, by degrees, thionyl chloride (1.5—2 grams) dissolved in benzene (30 c.c.) to the lukewarm solution, shaking meanwhile; a voluminous, yellow precipitate separates, which subsequently assumes a red or brown colour, and, finally, becomes green in the presence of excess of thionyl chloride. It is collected, air-dried, washed with water, and boiled with moderately concentrated hydrochloric acid, until, with the exception of a small quantity of yellow powder, it is dissolved. The mercury is then removed by a current of hydrogen sulphide, and on adding sodium hydroxide to the filtrate, the sulphine chloride is precipitated together with dimethylaniline. After washing the precipitate with a little water, it is dissolved in warm alcohol, and carbonic anhydride passed through the solution to precipitate any sodium as carbonate, a little water is then added, and the solution boiled to remove the dimethylaniline; on concentrating the solution and treating with animal charcoal, the sulphine chloride separates in colourless, glistening needles; it forms thick, yellow crystals, a centimetre in length, and is obtained pure by extraction from the aqueous solution with chloroform. It is very easily soluble in alcohol and chloroform, readily in hot water, but only sparingly in ether, light petroleum, and cold water; the hydrated compound melts in its water of crystallisation at 98° , resolidifies at 120° , and the anhydrous substance then melts at 150° ; it dissolves in acids. By the action of metallic sodium on an alcoholic solution of the sulphine chloride, or when its solution in hydrochloric acid is saturated with hydrogen sulphide and heated at 100° in a sealed tube, thiodimethylaniline and dimethylaniline are formed. The *platino-chloride*, $(C_{24}H_{30}N_3S)_2PtCl_6$, is a flocculent, yellowish-brown precipitate,

which melts at 190° with deflagration; the *mercuriochloride*,

is a dense, white precipitate which melts at 220° ; whilst the *picrate*, $\text{C}_{24}\text{H}_{30}\text{N}_3\text{SCl}_2\text{C}_6\text{H}_3\text{N}_3\text{O}_7$, crystallises from alcohol in quadratic plates, sparingly soluble in cold alcohol, and melts at 135° .

Hexamethyltriamidotriphenylsulphine hydroxide,

is prepared by shaking a lukewarm solution of the sulphine chloride with moist silver oxide, evaporating the filtered solution to dryness, adding water, and concentrating to a small volume. It forms delicate yellow needles, and is easily soluble in water; its solutions have an alkaline reaction, but do not absorb carbonic anhydride from the air; the hydrated compound melts at $80-90^{\circ}$, and the anhydrous at 200° . The *bromide*, $\text{C}_{24}\text{H}_{30}\text{N}_3\text{SBr}$, is precipitated in small, delicate, white needles, by carefully neutralising a solution of the hydroxide with hydrobromic acid; it is sparingly soluble in cold water, readily in alcohol and chloroform, but insoluble in ether, and melts at 240° . The *iodide*, $\text{C}_{24}\text{H}_{30}\text{N}_3\text{SI}$, separates from alcohol in small, glittering crystals, melts at 242° , and is not very soluble in hot water, sparingly in cold alcohol, readily in hot alcohol and chloroform, but insoluble in ether.

The authors believe that the sulphur in the above derivatives is in the quadrivalent condition, but, despite their apparent analogy with compounds of quadrivalent carbon, a comparison shows that their chemical and physical behaviour is quite different. For example, hexamethyltriamidotriphenylsulphine hydroxide corresponds with hexamethyltriamidotriphenylcarbinol; but whereas the former, on treatment with hydrochloric acid, yields the colourless sulphine chloride, the latter yields the intensely coloured methyl-violet; thionylbenzene does not react with phenylhydrazine, thus differing from benzophenone.

Chlorothiobenzene, $\text{SPh}\cdot\text{C}_6\text{H}_4\text{Cl}$, is obtained as a heavy, colourless oil, boiling at $305-315^{\circ}$, together with a small quantity of a compound melting at 88° (probably dichlorothiobenzene, Kraft, this Journal, 1873, 153), when thionylbenzene and phosphorus pentachloride are brought together in molecular proportion. A. R. L.

Thionylamines. By A. MICHAELIS (*Ber.*, 24, 745-757).—Thionylaniline, $\text{C}_6\text{H}_5\text{N}:\text{SO}$, already described by Michaelis and Herz (this vol., p. 310), is best prepared as follows:—Finely powdered aniline hydrochloride (100 grams) is suspended in dry benzene (200 c.c.), and boiled in a reflux apparatus with thionyl chloride (100 grams) until the evolution of hydrogen chloride has ceased; it is then isolated by distillation as previously described; the deposition on the condenser of a small quantity of aniline sulphite, produced by the action of moisture on the thionylaniline, indicates that the thionyl radicle is in combination with the nitrogen atom. Thionylaniline dissolves unchanged in alcohol, but when heated with it in a sealed tube at 150° , it is decomposed with the formation of hydrogen sulphide.

With concentrated hydrochloric acid, it reacts violently, forming aniline hydrochloride and sulphurous anhydride; it unites with dry hydrogen chloride at the ordinary temperature, but more readily when cooled by ice and salt, forming an unstable compound, $\text{SO} \cdot \text{NPh} \cdot 2\text{HCl}$, which, however, splits up into thionyl chloride and aniline hydrochloride when treated with an excess of the acid.

Thionyl bromide, SOBr_2 , which cannot be prepared in the same way as the chloride, is formed together with the hydrobromide of the tribromaniline melting at $118-120^\circ$, in accordance with the equation $\text{C}_6\text{H}_5 \cdot \text{N} \cdot \text{SO} + 3\text{Br}_2 = \text{C}_6\text{H}_5\text{Br}_3 \cdot \text{NH}_2\text{Br} + \text{SOBr}_2$, when thionylaniline (50 grams) is dissolved in several times its volume of light petroleum, and bromine (173 grams) gradually (during several days) run in. The precipitated tribromaniline hydrobromide is then filtered off, and after distilling off the petroleum, the thionyl bromide passes over between 130° and 140° as a brown liquid, the greater portion of which boils at 136° , on repeating the distillation. As it boils with partial decomposition into sulphur bromide, bromine and sulphurous anhydride, it was not obtained quite pure and devoid of colour; it appeared to contain free bromine, and although it could be decolorised by shaking with mercury, it was then decomposed.

Thionylaniline, although analogous to phenyl isocyanate, does not combine with aniline as readily as the latter; for example, a mixture of thionylaniline and aniline only reacts if heated in a sealed tube at 200° , a colouring matter containing sulphur being formed; whilst when water or moist ether is added to a mixture of the two in molecular proportion, Schiff's aniline sulphite (*Annalen*, 140, 125) is produced with the development of heat. The aniline sulphite described by Bocsenneck (*Abstr.*, 1888, 943) is analogous to phenylcarbamic acid, and probably has the constitution, $\text{NHPh} \cdot \text{SO} \cdot \text{OH}$, Schiff's compound (*loc. cit.*) being the aniline salt of the former, $\text{NHPh} \cdot \text{SO} \cdot \text{ONH}_2\text{Ph}$; or $\text{S}(\text{OH})_2(\text{NHPh})_2$.

Benzaniline sulphite is prepared by dissolving thionylaniline and aniline in molecular proportion in alcohol and adding benzaldehyde. The mixture becomes warm, and the precipitated compound is collected and crystallised from alcohol. The water contained in the alcohol employed in the preparation of the compound completes the reaction, for if the above-described mixture is dissolved in an anhydrous solvent half the thionylaniline remains unaltered, and benzyldeneaniline, $\text{CHPh} \cdot \text{NPh}$, together with benzaniline sulphite, is obtained. Benzaniline sulphite forms a felt-like mass of delicate, white needles, melts at 124° , and decomposes with evolution of sulphurous anhydride at a higher temperature; it is soluble in hot alcohol and water, but only sparingly in ether, and may be kept without decomposing; it is identical with a compound described by Schiff (*Annalen*, 140, 130; 210, 128), and may have one of the three formulæ

When thionylaniline and phenylhydrazine are mixed, a violent reaction ensues, and resinous substances, difficult to purify, are formed,

but when the former is shaken with an aqueous or alcoholic solution of phenylhydrazine acetate, *thionylphenylhydrazone*, $\text{NHPh}\cdot\text{N}\cdot\text{SO}$, and aniline acetate are formed. The hydrazone separates as a yellow compound after a short time, and is purified by crystallisation from alcohol. Similar compounds are obtained with other hydrazines and thionylaniline; they crystallise well, and volatilise with steam without decomposition. They are readily decomposed by alkalis into the hydrazine and a sulphite, and hence may be employed as a means of isolating and purifying the hydrazines. Thionylhydrazone could not be prepared from hydrazine chloride and thionylaniline, and it is probable that this compound is decomposed by water, and that free hydrazine is necessary for its preparation. Thionylparatoluidine has already been described by Michaelis and Herz (*loc. cit.*); its properties resemble those of thionylaniline. The compound *benzotoluidine sulphite*, $2\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{Ph}\cdot\text{COH}\cdot\text{SO}_2$, formed when benzaldehyde is added to a mixture of thionylparatoluidine and paratoluidine in molecular proportion in alcoholic solution, crystallises from alcohol in delicate, white needles, and melts at $119\text{--}120^\circ$.

Thionylorthotoluidine is prepared in a similar manner to the para-derivative (*loc. cit.*); it has a fainter odour than the latter, and is a bright-yellow liquid, which cannot be distilled at the ordinary pressure without decomposition; it boils at 184° under a pressure of 100 mm., does not solidify on cooling, and is easily decomposed by alkalis into orthotoluidine and a sulphite.

Thionylbenzidine, $\text{C}_{12}\text{H}_8(\text{N}\cdot\text{SO})_2$, is formed when thionyl chloride is heated for some time with benzidine dissolved in benzene; it separates on cooling in red, transparent needles, and is sparingly soluble in cold benzene, more readily in hot, and still more readily in chloroform.

Thionylparachloraniline, $\text{C}_6\text{H}_4\text{Cl}\cdot\text{N}\cdot\text{SO}$, is prepared by dissolving parachloraniline (20 grams) in benzene (40 c.c.), and gradually adding thionyl chloride (20 grams), and heating as long as hydrogen chloride is evolved; it boils at 237° , and when cooled, solidifies forming small, faintly-yellow crystals; it melts at 36° , and is slowly decomposed by cold water, but quickly by hot water and alkalis.

Thionylmetachloraniline is a yellow liquid boiling at 233° ; it solidifies when cooled.

Thionyltribromaniline, prepared by heating thionyl chloride with tribromaniline (m. p. $118\text{--}120^\circ$) dissolved in benzene, crystallises from benzene in delicate, yellow needles, melts at $74\text{--}75^\circ$, and is easily decomposed by water.

Thionylmetanitraniline is obtained by heating thionyl chloride with metanitraniline dissolved in benzene. The crystals obtained on cooling the solution are purified by dissolving in a little benzene and precipitating with light petroleum; if the latter is carefully added, so that the two liquids only mix by degrees, large, well-formed crystals are obtained. The compound forms yellow, flat prisms, melts at $63\cdot5^\circ$, and develops the odour of sulphurous anhydride on exposure to the air; alkalis and hot water decompose it.

Thionylparanitraniline is prepared in a manner similar to the meta-derivative, which it resembles, but is more soluble in benzene; it forms delicate yellow or yellowish-red needles, and melts at 70° .

Thionylethylamine, $\text{NEt}\cdot\text{SO}$, is not obtained from ethylamine hydrochloride and thionyl chloride, but is prepared as follows:—Anhydrous ethylamine (3 mols.) dissolved in several times its volume of ether is cooled in a mixture of ice and salt, and thionyl chloride (1 mol.) in ethereal solution slowly dropped in. The mixture, which is frequently shaken, is left for a long time in a closed flask; it is then filtered from ethylamine hydrochloride, and after washing the latter with ether, the ethereal solution, from which ethylamine sulphite separates if exposed to the air, is very slowly distilled on the water-bath. It is a colourless liquid of a penetrating odour, boils at 73° , and is decomposed by water with development of heat; alkalis and acids also decompose it.

A. R. L.

Aromatic Sulphonic Iodides. By R. OTTO and J. TRÖGER (*Ber.*, 24, 478—488).—It has previously been shown by Otto that chlorine acts on metallic sulphinates with formation of the corresponding sulphonic chlorides, and the authors now find that iodine acts in a similar manner. *Paratoluenesulphonic iodide*, $\text{C}_7\text{H}_7\text{SO}_2\text{I}$, is readily obtained by adding an alcoholic solution of iodine to a concentrated aqueous solution of sodium paratoluenesulphinate, and separates as a sulphur-yellow powder, which gradually darkens on exposure to the air. It becomes brown at 80° , melts at $84\text{--}85^\circ$, loses iodine above that temperature, and dissolves in light petroleum, ether, and carbon bisulphide, the solutions gradually undergoing decomposition. When heated with water, it loses iodine, and is converted into paratoluenesulphonic acid and paratoluene disulphoxide; these may be regarded as derived from the radicle $\text{C}_7\text{H}_7\text{SO}$, first formed, by the action of water. Alcohol converts it into ethyl paratoluenesulphonate, and small quantities of paratoluenesulphonic acid and sulphoxide, and with ammonia, it yields paratoluenesulphonamide, the iodine being simply displaced by the amido-group. Aqueous potash acts rather differently, the iodine being displaced by potassium with formation of potassium paratoluenesulphinate, and the iodine further acted on by the alkali present, and converted into potassium iodide and iodate.

The action of molecular silver on the iodide dissolved in dry, light petroleum was studied in the hope of obtaining a disulphone, according to the equation:—

Here also, however, paratoluene sulphoxide and paratoluenesulphonic acid were obtained; it is probable that the disulphone cannot exist, but at once decomposes as follows:—

The sulphonic anhydride remains as the portion insoluble in light petroleum, and is converted by the action of alcohol into the acid.

When paratoluenesulphonic iodide is heated on an iron plate at 100° , it decomposes with incandescence and evolution of iodine; the residue contains toluenesulphonic acid, and a small quantity of a substance which crystallises from acetic acid in small needles, melts at $192\text{--}194^\circ$, and contains both iodine and sulphur.

Benzenesulphonic iodide, $C_6H_5\cdot SO_2I$, is prepared in the same manner, and forms a somewhat darker powder. It melts at $42-45^\circ$, decomposes at a considerably higher temperature, and behaves towards reagents in exactly the same manner as the paratoluene compound. The different way in which the reaction proceeds with the several reagents makes it probable that these substances exist in two tautomeric modifications, as represented by the formulæ $R\cdot S^{VO}_2\cdot I$ and $R\cdot S^{VO}\cdot OI$.

An unsuccessful attempt was also made to prepare the corresponding *ethylsulphonic iodide*, but the product consisted of free ethylsulphinic acid, ethylsulphonic acid, and a little mercaptan.

H. G. C.

Action of Zinc Ethyl on Aromatic Sulphonic Iodides. By R. OTTO and J. TRÜGER (*Ber.*, 24, 488—491).—This investigation was undertaken in the hope that the product would either be an ethyl sulphone derivative or the ethyl salt of the sulphinic acid, and thus throw some light on the question of the formulæ of the iodides, which, as suggested in the previous abstract, may possibly exist in two tautomeric forms. This anticipation has not been realised, as the product of the action is simply ethyl iodide and the zinc salt of the sulphinic acid; a similar result was obtained by Kalle (*Annalen*, 119, 153), by treating benzenesulphonic chloride with zinc ethyl.

The reaction was carried out in light petroleum solution, and takes place almost immediately, but the zinc salt remains dissolved for some time, and only separates on allowing it to remain, or on pouring the solution into a vessel containing air or carbonic anhydride; it is then quite insoluble in light petroleum. Possibly this zinc salt exists in two tautomeric forms, corresponding with those previously given for the iodide.

H. G. C.

Aromatic Thiosulphonic Acids. By R. OTTO and J. TRÜGER (*Ber.*, 24, 491—495).—Molecular silver acts on an aqueous solution of potassium benzenethiosulphonate with formation of silver sulphide, and the solution, after the separation of the latter, contains only potassium benzenesulphinic acid. Silver also converts sodium thiosulphate into sodium sulphite under the same conditions. A double potassium and silver benzenethiosulphonate may be prepared by dissolving silver chloride in a solution of potassium benzenethiosulphonate; it has the composition $C_6H_5S_2O_2K, C_6H_5S_2O_2Ag$, and crystallises in needles. Paratoluenethiosulphonic acid yields a similar double salt, also crystallising in needles.

When ferric chloride is added to a solution of potassium benzenethiosulphonate, and the mixture gently warmed, the ferric salt is obtained as an orange or reddish-yellow precipitate. If the thiosulphonate is poured into a hot solution of ferric chloride, sulphur, ferrous chloride, potassium chloride, and benzenesulphonic chloride are formed in addition. The paratoluene compound behaves in a similar manner. If potassium benzenethiosulphonate is heated with concentrated aqueous potash, one sulphur atom is eliminated in the form of sulphide, and possibly also as thiosulphate, the solution becoming yellow, and containing in addition only potassium sulphinic acid.

Potassium paratoluenethiosulphonate separates from water in lustrous, colourless, transparent crystals, belonging to the monosymmetric system ($a : b : c = 0.8854 : 1 : 1.5436$, $\beta = 60^{\circ}8'$).

H. G. C.

Behaviour of Sulphonic Chlorides towards Thiophenols and Thioalcohols in presence of Alkalis. By R. OTTO (*Ber.*, 24, 713—716).—The ease with which the hydrogen atom of the hydroxyl group in phenols is displaced by the group $C_6H_5 \cdot SO_2$ in aqueous alkaline solution, led the author to attempt to displace the corresponding hydrogen atom of the thiophenols by a similar group. The results obtained, however, show that the reaction takes place in a different manner, a bisulphide and a sulphinic acid being formed. Thus benzenesulphonic chloride and thiophenyl yielded phenyl bisulphide and benzenesulphinic acid in almost quantitative proportions; this is probably the best method of preparing benzenesulphinic acid. A corresponding result was obtained with benzenesulphonic chloride and thioparacresol, paratoluenesulphonic chloride and thioparacresol, and also with ethylsulphonic chloride and ethyl mercaptan.

H. G. C.

Benzaldehydesulphonic Acid. By E. KAFKA (*Ber.*, 24, 791—797).—Benzaldehydesulphonic acid is obtained as described by Wallach and Wüsten (*Ber.*, 16, 150). The sodium salt crystallises from water or dilute alcohol in white aggregates.

Sodium benzaldoximesulphonate, $SO_3Na \cdot C_6H_4 \cdot CH \cdot NOH$, is obtained by heating a faintly alkaline mixture of sodium benzaldehydesulphonate (1 mol.), hydroxylamine hydrochloride ($1\frac{1}{2}$ mols.), and sodium carbonate for one hour on the water-bath. It crystallises in white, lustrous plates, and is very easily soluble in water, less soluble in alcohol.

Sodium phenylhydrazinebenzylidenesulphonate,

is obtained as a yellow, flocculent precipitate when the calculated quantity of phenylhydrazine, dissolved in dilute acetic acid, is added to an aqueous solution of the sodium sulphonate. It forms beautiful colourless needles, and is sparingly soluble in cold water, easily soluble in hot water, alcohol, and glacial acetic acid.

Sodium diphenylhydrazonebenzylidenesulphonate,

is obtained by adding an aqueous solution of diphenylhydrazone hydrochloride to an aqueous solution of the sodium sulphonate containing the required quantity of sodium acetate. The mixture is heated on the water-bath for some time, and, on cooling, nacreous plates separate. It is sparingly soluble in cold water and alcohol, easily soluble in hot water.

Sodium α -naphthylaminebenzylidenesulphonate,

is prepared by heating a mixture of α -naphthylamine dissolved in

alcohol and an aqueous solution of the sodium sulphonate. It crystallises in beautiful, pale-yellow prisms, and is easily soluble in water, sparingly so in alcohol

Sodium benzylidenesulphonaphthionate,

is obtained by heating sodium naphthionate with sodium benzaldehydesulphonate in aqueous solution; it crystallises in small, white needles, and is somewhat easily soluble in water, but only sparingly in alcohol.

Sodium paraphenylenediaminebenzylidenesulphonate,

is obtained by heating an alcoholic solution of paraphenylenediamine with an aqueous solution of the sodium sulphonate on the water-bath. It crystallises from dilute alcohol in yellow needles, and is easily soluble in water, but only sparingly in alcohol.

Sodium metaparatoluylenediaminebenzylidenesulphonate,

is obtained by heating a mixture of orthotoluylenediamine hydrochloride and the sodium sulphonate with sodium acetate on the water-bath for $1\frac{1}{2}$ hours. It is sparingly soluble in water and dilute alcohol, insoluble in absolute alcohol, and easily soluble in dilute hydrochloric acid.

Benziledisulphonic acid, $\text{C}_2\text{O}_2(\text{C}_6\text{H}_4\cdot\text{SO}_3\text{H})_2$, is prepared as follows:—Barium benzaldehydesulphonate (30 parts) dissolved in alcohol (150 parts, 50–55 per cent.) and potassium cyanide (5 parts) are heated in a reflux apparatus for four hours. The product is filtered, evaporated to dryness, extracted with 85 per cent. alcohol, and the residue, which consists of benzoindisulphonic acid, dissolved in water and precipitated with alcohol. The benzoindisulphonic acid, which is not at all well characterised, is oxidised with strong nitric acid, and easily yields benziledisulphonic acid. The latter is separated by means of its barium salt, which forms a colourless, crystalline powder, extremely soluble in water, and sparingly soluble in alcohol. Benziledisulphonic acid forms with phenylhydrazine a very soluble yellow dye, which gives an intense orange-yellow colour to wool, and is fast to alkalis and acids.

Barium di- α -naphtholbenzylidenesulphonate,

is prepared by mixing the barium salt of the sulphonic acid (10 parts) with α -naphthol (11 parts), dissolving the mixture in glacial acetic acid (60–70 parts), and gradually adding a 25 per cent. solution of hydrochloric acid (8–9 parts). The mixture is heated for seven hours on the water-bath, and must be kept from contact with water vapour; it is then filtered from barium chloride, the unattacked α -naphthylamine and acetic acid got rid of, the remaining barium precipitated with sulphuric acid, and the solution decolorised with animal

charcoal. The barium salt is prepared by adding barium carbonate to the solution, is easily soluble in water and alkalis, not so soluble in dilute alcohol, and insoluble in absolute alcohol. With diazo-compounds, it yields dyes; with diazobenzenesulphonic acid, a yellowish-red; with diazotised benzidinesulphonic acid, a brownish-red, of only weak tinctorial power; with diazo- β -naphthalenesulphonic acid, a dark-red, of strong tinctorial power.

Sulphocinnamic acid, $\text{SO}_2\text{H}\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{CH}\cdot\text{COOH}$, is obtained by heating a mixture of barium benzaldehydesulphonate (6 parts), anhydrous sodium acetate (3 parts), and acetic anhydride (10 parts) in a reflux apparatus for 8–9 hours. The acid is purified by conversion into the barium salt; the latter crystallises in white aggregates, and is easily soluble in water, sparingly soluble in alcohol.

Benzaldehydesulphonic acid, when treated with nitric acid, does not yield a nitro-compound. Ammonia has no effect on it. When the barium salt is exposed to the air, or when air is led through its solution at 90–95°, no oxidation takes place. When oxidised with nitric acid, it yields metasulphobenzoic acid. E. C. R.

Extraction of Indigotin from Commercial Indigo. By T. M. MORGAN (*Chem. Centr.*, 1891, i, 76; from *J. Amer. Chem. Soc.*, 12, 302).—The finely-powdered indigo is mixed with about an equal weight of zinc-dust, and is spread in layers of about 1 inch in thickness in a chamber through which steam can be passed; the chamber is also provided with an opening for the admission of sulphurous anhydride. The indigo is covered so as to prevent any condensed water from dropping on to it. After expelling the air, steam is allowed to pass slowly through the chamber, and the sulphurous anhydride is admitted in small quantities at a time until the reduction is complete; this occupies from one to two hours. The mass has then a dirty-yellowish or greenish-yellow appearance, and when dry does not oxidise very readily, and may be kept for several days. The indigo-white may be extracted with wood-spirit, from which pure indigotin may be obtained in crystals by exposing the solution to the air.

J. W. L.

Synthesis of Dimethylindigo from Parachloracetotoluidide and Paratolyglycin. By H. ECKENROTH (*Ber.*, 24, 693).—When 1 part of parachloracetotoluidide or of paratolyglycin is fused with 2 parts of potash in the manner described by Flinm (Abstr., 1890, 383) or Heumann (this vol. p. 75), an orange-coloured melt is obtained, which is readily soluble in water, and on exposure to the air, deposits dimethylindigo. The latter is physically indistinguishable from ordinary indigo. H. G. C.

Oxidation of Hydrated Pyridine Bases: Conversion of Tetrahydroquinoline into Isatin. By C. SCHOTTEN (*Ber.*, 24, 772–775).—Tetrahydroquinoline was prepared by reducing quinoline with tin and hydrochloric acid, the mixture steam-distilled, and the aqueous distillate shaken up with soda and benzoic chloride; benzoyl-tetrahydroquinoline soon separates.

Benzoylisatinic acid, $\text{C}_7\text{H}_5\text{O}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{COOH}$ (benzoylortho-

amidobenzoylformic acid), is obtained by heating benzoyltetrahydroquinoline with potassium permanganate (2·5 parts) and water (20 parts); the excess of permanganate is then destroyed, the solution filtered, and the acid precipitated with hydrochloric acid. The yield amounts to 50 per cent. of the tetrahydroquinoline employed; the product in the mother liquors was not examined; carbonic anhydride and oxalic acid are formed in small quantities. Benzoylisatinic acid crystallises from solutions of its salts on acidification in colourless prisms, from dilute alcohol in very pale-yellow prisms, is quite insoluble in water, easily soluble in alcohol, not so soluble in absolute ether, and melts at 188° with formation of its anhydride. The *alkali* salts are easily soluble in water. The *barium* salt is sparingly soluble in both hot and cold water. Benzoylisatinic acid, prepared by dissolving isatin in hot dilute soda, and shaking the cold solution with benzoic chloride, was identical in every respect with the above.

Benzoylisatin is obtained from the above acid by heating it for a few minutes above its melting point, or by heating for some time with excess of acetic anhydride. It crystallises from glacial acetic acid in intensely yellow needles, which yield a yellow powder when ground up, is sparingly soluble in cold, more soluble in hot acetic acid, very sparingly soluble in alcohol and ether, and melts at 206° with a brown coloration. It is insoluble in cold dilute alkali hydroxides and carbonates, but dissolves if allowed to remain some time in contact with them in the cold, or more quickly on warming, and is converted into benzoylisatinic acid. With sulphuric acid and benzene containing thiophen, it gives as beautiful a blue as isatin itself.

E. C. R.

New Synthesis of Indazole Derivatives. By C. PAAL (*Ber.*, 24, 959—966)—In their investigations on dihydroquinazolines (Abstr., 1890, 1443). Paal and Krecke obtained a base having the empirical formula $C_{11}H_{10}N_2$, by the reduction of orthonitrobenzylaniline, $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot NHBz$, with tin and hydrochloric acid. Further investigation has shown that the base is 2'-phenylindazole,

It is best prepared from the product of reduction by allowing the stannochloride to crystallise out, digesting it with ammonium sulphide, and extracting the washed residue with hot alcohol. On carefully adding water to the solution, 2'-phenylindazole separates in crystals; it melts at $83\text{--}84^{\circ}$, boils without decomposition at $344\text{--}345^{\circ}$ (uncorr.), and has a molecular weight, as determined by Raoult's method, in benzene solution, agreeing with the above formula. It is not altered by nitrous acid or acetic anhydride, and may be distilled over faintly red-hot zinc-dust almost without decomposition. Further, on heating with methyl iodide and methyl alcohol, it yields a *methiodide*, $C_{11}H_{10}N_2 \cdot MeI$, which crystallises from methyl alcohol in spherical aggregates of slender, white needles, and melts at 188° . From these results, it follows that both nitrogen atoms in the compound are in the tertiary condition, and from this fact and the method by which it is obtained, it must have the constitutional

formula given above. Especially noteworthy is the ease with which the indazole ring is formed, both in this and in the previous syntheses (Abstr., 1884, 440; 1885, 540; this vol., p. 312).

When 2'-phenylindazole is treated with sodium in absolute alcohol, it is converted into 2'-phenyl-1':3'-dihydrindazole, $C_6H_5 \langle \begin{smallmatrix} NH \\ CH_2 \end{smallmatrix} \rangle NPh$; some of the indazole, however, always remains unaltered, but is easily separated by its greater solubility in alcohol. The dihydro-compound crystallises from the latter solvent in nacreous plates, melts at about 98°, forms an unstable hydrochloride, which is decomposed by water, and is oxidised to 2'-phenylindazole by ferric chloride.

2'-Parachlorophenylindazole, $C_6H_4 \langle \begin{smallmatrix} N \\ CH \end{smallmatrix} \rangle N \cdot C_6H_4(Cl)$, is obtained by the reduction of orthonitrobenzylparachloraniline, and is isolated in a similar manner to the phenyl derivative. It forms lustrous plates, readily soluble in hot alcohol, benzene, and acetic acid, sparingly in light petroleum, and melts at 138°. 2'-Parabromophenylindazole is obtained by the same method from orthonitrobenzylparabromaniline. It does not, however, form a stannochloride, and is obtained directly from the reduced solution in flat, colourless needles melting at 147°, and sparingly soluble in alcohol, readily in benzene and acetic acid.

2'-Paraphenetylindazole, $C_6H_4 \langle \begin{smallmatrix} N \\ CH \end{smallmatrix} \rangle C_6H_4 \cdot OEt$, is prepared by the reduction of orthonitrobenzylparaphenetidine. The stannochloride separates on cooling in yellowish plates melting at 138°. These are dissociated by hot water, with formation of free paraphenetylindazole, which crystallises from alcohol in nacreous plates, from dilute acetic acid in flat needles, and from a mixture of benzene and light petroleum in short, colourless prisms. It melts at 118°, and forms salts which are dissociated by water. On treatment with phosphorus and hydriodic acid, it is converted into ethyl iodide and 2'-parahydroxyphenylindazole, $C_6H_4 \langle \begin{smallmatrix} N \\ CH \end{smallmatrix} \rangle N \cdot C_6H_4 \cdot OH$. The hydriodide of the new base separates on cooling in large, yellowish plates, melts at 200° with blackening, and is partially dissociated by water. To prepare the free base, the hydriodide is dissolved in dilute soda, dilute acetic acid added as long as a precipitate is formed, and the latter recrystallised from dilute alcohol. It is thus obtained in fascicular aggregates of short, colourless prisms melting at 195°, readily soluble in mineral acids, alcohol, acetic acid, and in aqueous alkalis. From the latter solutions, it is precipitated by carbonic anhydride, but not by dilution with water.

The exact method in which the formation of the indazole ring takes place is not quite certain. The most natural supposition is that orthamidobenzylaniline is first formed and is then further oxidised—

The author has, however, been unable to obtain 2'-phenylindazole from orthamidobenzylaniline itself, and thinks it possible that the nitro-group may first be reduced to the nitroso-group, the nitroso-compound then undergoing condensation in the following manner:—

H. G. C.

Action of Carbamide and Thiocarbamide on Dihydroxy-tartaric Acid, Benzile, and Benzoin. By R. ANSCHÜTZ and H. GÜLDERMANN (*Annalen*, 261, 129—138; compare Anschütz, Abstr., 1890, 365).—Ethyl dihydroxytartrate is formed when hydrogen chloride is passed into a well-cooled alcoholic solution of sodium dihydroxytartrate; the crude product is a thick, brownish-yellow syrup, which cannot be distilled even under greatly reduced pressure. The *dihydrazone*, $\text{C}_{20}\text{H}_{22}\text{N}_4\text{O}_4$, is obtained, together with various other compounds, when crude ethyl dihydroxytartrate is treated with phenylhydrazine in alcoholic or ethereal solution; it separates from boiling alcohol in large, yellow crystals and melts at 120—121°. The *dicarbamide*, $\text{C}_{10}\text{H}_{11}\text{N}_4\text{O}_6$, is obtained as a crystalline residue when an alcoholic solution of carbamide and crude ethyl dihydroxytartrate is evaporated on the water-bath; it separates from boiling water in broad needles, melts at 245° with decomposition, and is only sparingly soluble in cold water; on hydrolysis with the theoretical quantity of sodium hydroxide, it is converted into a colourless, crystalline sodium salt of the composition $\text{C}_9\text{H}_9\text{N}_4\text{O}_6\text{Na}_2$.

Two compounds are formed when an alcoholic solution of ethyl dihydroxytartrate is evaporated with thiocarbamide; the one crystallises in long, slender needles melting above 100° with decomposition; the other forms yellow crystals and has the same percentage composition as thiohydantoin, from which, however, it differs in appearance.

A compound of the composition $\text{C}_{18}\text{H}_{14}\text{N}_4\text{O}_3$ is obtained in crystals when benzile is heated with carbamide at 170—175° for 3 to 5 hours; it does not decompose at temperatures below 260°, is almost insoluble in alcohol, chloroform, ether, and benzene, and has possibly the con-

stitution represented by the formula $\text{CO} < \begin{smallmatrix} \text{NH}\cdot\text{CPh}\cdot\text{NH} \\ | \\ \text{NH}\cdot\text{CPh}\cdot\text{NH} \end{smallmatrix} > \text{CO}$. When benzile and thiocarbamide are heated together at 145° in alcoholic solution, a crystalline compound of the composition $\text{C}_{18}\text{H}_{14}\text{N}_4\text{S}_2$ is obtained; this substance decomposes at 300°, and is very sparingly soluble in alcohol.

A compound of the composition $\text{C}_{17}\text{H}_{13}\text{N}_4\text{O}$, which is possibly $\alpha\beta$ -diphenyl- μ -amidoxazole, $\begin{smallmatrix} \text{CPh}\cdot\text{N} \\ || \\ \text{CPh}\cdot\text{O} \end{smallmatrix} \Rightarrow \text{C}\cdot\text{NH}_2$, is formed when benzoin (1 mol.) is heated with carbamide at 165° in alcoholic solution for 3—4 hours (compare Hubacher, this vol., p. 222). It crystallises from hot alcohol, in which it is only moderately easily soluble, in colourless needles, and does not decompose at 260°. Thiocarbamide combines with benzoin under the same conditions, yielding a crystalline com-

pound which decomposes above 220° , is only sparingly soluble in alcohol, and has the composition $C_{11}H_{12}N_2S$. F. S. K.

Action of Carbamide on Benzile. By A. ANGELI (*Ber.*, 24, 606).—The condensation compound of carbamide and benzile described by R. Anschütz and H. Geldermann (preceding abstract) has been previously prepared by the author (*Abstr.*, 1890, 1290). The behaviour of tolanecarbamide (diphenylacetylenodiureino) towards acetic anhydride is best explained by the formula $CO < \begin{smallmatrix} NH \cdot CPh \cdot NH \\ NH \cdot CPh \cdot NH \end{smallmatrix} > CO$.

J. B. T.

Action of Nascent Hydrogen on β -Benzilemonoxime. By C. U. ZANETTI (*Gazzetta*, 20, 687—692).—Polonowski (*Abstr.*, 1888, 485) found that the product of the reduction of an alcoholic solution of β -benzilemonoxime with sodium amalgam and acetic acid is diphenylhydroxyethylamine, $OH \cdot CPh \cdot CPh \cdot NH_2$, melting at 161° ; Braun and Meyer (1888, 700) found that a solution of β -benziloxime in soda, when treated with sodium amalgam, yields tetramethylaldine, $CPh \cdot N \cdot CPh$, melting at 245 — 246° , and Braun (*Abstr.*, 1889, 613) obtained the base desylamine, $COPh \cdot CPh \cdot NH_2$, by reducing it with hydrochloric acid and stannous chloride. The author finds that when a solution of β -benziloxime in absolute alcohol is treated with metallic sodium, the product consists of an impure, uncrystallisable, semi-solid mass, which may be obtained from its hydrochloride in a purer form, crystallising from dilute alcohol in white flakes melting at 158 — 160° , and from boiling benzene as a white powder melting at 165° . It has the same composition as diphenylhydroxyethylamine; and even after prolonged boiling with hydroxylamine hydrochloride and sodium carbonate, it nearly all crystallises out unchanged on cooling, traces only of an alkaline oil passing into solution. It is almost insoluble in water, very sparingly soluble in ether, moderately in boiling benzene, and freely in alcohol. The hydrochloride prepared from the pure product crystallises in long, white needles, and melts at 210° with decomposition. The picrate is a yellow, crystalline compound which softens and turns brown at 175° , and melts with decomposition at 178 — 179° . The platinochloride, $(C_{11}H_{12}NO)_2 \cdot H_2PtCl_6$, crystallises in brilliant, hexagonal plates which become anhydrous at 100° , soften at 180° , and melt with decomposition at 185 — 186° .

β -Benziloxime, when reduced in this manner, thus yields principally diphenylhydroxyethylamine and, perhaps, traces of desylamine, but no tetramethylaldine is formed. S. B. A. A.

Reduction of Acetylorthonitrobenzylparatoluidine and of Benzoylorthonitrobenzylaniline. By E. LELLMANN (*Ber.*, 24, 718).—Lellman and Stickel obtained two compounds by the reduction of acetylorthonitrobenzylparatoluidine and of benzoylorthonitrobenzylaniline, which they regarded as paratolylbenzenylethylamine and phenylbenzylenebenzenylamine respectively (*Abstr.*, 1886, 793). Söderbaum and Widman have found that these compounds are, in

reality, orthamidobenzylparatoluidine and benzoylorthamidobenzylaniline (Abstr., 1890, 1258), and the author has, on re-examination of the compounds, been able to confirm this result. The first conclusion was brought about by an error in Stickel's analyses of the compounds. H. G. C.

Dyes of the Triphenylmethane Group. By E. NOELTING (*Ber.*, 24, 553—563).—The author has shown that triamidotriphenylmethane derivatives in which a methyl group occupies an ortho-position to the fundamental carbon atom yield dyes on oxidation (*Ber.*, 22, 2573). He now finds that the corresponding diamidotriphenylmethane derivatives also yield dyes on oxidation.

Paranitrodimethyldiamidodiphenyltolylmethane,

is prepared by heating a mixture of paranitrodimethylamidobenzhydrol (26 grams), metatoluidine (20 grams), concentrated hydrochloric acid (40 grams), and water (40 grams) for some hours on the water-bath. The base crystallises from alcohol in yellow needles, melts at 169°, and is insoluble in water, sparingly soluble in alcohol, more soluble in benzene. The *hydrochloride* crystallises from water, in which it is easily soluble, in white leaflets. On oxidation in hot alcoholic acetic acid solution with chloranil, or in cold aqueous acetic acid with lead peroxide, it yields a beautiful, yellowish-green dye which dyes silk, wool, and cotton mordanted with tannin as easily as malachite-green, and is faster to soap than the latter. The author draws attention to the production of greens from dimethylated diamidotriphenylmethane derivatives, whilst non-methylated diamidodiphenylmethane on oxidation yields a violet dye. Paranitrodimethyldiamidotriphenylmethane also yields a green dye. The *acetyl* compound of the above leuco-base is not oxidised by lead peroxide; when treated with chloranil, however, it yields a dye which imparts an orange-red colour to cotton. The colour is similar to that from dimethylmonamidotriphenylmethane. If the acetyl group be eliminated, the colour becomes green.

Dimethyltriamidodiphenyltolylmethane is obtained from the nitro-base by reduction with tin and hydrochloric acid, or with zinc-dust and acetic acid, and crystallises from a mixture of ether and light petroleum in white needles which become violet on exposure to air. On oxidation, it yields a reddish-violet dye. The *diacetyl* compound is obtained by boiling with acetic anhydride; it crystallises from alcohol in white needles, melts at 130°, and yields a dye which imparts a violet-red colour to cotton mordanted with tannin; on eliminating the acetyl groups, the colour is changed to violet.

Paranitrotetramethyldiamidodiphenyltolylmethane is obtained by heating a mixture of nitrodimethylamidobenzhydrol (6 grams), dimethylmetatoluidine (15 grams), hydrochloric acid (10 grams), and water (20 grams) for 10 hours on the water-bath. It crystallises from ether in beautiful, yellow leaflets, melts at 193°, is easily soluble in alcohol and benzene, and on oxidation gives a beautiful yellowish-

green. The *amido*-base, obtained from the *nitro*-base by reduction, yields a violet dye which rivals methyl-violet in shade.

Paranitrodimethyldiethyldiamidodiphenyltolylmethane, obtained in a similar way to the tetramethyl derivative, crystallises from alcohol in beautiful, yellow needles, and melts at 165—166°. Both the *nitro*-base and the *amido*-base, obtained from it on reduction, easily yield dyes on oxidation: the former giving a green, the latter a violet dye.

In the succeeding part of the paper, the author shows that *diamido*- and *triamido*-triphenylmethane derivatives, in which two methyl groups are in the *ortho*-position to the fundamental carbon atom, easily yield dyes on oxidation.

Tetramethyldiamidophenylditolylmethane, prepared from benzaldehyde and dimethylmetatoluidine according to the method described by Riedel, crystallises well from light petroleum and alcohol, melts at 123°, and yields a dye which colours cotton an intense green.

Paranitrotetramethyldiamidophenylditolylmethane is best prepared by heating a mixture of paranitrobenzaldehyde (12 grams), absolute alcohol (25 grams), dimethylmetatoluidine (25 grams), and concentrated sulphuric acid (15 grams) for 20 hours on the water-bath. It crystallises from a mixture of alcohol and benzene in yellow needles, melts at 224°, is sparingly soluble in alcohol, and yields a green dye resembling malachite-green.

Tetramethyltriamidophenylditolylmethane is obtained as described by Kock (Abstr., 1887, 836), and melts at 140°. On oxidation with lead peroxide and acetic acid, a dye is obtained which colours cotton, silk, and wool an intense violet: when oxidised with chloranil in dilute solution, no dye is formed, but in concentrated alcoholic acetic acid the above violet dye is obtained. The *acetyl* compound gives a green dye which, on elimination of the *acetyl* group, changes to violet.

Paranitrotetrayldiamidophenylditolylmethane, prepared in a similar way to the tetramethyl compound, crystallises from alcohol in yellow needles, melts at 155°, and yields a green dye. The *amido*-compound yields a violet dye.

Metanitrotetramethyldiamidophenylditolylmethane, prepared in a similar way to the *para*-compound, crystallises in small yellow needles, melts at 170°, is easily soluble in alcohol, ether, and benzene, and yields a green dye possessing remarkable fastness to soap. The *triamido*-compound, obtained by reduction of the above, crystallises in white needles, melts at 131°, and also yields a green dye.

Orthonitrotetramethyldiamidophenylditolylmethane, prepared in a similar way to the *para*-compound, crystallises from a mixture of benzene and light petroleum in yellow needles, melts at 146°, and yields a bluish-green dye. The *triamido*-compound is very unstable, and could not be oxidised. The *acetyl* compound, obtained from the hydrochloride of the *triamido*-base, yields on oxidation a green dye.

Hexamethyltriamidophenylditolylmethane, obtained in a similar way to the above compounds, is very soluble in all solvents, and is best purified by converting it into the *picrate*, which is obtained in beautiful, yellow needles on adding *picric acid* to a solution of the base in hot alcohol. The base, on oxidation, yields a beautiful violet which is of a bluer shade than crystal-violet.

Hexamethyltriamidotritolylmethane is prepared by heating a mixture of ethyl orthoformate (4 grams), dimethylmetatoluidine (12 grams), and zinc chloride (10 grams) for some hours on the water-bath. It crystallises from alcohol in small, white needles and melts at 190—191°. The salts of the base are easily soluble. On oxidation, it yields a beautiful, blue dye which dyes silk, wool, and cotton mordanted with tannin very well, and rivals crystal-violet in richness. The same dye is obtained by heating dimethylmetatoluidine and aluminium chloride with a solution of carbon oxychloride in toluene.

Hexamethyltriamidotrixylylmethane, $\text{CH}(\text{C}_6\text{H}_2\text{Me}_2\text{NMe})_3$, prepared in a similar way to the preceding compound, crystallises from alcohol in long, white needles, melts at 134—135°, and yields a green dye.

Hence the introduction of three methyl groups in the meta-position changes the violet colour of hexamethylrosaniline into blue, and of six methyl groups into green. E. C. R.

Naphthylglycollic Acid and β -Naphthyl Methyl Ketone. By R. SCHWEITZER (*Ber.*, 24, 546—549).—Both α -naphthyl methyl ketone and β -naphthyl methyl ketone are formed by the action of acetic chloride on naphthalene dissolved in carbon bisulphide in the presence of aluminium chloride. The β -compound is filtered from the α -compound and recrystallised from light petroleum. It melts at 54° and boils at 306° (Claus and Fersteegen give 51·5—52° and 301—303°). The α -compound cannot be obtained in a pure condition from the mother liquors.

β -Naphthyl methyl ketone dibromide, $\text{C}_{10}\text{H}_7\text{CO}\cdot\text{CHBr}_2$, is obtained by the action of bromine on β -naphthyl methyl ketone dissolved in carbon bisulphide, and melts at 101°.

β -Naphthylglycollic acid, $\text{C}_{10}\text{H}_7\text{CH}(\text{OH})\cdot\text{COOH}$, is obtained by allowing the above dibromide to remain in contact with aqueous potash (1:10) in the cold for 8—14 days. It melts at 158° (Claus and Fersteegen, 176°), is sparingly soluble in light petroleum and ether, more soluble in hot water, and easily soluble in acetic acid and hot alcohol. By oxidation with potassium permanganate, β -naphthaldehyde and β -naphthoic acid are formed. On sublimation, no pure product could be obtained. The *silver* salt is insoluble in cold or hot water. The *calcium* and *magnesium* salts are sparingly soluble. The *ethyl* salt crystallises from light petroleum in tufts of needles, and melts at 87°. The *methyl* salt crystallises from alcohol in needles and melts at 75°. The acid is more readily obtained by brominating the mixed ketones, treating with potash, and converting into barium salts. On crystallising the barium salts from a large quantity of hot water, only the β -salt separates on cooling; and by decomposing this the acid is obtained quite pure.

β -Acetylnaphthylglycollic acid is formed by dissolving naphthylglycollic acid in acetic anhydride and crystallising the product from dilute acetic acid. It melts at 150° (uncorr.).

β -Naphthylglycolamide separates from an ammoniacal alcoholic solution of the ethyl salt when it is allowed to remain for 8—14 days. It crystallises from absolute alcohol in plates and melts at 227—228°.

β -Naphthylacetic acid, $C_{10}H_7 \cdot CH_2 \cdot COOH$, is obtained by reducing naphthylglycollic acid with hydrogen iodide; it crystallises from water in plates and melts at 141° . The *methyl* and *ethyl* salts form needles which melt at the temperature of the hand, and have an odour resembling that of acetic acid. The *barium* salt crystallises from water in plates.

α -Naphthylglycollic acid is obtained from the mother liquors of the barium salt of the β -compound when the latter is prepared from the mixed ketones. The acid so obtained is converted into the *methyl* salt and this is extracted by shaking with petroleum, when only the α -compound dissolves. The latter crystallises in microscopic needles and melts at 79° (uncorr.). The ethereal salt is treated with alcoholic caustic soda and the resulting sodium salt decomposed with hydrochloric acid and the acid recrystallised from water. It melts at 91 – 93° (uncorr.), and on oxidation with dilute nitric acid yields α -naphthaldehyde. The *barium* salt is easily soluble in water. The *ethyl* salt is an oil. W. C. R.

β -Isoamyl-naphthalene. By G. ODINO and E. BARABINI (*Gazzetta*, 20, 719–720).—The isoamyl-naphthalene obtained by Roux (Abstr., 1884, 1357) by the action of aluminium chloride on naphthalene and amyl bromide, has now been prepared by the authors from β -bromonaphthalene by treating it with sodium and isoamyl bromide according to Fittig and Tollens' method. The product boils between 289 – 292° , has the composition $C_{15}H_{18}$, and forms a *picrate* extremely soluble in alcohol, which crystallises in slender needles and melts at 108 – 110° . S. B. A. A.

Derivatives of Chrysene. By R. ARREGG (*Ber.*, 24, 940–958).—The amidochrysene previously described by the author (Abstr., 1890, 789) is identical with the compound obtained by Bamberger and Burgdorf (Abstr., 1890, 1312), the difference of 3° in the melting point being probably due to variations in the thermometers employed. Amidochrysene may be readily converted into other derivatives containing the radicle $C_{18}H_{11}$, for which the author proposes the term *chrysyl*.

Benzoylamidochrysene, $C_{18}H_{11} \cdot NHBz$, is obtained by the action of benzoic chloride and aqueous soda on amidochrysene; it is a yellowish-brown substance, melts at 248° , and is moderately soluble in cold benzene and toluene, readily in the hot liquids and in cumene. *Ethyl chrysylcarbamate*, $C_{18}H_{11} \cdot NH \cdot COOEt$, is obtained in a similar manner by the action of ethyl chloroformate on amidochrysene, and is a white, crystalline compound melting at 214° . By the action of carbonyl chloride on amidochrysene in toluene solution, a substance is obtained which is insoluble in all ordinary solvents and could not be prepared in a pure condition; it is probably *dichrysylcarbamide* or *chrysyl-carbimide*.

Acetamidochrysene or *chrysylacetamide*, $C_{18}H_{11} \cdot NHAc$, is prepared by heating amidochrysene with acetic acid and some acetic anhydride; it crystallises from acetic acid or amyl alcohol in slender, greenish needles and melts at 285° . If acetic anhydride be employed alone,

diacetamidochrysene, $C_{18}H_{11}NAc_2$, is obtained; it closely resembles the monacetyl compound, but melts at $206-208^\circ$. The comparative facility with which both hydrogen atoms of the amido-group are substituted by acetyl is very remarkable.*

By the action of bromine-water on chrysylacetamide, it yields *bromochrysylacetamide*, $C_{18}H_{10}Br \cdot NHAc$; the latter separates from acetic acid in brown, seemingly amorphous flakes, which ball together at 180° without melting, and decompose at 215° . Fuming nitric acid dissolves chrysylacetamide, with formation of *dinitrochrysylacetamide*, $C_{18}H_9(NO_2)_2 \cdot NHAc$; the latter separates from light petroleum in amorphous plates, melts at 160° , and on heating with concentrated hydrochloric acid at 120° is converted into a glassy mass consisting of *dinitrochrysylamine hydrochloride*, $C_{18}H_9(NO_2)_2 \cdot NH_2 \cdot HCl$.

When chrysylacetamide or chrysylacetamide is heated with nitric acid of sp. gr. 1.25, nitrous fumes are evolved, and the nitrochrysoquinone, $C_{18}H_9O_2NO_2$, described by Bamberger and Burgdorf, formed (*loc. cit.*). It melts at 252° , and on treatment with hydriodic acid and phosphorus, yields *amidochrysoquinol hydriodide*, $C_{18}H_9(OH) \cdot NH_2 \cdot HI$, which readily passes into the corresponding *amidochrysoquinone salt*, $C_{18}H_9O_2 \cdot NH_2 \cdot HI$, mixed with some periodide. If chrysoquinone hydriodide is boiled with silver chloride and platinum chloride added, the *platinochloride*, $(C_{18}H_9O_2 \cdot NH_2)_2 \cdot H_2PtCl_6$, is formed. When nitrochrysoquinone is reduced with tin and hydrochloric acid, *amidochrysoquinone* is first formed, and is afterwards converted into *amidochrysoquinol hydrochloride*.

Chrysylthiocarbimide, $C_{18}H_{11} \cdot N \cdot CS$.—When *amidochrysene* is boiled with carbon bisulphide, it is simply dissolved, but if potash and sufficient alcohol for its solution be added, a greenish product remains on evaporating off the carbon bisulphide, from which hot water extracts potassium xanthate and sulphide; from the residuo, acetic acid extracts chrysylthiocarbimide. It crystallises in pale-green or brownish needles, melts at 176° , is readily soluble in acetic acid and carbon bisulphide, scarcely in alcohol, ether, and light petroleum. The residue insoluble in acetic acid is a greenish powder melting at 225° , and only soluble in hot benzene; it appears to be impure *dichrysylthiocarbimide*, $CS(NHC_{18}H_{11})_2$. *Monochrysylthiocarbimide*, $C_{18}H_{11} \cdot NH \cdot CS \cdot NH_2$, is prepared by the action of ammonia on a benzene solution of chrysylthiocarbimide; it forms almost white crystals and melts at 238° with decomposition. The crystals contain 1 mol. benzene of crystallisation, which is not evolved at 100° . From a toluene solution, crystals are obtained also melting at 238° , but free from toluene, and if phenylcarbimide be prepared in benzene solution, it is also free from benzene. *Methylchrysylthiocarbimide*, $C_{18}H_{11} \cdot NH \cdot CS \cdot NHMe$, formed by the action of methylamine on a benzene solution of chrysylthiocarbimide, melts at 231° , and also contains no benzene of crystallisation. *Phenylchrysylthiocarbimide*, $C_{18}H_{11} \cdot NH \cdot CS \cdot NHPh$, is prepared by treating a benzene solution of *amidochrysene* or chrysylthiocarbimide with the calculated quantity of phenylthiocarbimide or aniline respectively, and separates

* *Note by Abstractor.*—Amidoacennaphthene behaves in a similar manner when heated with acetic anhydride (*Ber.*, 21, 1458).

after 1—3 days in yellowish-white crystals melting at 186° . It is, however, only formed from solutions of chrysyl derivatives; if chrysylamine and phenylthiocarbamide are heated together alone, chrysylthiocarbimide and aniline are formed, the latter at once combining with part of the phenylcarbimide, with formation of diphenylcarbamide. H. G. C.

Formation of an Asphalt-like Substance from Oil of Cassia. By E. HIRSCHSOHN (*Chem. Centr.*, 1891, i, 87—88; from *Pharm. Zeit. Russ.*, 29, 692—695).—When oil of cassia was heated for four hours at 260 — 280° , it became dark-coloured and lost 12 per cent. of its weight; when the heating was continued up to 355° during six hours, a further loss of 7 per cent. was experienced, and the distillate amounted to 16 per cent. The flask, covered with glass wool and asbestos, was now heated for six hours, when 15 per cent. more distillate was obtained, and it was finally heated for six hours longer. The residue remaining amounted in one case to 54 per cent., and in a second to 60 per cent. of the original oil. The distillates contained a substance similar to xylone, acetic acid, and phenol. The residue in the retort was a black solid, and could be readily reduced to a strongly electrical powder; it smelt like asphalt and behaved with solvents similarly to Trinidad asphalt or artificial asphalt. The author suggests that these observations on oil of cassia explain to some extent the formation of asphalt in nature, possibly brought about by superheating resins and ethereal oils under pressure.

J. W. L.

Pyridine Compounds. By R. VARET (*Compt. rend.*, 112, 390—392).—When finely divided and dry cadmium bromide is added to pyridine, heat is developed and a white paste is formed. Excess of pyridine is then added and the mixture is heated on a water-bath for two hours, and allowed to cool with occasional agitation. After some time, the amorphous precipitate changes into a crystalline precipitate, which is rapidly dried between filter paper. The product consists of small, brilliant, white crystals of the composition $\text{CdBr}_2 \cdot 6\text{C}_5\text{NH}_5$. It is only slightly soluble in pyridine; boiling water converts it into a curdy precipitate which completely dissolves, and on cooling, long needles of a different compound of cadmium bromide and pyridine separate. The compound $\text{CdBr}_2 \cdot 6\text{C}_5\text{NH}_5$ loses all its pyridine when heated.

Silver cyanide under similar conditions yields transparent, acicular prisms of the compound $\text{AgCy} \cdot \text{C}_5\text{NH}_5$, slightly soluble in pyridine and decomposed by water. When exposed to air, the crystals become opaque, and then brown, and at 110° they lose the whole of their pyridine.

Mercuric cyanide yields granular, transparent crystals of the compound $\text{HgCy}_2 \cdot 2\text{C}_5\text{NH}_5$, very soluble in pyridine, especially on heating. They lose their pyridine at 110° .

Cuprous cyanide yields large, yellow lamellæ of the composition $\text{Cu}_2\text{Cy}_2 \cdot 4\text{C}_5\text{NH}_5$, very soluble in warm pyridine. When exposed to the air, it evolves pyridine and it loses the whole of this substance at a temperature below that at which cuprous cyanide decomposes.

Cuprous iodide yields small, yellow crystals of the compound $\text{Cu}_2\text{I}_2 \cdot 2\text{C}_5\text{NH}_5$, very soluble in hot pyridine, less soluble in the cold. When treated with 10 vols. of ether, it becomes white, but does not lose all its pyridine even after several days. When exposed to air, it becomes green, then brown, and when heated, it loses the whole of its pyridine.

C. H. B.

Non-nitrogenous Acids derived from Pyridinecarboxylic Acids. By H. WEIDEL (*Monatsb.*, 11, 501—525).—The author has previously (*Sitzber. k. k. Akad. Wien*, 1874, 239; 1879, 460) investigated the action of sodium amalgam on cinchomeronic acid, whereby ammonia and cinchonic acid, $\text{C}_7\text{H}_7\text{O}_6$, are obtained. When distilled, the last-named compound loses water and carbonic anhydride, forming the anhydride of dimethylfumaryl acid (pyrocinchonic anhydride), a substance which takes up water and hydrogen to form an acid isomeric with adipic acid, and melting at 182° . In order to determine the constitution of cinchonic acid and other non-nitrogenous acids formed under similar conditions, the author has fully studied the products derived from the three pyridinecarboxylic acids by the action of sodium amalgam, and finds that these acids are almost quantitatively converted into saturated bibasic hydroxy-acids, according to the equation $\text{C}_6\text{H}_5\text{NO}_2 + \text{H}_2 + 3\text{H}_2\text{O} = \text{C}_6\text{H}_{10}\text{O}_6 + \text{NH}_3$. The three hydroxy-acids are derived from three isomeric adipic acids, and, since they have the hydroxyl group in the δ -position relatively to one of the carboxyl groups, are partially, with loss of water, converted into lactonic acids. The products of the action of sodium amalgam on the carboxylic acids consist, in fact, of the hydroxy-acids and the corresponding lactonic acids.

Products from Nicotinic Acid.—Nicotinic acid (40 grams) was dissolved in water (800 c.c.) containing potash (200 grams), and the resulting solution heated to the boiling point and treated with 4 per. cent. sodium amalgam, added little by little until no more ammonia was evolved, the operation lasting 3—4 hours. The product was made slightly acid with hydrochloric acid, evaporated to dryness, and exhausted with alcohol, the extract again evaporated and freed from potassium chloride and a resinous, nitrogenous substance by solution in absolute alcohol and addition of ether. The almost colourless, syrupy acid obtained on evaporation of the ethereal alcoholic solution, which crystallised only after some months, was dissolved in three times its weight of absolute alcohol, saturated with hydrogen chloride, and the product repeatedly fractionated under a reduced pressure of 60 mm., whereby two distinct fractions were obtained, one boiling at 184° (60 mm.), the other at 245 — 247° (56 mm.). The fraction of lower boiling point proved to be diethyl chloroglutarate, $\text{C}_4\text{H}_7\text{Cl}(\text{COOEt})_2$, since sodium amalgam reduced it to α -methylglutaric acid, $\text{COOH} \cdot \text{CHMe} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{COOH}$, which melts at 75.7° (Wislicenus and Limpach, *Annalen*, 192, 134). The fraction of higher boiling point was a colourless, syrupy liquid, having a bitter, burning taste. On analysis, it gave numbers corresponding with the formula $\text{C}_6\text{H}_{14}\text{O}_4$; when saponified with baryta-water, it furnished the salt $\text{C}_6\text{BaH}_4\text{O}_6$, and on treatment with phosphorus diiodide and water was converted into an iodo-acid, which, on

reduction with zinc and sulphuric acid, also gave α -methylglutaric acid. Both the compounds $C_6H_7Cl(COOEt)_2$ and $C_8H_{11}O_4$ consequently give rise to a (γ - or δ -) hydroxy- α -methylglutaric acid, $C_8H_{10}O_5$, capable of furnishing the lactone $C_6H_8O_4$. The original non-nitrogenous products derived from nicotinic acid must, therefore, be regarded as a mixture of hydroxy- α -methylglutaric acid and the corresponding lactone, and their behaviour makes it probable that the hydroxyl group occupies the δ -position relatively to the carboxyl group. This view is confirmed by the formation of piperidone when chloro- α -methylglutaric acid is treated with potassium phthalimide, and the resulting product treated with hydrochloric acid, and by the fact that the original reduction product on dry distillation furnishes a mixture of a dibasic acid, $C_6H_8O_4 + H_2O$, melting at 133.5° , which is easily reduced to methylglutaric acid and an oil, most probably γ -valerolactone, boiling at $222-226^\circ$ (56 mm.). The formation of δ -hydroxy- α -methylglutaric acid from nicotinic acid is explained by

supposing that the nicotinic acid, $\begin{array}{c} CH:CH:C-COOH \\ | \\ OH=N-CH \end{array}$, first of all takes

up two atoms of hydrogen, the linkage shifting, $\begin{array}{c} CH-CH_2:C-COOH \\ | \\ CH-NH-CH \end{array}$;

the dihydro-compound then reacts with 1 mol. of water, oxygen is substituted for imidogen, and ammonia evolved, $\begin{array}{c} CH-CH_2:C-COOH \\ | \\ CH-O-CH \end{array}$.

By the addition of another molecule of water, the closed chain is then broken, and the compound $OH\cdot CH\cdot CH\cdot CH_2\cdot C(COOH)\cdot CH\cdot OH$ formed, and this in its turn by assimilation, loss, and further assimilation of water, gives rise to the compounds

respectively.

Products from Isonicotinic Acid.—Isonicotinic acid (pyridine- γ -carboxylic acid) is more readily acted on by sodium amalgam than is nicotinic acid. On treating the product with alcohol and hydrochloric acid and distilling, two fractions were obtained; the one, boiling at $188-191^\circ$ (63 mm.), has the formula $C_{10}H_{17}ClO_4$, and is converted by water at 100° into the acid originally present in the reduction product; the other, boiling at $240-244^\circ$ (63 mm.), has the formula $C_8H_{13}O_4$, is converted by baryta-water into the non-crystalline barium salt, $C_6H_8BaO_4$, and gives, on treatment with phosphorus diiodide and water, a readily soluble iodoethylsuccinic acid which melts at 152° , and is reduced by zinc and sulphuric acid to Huggenborg's ethylsuccinic acid (m. p. 38.7°).

Products from Picolinic Acid.—Picolinic acid (pyridine- α -carboxylic acid) is as readily reduced as isonicotinic acid, and gives what is most probably δ -hydroxyadipic acid, $COOH\cdot[CH_2]_3\cdot CH(OH)\cdot COOH$. On treating the syrupy reduction product with phosphorus diiodide, adipic acid, melting at 151° and agreeing in the crystallographic

characteristics of its ammonium salt with Arppe's acid melting at 148—149° (*Annalen*, **149**, 220), was formed. G. T. M.

Piperylbiquanide. By E. BAMBERGER (*Ber.*, **24**, 605).—Dicyanodiamide combines with piperidine at the ordinary temperature to form *piperylbiquanide*, $\text{NH}_2\text{C}(\text{NH})\cdot\text{NH}\cdot\text{C}(\text{NH})\cdot\text{C}_6\text{H}_{10}$; this crystallises readily, and yields a characteristic *cupro-derivative*, which is deposited in rose-coloured needles. J. B. T.

Piperidinecarboxylic Acids. By A. LADENBURG (*Ber.*, **24**, 640—643).— α -Piperidinecarboxylic acid (pipecolinic acid), $\text{C}_6\text{H}_{11}\text{NO}_2$, can be obtained by reducing picolinic acid; it is isolated in the form of the hydrochloride, $\text{C}_6\text{H}_{11}\text{NO}_2\cdot\text{HCl}$. This salt separates from very dilute hydrochloric acid in small, nodular crystals, melts at 264°, and is soluble in alcohol. It has been previously obtained by Ost (Abstr., 1883, 791), but only in an impure condition. α -Piperidinecarboxylic acid is most easily obtained in the free state by decomposing the sulphate with the theoretical quantity of barium hydroxide; it separates from alcohol in crystals, is readily soluble in water, and forms a blue, readily soluble copper salt. The *platinochloride* forms large, monoclinic crystals, $a : b : c = 1.2880 : 1 : 1.0902$; $\beta = 66^\circ 37'$, and melts at 184°. The *aurochloride* is readily soluble, and is decomposed when boiled with water with evolution of carbonic anhydride.

Methyl α -piperidinecarboxylate hydrochloride, $\text{C}_7\text{H}_{13}\text{NO}_2\cdot\text{HCl}$, prepared by passing hydrogen chloride into a methyl alcoholic solution of the acid, crystallises from alcohol in small, colourless needles, melts at 191° with decomposition, and is readily soluble in water, but more sparingly in alcohol. The *platinochloride*, $(\text{C}_7\text{H}_{13}\text{NO}_2)_2\cdot\text{H}_2\text{PtCl}_6$, forms well-defined prisms; the *aurochloride* is readily soluble. When a solution of the hydrochloride of the methyl salt is treated with potassium nitrite, the *nitroso-derivative*, $\text{C}_7\text{H}_{13}\text{NO}_2\cdot\text{NO}$, is deposited as an oil.

Hexahydronicotinic acid (pipecolinic acid) hydrochloride,

forms small crystals and melts at 235°; the *platinochloride* crystallises well and melts at 210—212°. F. S. K.

Piperazine. By A. BISCHLER (*Ber.*, **24**, 716—718).—Paradinitrosodiphenylpiperazine is acted on by alkalis in the same way as nitrosodimethylaniline, &c., piperazine and in all probability nitrosophenol being formed. To carry out the reaction, paradinitrosodiphenylpiperazine is boiled with aqueous potash and a little alcohol; it dissolves after a time, and the alcohol is then distilled off, more potash added, and the product distilled until only small quantities of liquid pass over. The alkaline distillate is treated with hydrochloric acid, and the piperazine hydrochloride purified by precipitation from its aqueous solution with absolute alcohol; it is thus obtained in snow-white, matted needles having the composition $\text{C}_4\text{H}_{10}\text{N}_2\cdot 2\text{HCl} + \text{H}_2\text{O}$. The *platinochloride*, $\text{C}_4\text{H}_{10}\text{N}_2\cdot\text{H}_2\text{PtCl}_6$, forms yellow, four-sided plates, and the *dibenzoyl* compound crystallises in transparent, rhomboïdal crystals, and melts at 190°. H. G. G.

1-Methyl-3-diphenyl-4.5-diphenylpyrrolone. By F. KLINGMANN (*Ber.*, 24, 516—519).—1-Methyl-3-diphenyl-4.5-diphenylpyrrolone is obtained when the methylanide of benzoyltriphenylpropionic acid is boiled with alcoholic potash and the solution precipitated with water. It crystallises from acetic acid in beautiful, yellow crystals, and melts at 159°. These crystals contain a small quantity of the unaltered methylanide, which can be separated by recrystallisation from carbon bisulphide. The product crystallises from alcohol in small, yellow plates. It was obtained in measurable crystals from ethyl acetate, as also was the product from dibenzoylstilbene and methylamine, and that from benzoyltriphenylpropiomethylamide, by distillation (*Trans.*, 1891, 146). These three compounds are crystallographically identical. The crystals belong to the monosymmetric system, $a : b : c = 0.79308 : 1 : 0.92709$; $\beta = 89^\circ 41'$. A full description of the crystals is given in the paper. The author points out that the action of alcoholic potash on benzoyltriphenylpropiomethylamide is similar to the action of alkalis on methylhydrastamide.

E. C. R.

Substituted Ammonium Compounds. By H. DECKER (*Ber.*, 24, 690—692).—The action of alkalis on the compounds of quinoline derivatives with the alkyl haloids has been frequently examined, but the results are not concordant; the author has, therefore, repeated the experiments on a wider basis, employing the methiodides or ethiodides of 22 derivatives of quinoline, isoquinoline, and acridine. He finds that the first action of alkalis is to convert the compounds into the corresponding ammonium hydroxides, which, however, can only be isolated in certain cases, owing to further reactions taking place. Only α -nitro- γ -bromoquinolinium hydroxide and methylphenylacridinium hydroxide have been obtained in the crystalline condition.

These hydroxides readily pass into the corresponding ethoxy-compounds when gently warmed with alcohol, and also oxidise rapidly in the air or when treated with alkaline potassium ferricyanide, yielding well-crystallised substances with a strong lustre, which melt about 100° higher than the parent substances. They are formed from the ammonium hydroxide by the loss of two atoms of hydrogen, and are identical with the lactam-ethers. Thus, with γ -bromoquinoline, the reaction proceeds as follows:—

Acridine also yields a new base, in which the oxygen atom probably occupies the meso-position, but phenylacridinium hydroxide is not attacked by potassium ferricyanide.

H. G. C.

Juloles. By A. REINSETT (*Ber.*, 24, 841—856).—Ethyl acetate (10 grams) is heated with tetrahydroquinoline in molecular proportion for about two hours in a reflux apparatus; a pale-red, viscid liquid is formed which contains *acetoacetic tetrahydroquinolide*, $\text{CH}_2\text{Ac} \cdot \text{CO} \cdot \text{C}_6\text{NH}_{10}$. On treating this compound with sulphuric acid at low temperatures and neutralising with soda, a

compound is precipitated which crystallises from water or light petroleum in colourless, somewhat lustrous needles melting at $129\cdot8^{\circ}$ (corr.); it is readily soluble in concentrated mineral acids, and is recovered unchanged on dilution; it has the formula

and the author proposes to term it α_1 -keto- γ_1 -methyljuloline; the different positions in the rings are distinguished as follows:—

the addition of 2 atoms of hydrogen to juloline gives *julolidine*, whilst the compound with 2 atoms of hydrogen less is called *julole*. The above ketomethyljuloline forms salts with acids, does not yield a phenylhydrazone, and has no physiological action. The *hydrochloride*, $\text{C}_{13}\text{H}_{13}\text{NO} \cdot \text{HCl} + 1\frac{1}{2}\text{H}_2\text{O}$, is crystalline, and decomposes when heated at 100° . The *platinochloride* crystallises from concentrated hydrochloric acid in pale, orange-yellow needles, and blackens at about 200° . On treating the ketomethyljuloline with bromine in benzene solution, a dibromo-additive compound is formed, which is excessively unstable, and has not yet been isolated; by boiling with water, hydrogen bromide is eliminated, and β_1 -bromoketomethyljuloline is obtained, crystallising from hydrochloric acid in colourless, voluminous needles melting at $178\cdot5^{\circ}$ (corr.). A *dibromo-derivative* of the formula $\text{C}_{13}\text{H}_{11}\text{NOBr}_2$ is formed by heating the juloline with 2 mols. of bromine at 100° under pressure; it is deposited from absolute alcohol in small, hard, yellow, rhombic crystals, melts at 153° (corr.), and is insoluble in hot concentrated hydrochloric acid.

Nitrous acid appears to have no action on ketomethyljuloline, whilst nitric acid only acts in presence of concentrated sulphuric acid; two isomeric *nitro-substitution* products of the formula $\text{C}_{13}\text{H}_{13}\text{NO} \cdot \text{NO}$, are formed; the first crystallises from glacial acetic acid in pale-yellow needles, melts at $223\cdot8^{\circ}$ (corr.), and is sparingly soluble in alcohol. The isomeric derivative is contained in the mother liquors, crystallises from dilute alcohol in small, yellow needles, and melts at $149\cdot1^{\circ}$ (corr.).

The oxidation of the ketomethyljuloline is best accomplished by dissolving it in dilute sulphuric acid, and adding 4·5 parts of potassium permanganate dissolved in hot water; as soon as the addition is completed, the solution is rapidly boiled and filtered; on cooling, α -hydroxylepidine-1-carboxylic acid is deposited; it crystallises from dilute alcohol in small, colourless needles, melts at $812\cdot4^{\circ}$ (corr.), and is insoluble in benzene, light petroleum, ether, and chloroform. Two other acids are also formed in small quantity during the oxidation; the one is insoluble in ammonia, crystallises from dilute acetic acid,

and melts at 245°. The second acid is separated from the lepidino-carboxylic acid by treatment of the aqueous solution with ether, melts at about 230°, and is free from nitrogen.

Silver hydroxylepidinecarboxylate, $C_{11}H_8NO_3Ag$, is the most characteristic salt; it is crystalline and very sparingly soluble, and on distillation yields α -hydroxylepidino. It thus appears that the action of tetrahydroquinoline on ethyl acetonedicarboxylate is precisely analogous to that of aniline.

J. B. T.

Action of Nitrous Acid on Ethyl Acetonedicarboxylate.

By H. v. PECHMANN (*Ber.*, 24, 857—867).—Ethyl acetonedicarboxylate is treated with 10—15 drops of alcoholic hydrochloric acid and amyl nitrite in molecular proportion; after remaining for an hour at the ordinary temperature, the liquid is heated on the water-bath, dissolved in sodium carbonate solution, the amyl alcohol removed, and the residue, after acidifying, extracted with ether; after the removal of the ether by evaporation, a yellow, viscid, undistillable liquid is obtained consisting of *ethyl nitrosoacetonedicarboxylate*,

By the action of nitrous acid on this nitroso-compound, or by treating ethyl acetonedicarboxylate with amyl nitrite (3 mols.), *ethyl hydroxyisoxazoledicarboxylate*, $COOEt \cdot C \begin{smallmatrix} \diagup C(OH) \\ \diagdown N-O \end{smallmatrix} \cdot C \cdot COOEt$, is formed, which crystallises from dilute alcohol in long, silky, lustrous, concentric needles, and melts at 104—105°; the yield is 75 per cent. of theory. The reaction which takes place is probably represented by the equation $C_8H_{14}O_6 + 3HNO_2 = C_8H_{11}NO_6 + 3H_2O + 2NO$. In small quantities the isoxazole may be distilled without decomposition; ferric chloride gives a red coloration, alkalis and alkaline carbonates a yellow one, but on testing with phenol and sulphuric acid, the isonitroso-reaction is not observed; by the action of phosphorus pentachloride, an uncrystallisable compound is formed, from which the isoxazole is regenerated on the addition of water; sodium amalgam causes the production of substances which are difficult to isolate, and have strong reducing properties. The *acetyl derivative*,

is obtained by the action of acetic anhydride; it crystallises from dilute alcohol in lustrous needles, and melts at 42°.

Hydroxyisoxazoledicarboxylic acid, $COOH \cdot C \begin{smallmatrix} \diagup C(OH) \\ \diagdown N-O \end{smallmatrix} \cdot C \cdot COOH$, is prepared by the hydrolysis of the ethereal salt with soda; it crystallises from water with 2 mols. H_2O in prisms, becomes brown at about 145°, and melts at 183—184° or at 176—177°, according to whether the heating is done quickly or slowly. The *trisodium salt* is readily soluble in water, and crystallises in yellow needles; the *disodium salt* crystallises in colourless plates, and is formed by the addition of acetic acid to the trisodium derivative; the *monosodium salt*, $C_8H_7NaNO_6 + 2H_2O$, is obtained by treating the trisodium salt with

hydrochloric acid, and crystallises in aggregates of small needles. The *silver salt*, $C_6H_4Ag_2NO_6$, is crystalline.

Methoxyisoxazoledicarboxylic acid, $COOH \cdot C \begin{smallmatrix} \diagup C(OMe) \\ \diagdown N \end{smallmatrix} \begin{smallmatrix} \diagdown O \\ \diagup \end{smallmatrix} > C \cdot COOH + H_2O$, crystallises from a mixture of ethyl acetate and light petroleum in small, colourless needles, and melts at $157-158^\circ$ with previous softening at $90-100^\circ$. The *diethyl salt* melts at 81° , and boils at $200-210^\circ$ under a pressure of 40 mm. The *sodium salt*, $C_6H_4NO_4Na + 2H_2O$, is deposited from water, in which it is sparingly soluble, in long, lustrous crystals. The *silver salt*, $C_6H_4NO_4Ag_2$, explodes on heating.

Ethyl isoxazoledicarboxylate is oxidised by the action of concentrated nitric acid or of bromine, hydrogen cyanide being evolved in considerable quantity; on treating the product with phenylhydrazine, *ethyl phenylhydrazonemesoxalate*, $COOH \cdot C(N_2HPh) \cdot COOEt$, is formed; this crystallises from alcohol in pale-yellow needles, melts at 115° , and is soluble in alkalis; with ferric chloride, a dull yellow coloration is obtained, changing to dark-red; potassium dichromate yields a violet solution. Phenylhydrazonemesoxalic acid is prepared by the hydrolysis of the preceding compound with soda.

This synthesis of isoxazole derivatives corresponds with the formation of pyrazolines and pyrazoles from the phenylhydrazones of unsaturated aldehydes and ketones, since it is probable that ethyl nitrosoacetonedicarboxylate reacts in its tautomeric form

and yields the unknown isoxazoline, $COOEt \cdot C \begin{smallmatrix} \diagup CH(OH) \\ \diagdown N \end{smallmatrix} \begin{smallmatrix} \diagdown O \\ \diagup \end{smallmatrix} > CHPh$, which is oxidised, at the moment of its formation, to the isoxazole.

J. B. T.

Action of Hydroxylamine on β -Ketonic Acids and β -Diketones. By A. HANTZSCH (*Ber.*, 24, 495-506).—The author has already shown that the oximes of the α -ketonic acids rarely exist in both the possible stereo-isomeric forms (this vol., p. 413). With the β -ketonic acids, no case has been found in which both stereo-isomeric oximes exist, and, indeed, no oxime has been obtained in the free state, owing to the fact that, like the γ -hydroxy-acids, they readily form anhydrides:

The formation of such anhydrides, which are best termed, according to Claisen's suggestion, "*isoxazolones*," shows that the oximes from which they are formed have the β -configuration.

The action of hydroxylamine on ethyl acetonedecarboxylate has been already examined by Westenborger (*Abstr.*, 1884, 581), but the author has not been able to confirm all his results, some of his products having evidently been impure. By the action of hydroxylamine in alkaline solution, and subsequent acidification, the chief product is *methyl*

isoxazolone, $\text{CMe} \begin{smallmatrix} \text{N} - \text{O} \\ \diagup \quad \diagdown \\ \text{CH}_2 \quad \text{CO} \end{smallmatrix}$, the formation of which corresponds with that of methylphenylpyrazolone from phenylhydrazine and ethyl acetoacetate. To obtain it quite pure, it must be boiled with barium carbonate, and the barium salt precipitated with hydrochloric acid. It crystallises in long, slender, silky needles, melts at $169-170^\circ$, is sparingly soluble in cold water and ether, readily in hot water and alcohol. It behaves as a base towards strong acids, forming a hydrochloride, which is at once decomposed by water, and may be heated with hydrochloric acid at 200° , or boiled with concentrated sulphuric acid, without undergoing decomposition. In its aqueous and alkaline solutions, it undoubtedly is at least partially converted into the free oximidobutyric acid, as the former has an acid reaction, and the solutions in soda and ammonia are not precipitated by acetic acid. Barium oximidobutyrate, $(\text{C}_4\text{H}_5\text{O}_3\text{N})_2\text{Ba} + 2\text{H}_2\text{O}$, forms readily soluble, microscopic needles, and decomposes with explosion when heated. Ammonium oximidobutyrate may be crystallised from acetic acid solution, and forms silky, matted needles, which do not lose ammonia over sulphuric acid or at 100° ; it melts at $206-207^\circ$ with decomposition. With acetic anhydride or chloride, methylisoxazolone yields an acetyl derivative, which appears to have the composition $\text{C}_{10}\text{H}_{10}\text{N}_2\text{O}_4$, but is reconverted into the original oxazolone when boiled with water.

By the action of hydroxylamine on ethyl acetoacetate in neutral or acid solution, Westenerger obtained an oil which he regarded as ethyl oximidobutyrate; it is, however, at any rate, not a pure compound, and yields, on hydrolysis, a crystalline substance which is not oximidobutyric acid. This is scarcely soluble in the ordinary solvents, and has the composition $\text{C}_{20}\text{H}_{26}\text{N}_4\text{O}_7$, and is probably formed from ethyl oximidobutyrate according to the equation

It dissolves without alteration in concentrated nitric acid, melts at 140° , and is resolved on hydrolysis into 2 mols. alcohol and 4 mols. methylisoxazolone.

If the reaction with hydroxylamine be carried out in ammoniacal solution, an unstable product is obtained, which could not be purified, but may possibly be the hydroxamic acid of acetoacetic acid,

The author has further examined the action of hydroxylamine on ethyl benzoylacetate, and his results agree with those recently published by Claisen and Zedel (this vol., p. 468). One and the same product, namely, phenylisoxazolone, $\text{CPh} \begin{smallmatrix} \text{N} - \text{O} \\ \diagup \quad \diagdown \\ \text{CH}_2 \quad \text{CO} \end{smallmatrix}$, is obtained in acid, alkaline, and neutral solutions; the properties of this compound are given by Claisen and Zedel, but the author has also determined the molecular weight by Raoult's method in phenol solution, and finds it to agree with the above formula. It is much more stable in alkaline solution than methylisoxazolone, and unites with ammonia, forming an additive compound having one of the following formulæ:—

On exposure to moist air or over sulphuric acid, or by the action of acetic acid, it is reconverted into phenylisoxazolone. The latter is more readily acted on by acids than the methyl compound, as it is decomposed by concentrated hydrochloric acid at 120° into carbonic anhydride and acetophenonoxime. Concentrated sulphuric acid acts similarly, but the acetophenonoxime undergoes the Beckmann intramolecular change into acetanilide, which is further resolved into acetic and sulphanilic acids. The author regards it as probable that the anhydride first forms the acid $\text{Ph} \cdot \text{C} \begin{array}{c} \text{N-OH} \\ \parallel \\ \text{CH}_2 \cdot \text{COOH} \end{array}$, which then in

the stereo-isomeric form, $\text{Ph} \cdot \text{C} \begin{array}{c} \text{N} \\ \parallel \\ \text{HO} \end{array} \text{CH}_2 \cdot \text{COOH}$, loses carbonic anhydride, forming acetophenonoxime; the latter has already been shown to have the configuration $\text{Ph} \cdot \text{C} \begin{array}{c} \text{Me} \\ \parallel \\ \text{HO} \cdot \text{N} \end{array}$, and the reason of the greater stability of the methyl compound may be due to the fact that the stereo-isomeride, $\text{Me} \cdot \text{C} \begin{array}{c} \text{CH}_2 \cdot \text{COOH} \\ \parallel \\ \text{HO} \cdot \text{N} \end{array}$, like all oximes in which the hydroxyl and methyl groups are adjacent, is either incapable of existence or exceptionally labile.

The researches of Claisen on the oximes of the β -diketones lead to similar results; thus the monoxime of benzoylacetone does not exist, but at once passes into the anhydride, *methylphenylisoxazole*,

which shows that the oxime must have the configuration

On the other hand, benzoylacetaldoxime exists in the free state, and only yields phenylisoxazole with difficulty, namely, by boiling with acetic chloride, whilst with acetic anhydride, it readily yields cyanacetophenone $\text{Ph} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{CN}$, and must therefore have the configuration $\text{Ph} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{C} \begin{array}{c} \text{H} \\ \parallel \\ \text{N} \cdot \text{OH} \end{array}$; the action of acetic chloride is due to the fact that the hydrogen chloride set free converts the β -acetyl compound first formed into the α -acetyl compound, which then condenses to phenylisoxazole (compare this vol., p. 443). H. G. C.

So-called Phenylketohydroxydimethylanilidotetrahydropyridinecarboxylic Lactone, a Contribution to the Knowledge of β -Anilidoglutaranil. By R. ANSCHÜTZ (*Annalen*, 261, 138—151: compare Reissert's this vol., p. 567).—The author has proved that Reissert's phenylketohydroxydimethylanilidotetrahydropyridinecarb-

oxylic lactone is β -anilidoglutaranil, $\text{NPh}\cdot\text{CMe} < \begin{smallmatrix} \text{CO-NPh} \\ \text{CH}_2\cdot\text{CO} \end{smallmatrix}$, (m. p. 131°). This compound is best prepared by heating β -anilidoglutaric acid (1 mol.) with aniline (1 mol.) at 160 – 180° ; it forms monosymmetric crystals, $a : b : c = 0.8093 : 1 : 0.5128$, $\beta = 89^\circ 18'$, and is identical crystallographically with the compound obtained by heating anilidoglutaric acid alone, as described by Reissert.

β -Acetanilidoglutaranil, $\text{NPhAc}\cdot\text{CMe} < \begin{smallmatrix} \text{CO-NPh} \\ \text{CH}_2\cdot\text{CO} \end{smallmatrix}$, prepared by heating β -anilidoglutaranil (m. p. 131°) with acetic chloride at 100° , separates from dilute alcohol in crystals, melts at 168° , and is readily soluble in alcohol and acetone, but only sparingly in ether, and insoluble in water.

β -Acetanilidoglutaric anhydride, $\text{NPhAc}\cdot\text{CMe} < \begin{smallmatrix} \text{CO-O} \\ \text{CH}_2\cdot\text{CO} \end{smallmatrix}$, is formed when β -anilidoglutaric acid is boiled with excess of acetic chloride for four to five hours. It separates from ether in well-defined, monosymmetric crystals, $a : b : c = 0.66654 : 1 : 0.90258$, $\beta = 74^\circ 42'$, melts at 136° , and is readily soluble in chloroform and benzene, but only sparingly in ether.

β -Acetanilidoglutaranilic acid, $\text{NPh}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CMe}(\text{NPhAc})\cdot\text{COOH}$, is obtained when the preceding compound is treated with the theoretical quantity of aniline in benzene, acetone, or ethereal solution; it separates from water in crystals containing 1 mol. H_2O , and from acetone in monosymmetric forms, $a : b : c = 0.7973 : 1 : 0.7642$, $\beta = 87^\circ 34'$, melting at 140 – 141° . When boiled with acetic chloride, it is converted into β -acetanilidoglutaranil (m. p. 168 – 169°), which is identical with the acetyl derivative obtained by heating the so-called phenylketohydroxydimethylanilidotetrahydropyridinecarboxylic lactone with acetic chloride. F. S. K.

Thiazole Derivatives from Bromopyruvic Acids and from Ethyl Bromoacetate. By M. STEUDE (*Annalen*, 261, 22–47).

—The principal objects of this investigation were to determine the constitution of the so-called thiouvinuric acid described by Nencki and Sieber (*Abstr.*, 1882, 501), and to ascertain the position of the bromine atom in ethyl bromoacetate (compare Hantzsch, *Abstr.*, 1890, 1238).

Thiouvinuric acid can be obtained by treating thiocarbamide with monobromopyruvic acid, but it is most conveniently prepared from dibromopyruvic acid, as described by Nencki and Sieber (*loc. cit.*). The ethyl salt, $\text{C}_6\text{H}_5\text{O}_2\text{N}_2\text{S}$, is formed when ethyl bromopyruvate, prepared by brominating ethyl pyruvate in carbon bisulphide solution, is treated with thiocarbamide, an energetic reaction taking place; the product, which consists of the hydrobromide, is decomposed with ammonia and recrystallised from hot water. It melts at 173° , and is almost insoluble in cold water, but more readily in hot water, alcohol, and ether; on hydrolysis with boiling alcoholic potash, it yields thiouvinuric acid. The formation of the ethyl salt of thiouvinuric acid

in this way proves that the acid is μ -amidothiazole- α -carboxylic acid,

The thiazole derivatives, obtained by treating ethyl bromacetoacetate with thiocarbamide and thiacetamide respectively, are isomeric with the ethereal salts obtained from ethyl chloracetoacetate in like manner, but, on hydrolysis, they give acids which, when heated at a suitable temperature, are decomposed with evolution of carbonic anhydride, yielding μ -amido- α -methylthiazole and $\alpha\mu$ -dimethylthiazole respectively. As these two thiazole derivatives are identical with the compounds obtained from ethyl chloracetoacetate in a similar manner, it follows that the original condensation products of ethyl bromacetoacetate are derivatives of thiazylacetic acid, and consequently that ethyl bromacetoacetate has the constitution $\text{CH}_2\text{Br} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{COOEt}$ (compare Hantzsch, *loc. cit.*).

Ethyl μ -amidothiazylacetate, $\text{S} \begin{array}{c} \text{— CH} \\ \text{C}(\text{NH}_2) \cdot \text{N} \end{array} \text{C} \cdot \text{CH}_2 \cdot \text{COOEt}$, is obtained when ethyl bromacetoacetate, prepared according to Duisberg's method (Abstr., 1882, 1193), is treated with thiocarbamide in alcoholic solution, and the resulting hydrobromide decomposed with ammonia. It separates from hot alcohol in yellowish, well-defined, seemingly monosymmetric crystals, melts at 94° , and is only sparingly soluble in cold water, but very readily in alcohol and ether; it dissolves freely in dilute acids, yielding salts which are soluble in alcohol. The free acid, $\text{C}_5\text{H}_6\text{O}_2\text{N}_2\text{S}$, prepared by hydrolysing the ethereal salt with potash, melts at about 130° , and is sparingly soluble in water, but readily in alcohol; when warmed with acids, or heated alone for some time at its melting point, it is completely decomposed into carbonic anhydride and amidomethylthiazole.

Ethyl thiacetamidacetoacetate, $\text{NH} \cdot \text{CMe} \cdot \text{S} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{COOEt}$, is formed, together with ethyl μ -methylthiazylacetate, when ethyl bromacetoacetate is treated with thiacetamide in alcoholic solution; on cooling the solution and stirring vigorously, the hydrobromide of ethyl thiacetamidacetoacetate is deposited in crystals, but if the solution is kept still and not cooled too quickly, no precipitation takes place, and the last-named compound is gradually but completely converted into ethyl methylthiazylacetate hydrobromide. Ethyl thiacetamidacetoacetate, prepared by decomposing the hydrobromide with sodium carbonate, crystallises in transparent rhombohedra, melts at 94° , and is decomposed by warm alkalis with evolution of ammonia; attempts to convert the pure compound into ethyl methylthiazylacetate were unsuccessful, although it was proved by various experiments that it is, in fact, an intermediate product in the formation of the thiazole derivative.

Ethyl methylthiazylacetate, $\text{C}_5\text{H}_{11}\text{O}_2\text{NS}$, obtained by decomposing the hydrobromide with sodium carbonate, is a colourless liquid boiling at $238\text{--}240^\circ$; the *platinochloride*, $(\text{C}_5\text{H}_{11}\text{O}_2\text{NS})_2 \cdot \text{H}_2\text{PtCl}_6$, is a yellow, crystalline compound melting at 89° . The free acid, $\text{C}_5\text{H}_8\text{O}_2\text{NS}$, prepared by treating the ethereal salt with moderately concentrated potash at the ordinary temperature, crystallises in small needles,

melts at 121°, and is only sparingly soluble in water, but more readily in alcohol and ether; when the acid is distilled, it is completely converted into $\alpha\mu$ -dimethylthiazole with evolution of carbonic anhydride.

Ethyl γ -thiacetoacetoacetate, $\text{COEt}\cdot\text{S}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{CH}_2\cdot\text{COOEt}$, is precipitated as an oil when ethyl thiacetamidacetoacetate hydrobromide is warmed with water. It boils at 155° under a pressure of 15 mm., is insoluble in dilute acids, and only sparingly soluble in water, but miscible with alcohol and ether; it is acted on by concentrated nitric acid with almost explosive violence, yielding small quantities of a crystalline compound, which is free from sulphur and explodes when heated.

A compound of the composition $\text{C}_6\text{H}_8\text{O}_2\text{S}$ is formed, together with acetic acid, when ethyl thiaceoacetoacetate is carefully mixed with concentrated sulphuric or hydrochloric acid, and, after cooling and adding a little water, the product is deposited in crystals; the same compound is produced in small quantities when ethyl bromacetoacetate is shaken with a 2 per cent. solution of sodium hydrosulphide. It separates from alcohol in slender needles, melts at 168°, and is moderately easily soluble in alcohol and ether, but insoluble in water and acids; its physical properties indicate a high molecular weight, and its constitution is probably represented by the formula

$\text{COOEt}\cdot\text{CH}_2\cdot\text{C}\begin{smallmatrix} \text{CH}\cdot\text{S} \\ \text{S}\cdot\text{CH} \end{smallmatrix}\text{C}\cdot\text{CH}_2\cdot\text{COOEt}$. When hydrolysed with alcoholic potash, it yields a crystalline potassium salt, from which a colourless, crystalline acid, melting at about 140°, is obtained on treatment with hydrochloric acid.

F. S. K.

Attempts to Prepare Hydrothiazole Derivatives. By P. SCHATZMANN (*Annalen*, 261, 1—21).—Various experiments were made with the object of synthesising hydrothiazole derivatives, but without success. When glycol chlorhydrin is warmed with thiocarbamide, the product extracted with water, and the solution evaporated, small, hygroscopic crystals of hydroxyethylthiocarbamide hydrochloride, $\text{OH}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{S}\cdot\text{C}(\text{NH})\cdot\text{NH}_2\cdot\text{HCl}$, are deposited; attempts to convert this substance into dihydroamidothiazole were unsuccessful.

Ethylenedithiocarbamide hydrobromide is formed when ethylene bromide (1 mol.) is treated with thiocarbamide (1 mol.). The free base, $\text{C}_4\text{H}_{10}\text{S}_2\text{N}_4$, prepared by digesting the salt with silver oxide, forms grey crystals, and is readily soluble in water, alcohol, ether, and acids.

Dimethylthiazole is completely decomposed on treatment with sodium in alcoholic solution, the products being ethylamine and propyl mercaptan; other reducing agents, such as zinc and hydrochloric acid, zinc-dust and acetic acid, have no action on dimethylthiazole.

Phenylmethylthiazole is not acted on by sodium and alcohol, or by concentrated ammonia at 280°.

An orange-yellow compound is formed when amidothiazole hydrochloride is treated with sodium nitrite in well-cooled aqueous solution; this substance is doubtless either diazothiazole hydrate or nitrosoimidothiazoline, as is shown by its behaviour with halogen acids, but it was not analysed on account of its instability.

μ-Chlorothiazole, $\begin{array}{c} \text{S}-\text{CCl} \\ | \\ \text{CH}:\text{CH} \end{array} \gg \text{N}$, is obtained when a concentrated solution of amidothiazole hydrate is treated with the theoretical quantity of sodium nitrite in the cold and then boiled with excess of concentrated hydrochloric acid. It is a colourless oil, specifically heavier than water, boils at $144-144.5^\circ$, and is readily volatile with steam; it is only sparingly soluble in water, but miscible with alcohol and ether in all proportions. It dissolves freely in concentrated mineral acids, but its salts are very unstable. The *platinochloride*, $(\text{C}_3\text{H}_2\text{NSCl})_2 \cdot \text{H}_2\text{PtCl}_6$, is a yellow, crystalline, unstable compound, sparingly soluble in alcohol.

μ-Bromothiazole, $\text{C}_3\text{H}_2\text{SNBr}$, prepared in like manner, is a colourless liquid, boils at 171° , and is very similar to the corresponding chloro-derivative in all respects. The *platinochloride*, $(\text{C}_3\text{H}_2\text{SNBr})_2 \cdot \text{H}_2\text{PtCl}_6$, is unstable, and melts at 197° with decomposition. The corresponding iodo-derivative could not be obtained; the chloro- and bromo-compounds just described are readily acted on by zinc-dust and acetic acid, being converted into thiazole.

Phenyldiazothiazole hydrate, or *phenylnitrosoimidothiazoline*, $\text{C}_6\text{H}_7\text{N}_3\text{SO}$, can be obtained by treating phenylamidothiazole hydrobromide with sodium nitrite in aqueous solution; it is a yellow, unstable compound, and is decomposed by boiling hydrochloric acid, yielding benzoic acid.

Phenylhydroxychlorothiazole, $\begin{array}{c} \text{S}-\text{C}(\text{OH}) \\ | \\ \text{CO}:\text{CPh} \end{array} \gg \text{N}$, is formed in small quantity when phenylhydroxythiazole is melted with phosphorus pentachloride, but the principal product is a substance melting at 98° , the nature of which could not be determined; phenylchlorhydroxythiazole separates from ether in yellowish crystals, melts at 206° , and is soluble in soda.

When carbaminethiacetophenone, $\text{COPh} \cdot \text{CH}_2 \cdot \text{S} \cdot \text{CO} \cdot \text{NH}_2$, an intermediate product obtained in the preparation of phenylhydroxythiazole from acetophenone thiocyanate is oxidised with boiling dilute nitric acid, it is converted into a yellow, crystalline compound melting at 75° ; this substance has the composition $\text{C}_8\text{H}_6\text{SO}_2$, and its constitution is probably expressed by the formula $\begin{array}{c} \text{S}-\text{CO} \\ | \\ \text{CH}:\text{CPh} \end{array} > \text{O}$.

F. S. K.

Pheno-2'-methylmetadiazine (2'-Methylquinazoline). By A. BISCHLER (*Ber.*, 24, 506—508).—By the action of alcoholic ammonia at 100° on acetylorthamidobenzaldehyde, the following reaction takes place:—

pheno-2'-methylmetadiazine being formed. The oily product is distilled in a current of steam, the distillate extracted with ether, and the ethereal solution evaporated and fractionated. *Pheno-2'-methylmetadiazine* distils at 235° under 713 mm. pressure, solidifies after a time,

and then melts at 35.5° . It is hygroscopic, and forms a crystalline hydrochloride, $C_6H_5N_2HCl$, and a yellow, crystalline *platinochloride*, $(C_6H_5N_2)_2H_2PtCl_4$. The above reaction is quite general, and is being thoroughly investigated. H. G. C.

Action of Orthodiamines on Orthaldehydobenzoic Acids.
By A. BISTRZYCKI (*Ber.*, 24, 627—630; compare Abstr., 1890, 969).
—*Toluylenamidinedimethoxybenzenylcarboxylic acid*,

is formed when opianic acid (2 mols.) is boiled with metaparatoluylenediamine (1 mol.) in 80 per cent. alcoholic solution. It crystallises from 80 per cent. acetic acid in small, colourless needles, melts and decomposes at about 234° when quickly heated, and is readily soluble in hot glacial acetic acid, but only moderately in chloroform, very sparingly in alcohol, and is almost insoluble in ether and light petroleum; it dissolves freely in dilute mineral acids and in alkalis. The calcium salt, $(C_{17}H_{15}N_2O_4)_2Ca$, is only sparingly soluble in hot water.

Bromotoluylenamidinedimethoxybenzenylcarboxylic acid,

prepared from opianic acid and metabromometaparatoluylenediamine in like manner, crystallises from alcohol in small, flat, colourless needles, melts at 240° with decomposition, and resembles the preceding compound in general behaviour, but is more sparingly soluble.

Toluylenedimethoxyphthalamidone, $\begin{array}{c} C_6H_5Me \cdot N \cdot CO \\ | \\ N = C \cdot C_6H_2(OMe)_2 \end{array}$, is formed

when toluylenamidinedimethoxybenzenylorthocarboxylic acid is boiled with acetic anhydride. It crystallises from benzene or alcohol in slender, yellow needles, melts at 228° with decomposition and previous softening, and is readily soluble in hot benzene, alcohol, glacial acetic acid, chloroform, and acetone, but only sparingly in ether, and insoluble in light petroleum; its solution in benzene shows a green fluorescence. It dissolves in concentrated sulphuric acid with an orange coloration, but on adding water, and heating, the solution becomes colourless. F. S. K.

Relations of the Eurhodines to the Indulines and Saffranines. By F. KEHRMANN and J. MESSINGER (*Ber.*, 24, 584—592; compare Abstr., 1890, 1265).—Rosindone is obtained by mixing hydroxynaphthaquinone and phenylorthophenylenediamine dissolved in molecular proportion in alcohol at the ordinary temperature; it melts at 261 — 262° , and is identical with the compound obtained by O. Fischer and E. Hepp from rosinduline (Abstr., 1890, 908). The authors propose to term the ketoinduline derivatives "indulones," so as to avoid confusion with the ketoindene derivatives; "rosindone" of Fischer and Hepp would, therefore, become the "*rosindulone*" or naphthaphenindulone corresponding with rosinduline or naphthapheninduline.

Rosinduline is prepared in a similar manner to the indulone, by heating hydroxynaphthaquinonimide and phenylorthophenylenediamine with alcohol and a little glacial acetic acid at 100° under pressure; the yield is 40–60 per cent. of the quinonimide taken. It is suggested that the salts of rosinduline are derived from an unstable ammonium base with the formula

this would account for their similarity in properties to the saffranines.

Chlorhydroxyphenindulone, $\text{OH} \cdot \text{C}_6\text{H}_3\text{OCl} \left\langle \begin{array}{c} \text{N}^1 \\ \text{NPh}^2 \end{array} \right\rangle \text{C}_6\text{H}_4$, prepared from chlorodihydroxyquinone and phenylorthophenylenediamine, crystallises from glacial acetic acid in chocolate-coloured, highly lustrous plates, melts at 270–272° with decomposition, and is sparingly soluble in ordinary media, but dissolves in sulphuric acid with a green colour, and is precipitated unchanged on dilution; the solution in dilute soda or concentrated ammonia is red. The *benzoyl derivative* crystallises from alcohol in bronze, lustrous, concentrically grouped needles melting at 234–235°.

Hydroxythymophenindulone, $\text{OH} \cdot \text{C}_6\text{Me}_3\text{O} \left\langle \begin{array}{c} \text{N}^1 \\ \text{NPh}^2 \end{array} \right\rangle \text{C}_6\text{H}_4$, obtained from dihydroxythymoquinone and phenylorthophenylenediamine, crystallises from alcohol in ruby-red plates and prisms, melts at 174–175°, and gives an olive-green colour with sulphuric acid. No other condensation product could be detected. J. B. T.

A New Class of Fluorescent Colouring Matters of the Quinoxaline Series. By O. FISCHER (*Ber.*, 24, 719–723).—When orthamidoditolylamine is fused with benzoïn, 2 mols. of water are eliminated, and a dihydroquinoxaline derivative of the following constitution formed:—

The reaction is a general one, and all the dihydroquinoxaline derivatives thus obtained are colouring matters with a yellowish- or brownish-green fluorescence, whilst the corresponding simple quinoxalines have no similar properties.

Diphenyldihydroquinoxaline, $\text{C}_6\text{H}_4 \left\langle \begin{array}{c} \text{N}=\text{CPh} \\ \text{NH} \cdot \text{CHPh} \end{array} \right\rangle$, is prepared by heating orthodiamidobenzene and benzoïn, in molecular proportions, in a sealed tube at 170° for three hours, as in the presence of air large quantities of diphenylquinoxaline are formed. It crystallises in thick, dark-yellow, prismatic crystals, certain faces of which reflect a beautiful, green light, melts at 148–149°, and is readily soluble in benzene and hot alcohol, sparingly in ether and light petroleum, insoluble in water; the solutions in ether and benzene show a beautiful, yellowish-green fluorescence, and colour paper an intense yellow.

It is a feeble base, forming orange-red salts, which are dissociated by water, distils unchanged in small quantities, and is oxidised by ferric chloride to diphenylquinoxaline.

Diphenyltolyltoludihydroquinoxaline, $C_6H_5Me < \begin{matrix} N \\ \text{N}(C_6H_5) \end{matrix} \begin{matrix} \text{CPh} \\ \text{CHPh} \end{matrix}$ is obtained by heating orthamidoditolylamine and benzoïn, in molecular proportion, at 180° for several hours; it crystallises from light petroleum in pale-yellow, thick prisms, certain faces of which have a green reflex. Its solubility and fluorescence are the same as with the diphenyl derivative, but it dissolves in mineral acids with a magenta colour. The formula $C_{28}H_{24}N_2$ has been confirmed by a determination of the molecular weight by Raoult's method.

Diphenyl-1:3:4-triamidobenzene (Abstr., 1890, 614) reacts with benzene at 160° , forming a yellow, fluorescent compound, having the constitutional formula $NHPh \cdot C_6H_5 < \begin{matrix} N \\ \text{NPh} \end{matrix} \begin{matrix} \text{CPh} \\ \text{CHPh} \end{matrix}$; it crystallises from absolute alcohol in beautiful, greenish-yellow, lustrous plates, melts at 223° , and is readily soluble in benzene and chloroform, sparingly in alcohol, ether, and light petroleum, the yellow solutions showing a deep green fluorescence. Its salts have a pink colour.

β -Phenylorthonaphthylenediamine also yields a similar colouring matter with benzoïn at 200° , which crystallises from alcohol in deep-yellow plates or needles, melts at $163\text{--}164^\circ$, is readily soluble in ether and benzene, but only sparingly in alcohol and light petroleum, the solutions having a greenish-yellow fluorescence. It yields deep-red salts, which are decomposed by water. It has the constitutional formula $C_{20}H_{16} < \begin{matrix} N \\ \text{NPh} \end{matrix} \begin{matrix} \text{CPh} \\ \text{CHPh} \end{matrix}$.

H. G. C.

Alkaloids of Belladonna. By O. HESSE (*Annalen*, 261, 87—107; compare this vol., p. 228).—Atropamine, $C_{17}H_{21}NO_2$, is easily isolated from the roots of *Atropa belladonna* by dissolving the crude mixture of alkaloids in acetic acid, and adding sodium chloride to the solution until a permanent turbidity is produced, when atropamine hydrochloride is deposited in crystals. The free base is obtained in the form of a colourless, semi-solid resin, when the pure hydrochloride is decomposed with ammonia, the base extracted with ether, the ethereal solution washed with ammonia and water consecutively, and then evaporated over sulphuric acid; it is very readily soluble in benzene, but only sparingly in light petroleum and water. Its alcoholic solution has a bitter taste, and turns red litmus-paper blue, but is without action on phenolphthaleïn-paper. The *hydrochloride*, $C_{17}H_{21}NO_2 \cdot HCl$, crystallises from boiling water in colourless plates, melts at 236° , and is moderately easily soluble in hot water, but only sparingly in alcohol and acetone, and insoluble in ether. The *platinochloride*, $(C_{17}H_{21}NO_2)_2H_2PtCl_6$, forms small, reddish-yellow needles, and is only sparingly soluble in cold water. The *aurochloride*, $C_{17}H_{21}NO_2 \cdot HAuCl_4$, crystallises in small, lustrous plates melting at 112° . The *mercuriochloride* forms small, colourless plates, and is moderately easily soluble in boiling water. The *hydrobromide*, $C_{17}H_{21}NO_2 \cdot HBr$, crystallises in

colourless plates, melts at 230° , and is readily soluble in hot water. The *hydriodide*, *nitrate*, normal *sulphate*, and *picrate* are crystalline.

When atropamine is dissolved in cold concentrated sulphuric acid, or boiled with barium hydroxide or dilute hydrochloric acid, or when its hydrochloride is moistened with hydrochloric acid and exposed to sunlight, it is converted into belladonnine, $C_{27}H_{31}NO_3$, an alkaloid which has been previously investigated by Kraut (Abstr., 1880, 410), Merling (Abstr., 1884, 1055), Ladenburg and Roth (Abstr., 1884, 761), and others. On prolonged boiling with alcoholic barium hydroxide or with moderately concentrated hydrochloric acid, atropamine is decomposed into a volatile base and various acids, amongst which is α -isatropic acid (m. p. 239°). The volatile base seems to be identical with pseudotropine; it is a crystalline, deliquescent compound, very readily soluble in alcohol and water, but very sparingly in ether. The *platinochloride*, $(C_8H_{13}NO)_2 \cdot H_2PtCl_6$, melts at 186° with decomposition, and differs in crystalline form from the corresponding salt of tropine; the aurochloride crystallises in plates, and melts at 195 – 198° with decomposition.

When atropamine is heated at 100° with fuming hydrochloric acid, it yields atropic acid (m. p. 107°), identical with the compound obtained from atropine under the same conditions.

The author's experiments show that atropamine stands in the same relationship to hyoscine that apoatropine does to atropine.

F. S. K.

Tropinic Acid and Oxidation Products of Dextro- and Lævo-ecgonine and of Tropine. By C. LIEBERMANN (*Ber.*, 24, 606–617; compare Abstr., 1890, 1449).—The acid $C_7H_{11}NO_3$, obtained by the oxidation of lævo-ecgonine, is termed *ecgonic acid*, and is much more soluble in water than tropinic acid; it is lævorotatory, $[\alpha]_D = -43.2^{\circ}$, and is also formed, together with tropinic acid, by the oxidation of dextro-ecgonine and of tropigenine. On oxidising tropine, optically inactive tropinic acid is obtained, together with a compound which exhibits all the properties of ecgonic acid, except that it melts at 90° instead of at 117° ; this may, however, be due to the presence of some impurity. *Ethyl ecgonate*, $C_7H_{10}EtNO_3$, is a colourless, viscid liquid.

Tropinic acid is bibasic; its rotatory power is $[\alpha]_D = +14.8^{\circ}$; the silver salt is not well adapted for analysis; the *cupric salt*, obtained by crystallisation from water, has the formula $C_8H_{13}NO_4 \cdot CuOH$; on heating this for some time at 165 – 170° , a molecule of water is eliminated, and the *normal salt*, $C_8H_{11}NO_4 \cdot Cu$, remains as a pale-blue powder. *Methyl tropinate*, $C_8H_{11}Me_2NO_4$, and *ethyl tropinate*, $C_8H_{11}Et_2NO_4$, are colourless, viscid liquids, insoluble in water.

These results point to the incorrectness of Ladenburg's formula for tropine, and of Einhorn's formula for ecgonine, since each of these has only one side chain linked to the pyridine nucleus; the author adopts Merling's formulæ for this group of compounds, the relative position of the side chains being as yet undetermined:—

Tropine.

Tropidine.

Hydrotropidine.

Ecgonic acid is probably an aldehyde acid, analogous to opianic acid, and may have the formula $\text{C}_5\text{NH}_5 \begin{array}{l} \text{CH(OH)} \\ \diagup \quad \diagdown \\ \text{CO-} \end{array} > \text{O}$.

J. B. T.

Cytisine. By A. PARTHEIL (*Ber.*, 24, 634—640; compare this vol., p. 231, and Buchka and Magalhaes, this vol., p. 587). Cytisine melts at 152—153° (uncorr.) and can be crystallised from hot chloroform; when treated with hydriodic acid, it does not yield methyl iodide; its molecular weight was determined, in aqueous solution, by Raoult's method, with results agreeing well with the molecular formula $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O}$. The *hydrobromide*, $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O} \cdot \text{HBr}$, crystallises from cold water in small, colourless needles, containing 1 mol. H_2O . The *hydriodide* with 1 mol. H_2O , *nitrate*, $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O} \cdot \text{HNO}_3 + \text{H}_2\text{O}$, and *sulphate*, $(\text{C}_{11}\text{H}_{14}\text{N}_2\text{O})_2 \cdot \text{H}_2\text{SO}_4 + \text{H}_2\text{O}$, crystallise in colourless needles. The *methiodide*, $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O} \cdot \text{MeI}$, prepared by heating cytisine with methyl iodide at 100°, crystallises from dilute alcohol in needles containing 2 mols. H_2O , and is readily soluble in water. The *ethiodide*, $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O} \cdot \text{EtI}$, separates from alcoholic ether in almost colourless crystals. When cytisine is oxidised with alkaline potassium permanganate, ammonia is evolved; under the same conditions, the methiodide is decomposed with evolution of methylamine.

A direct comparison of ulexine, prepared from the seeds of *Ulex europæus*, with cytisine proved that the two compounds are identical (compare Gerrard and Symons, this vol., p. 334). F. S. K.

Cytisine. By K. BUCHKA and A. MAGALHAES (*Ber.*, 24, 674—680; compare preceding abstract).—Measurements of the electrical conductivity of aqueous solutions of cytisine showed that it is only a feeble base.

Methylcytisine hydriodide (cytisine methiodide), $\text{C}_{12}\text{H}_{16}\text{N}_2\text{O} \cdot \text{HI}$, melts at 253·5°, and is decomposed by hot potash yielding methylcytisine; this base separates from chloroform in crystals and melts at 245°. The *hydrochloride*, $\text{C}_{12}\text{H}_{16}\text{N}_2\text{O} \cdot 2\text{HCl} + 1\frac{1}{2}\text{H}_2\text{O}$, forms colourless crystals, melts at 249—250°, and is readily soluble in water. The *aurochloride*, $\text{C}_{12}\text{H}_{16}\text{N}_2\text{O} \cdot \text{HAuCl}_4$, is a yellow, crystalline compound melting at 196°.

Acetylcytisine, $\text{C}_{13}\text{H}_{16}\text{N}_2\text{O}_2$, prepared by heating cytisine with acetic anhydride, separates from alcohol in almost colourless crystals, melts at 208°, and is decomposed by alkalis.

Nitrosocytisine, $\text{C}_{11}\text{H}_{13}\text{N}_3\text{O}_2$, is obtained when an aqueous solution of cytisine hydrochloride is treated with sodium nitrite in the cold; it crystallises in colourless needles, melts at 174°, and gives Liebermann's reaction very distinctly.

The authors compared several derivatives of cytisine with the corresponding derivatives of ulexine, prepared from the seeds of *Ulex europæus*; the result of the comparison was in favour of the identity of the two bases, but, on the other hand, when ulexine is heated with

methyl iodide, it yields a compound melting at 290° , whereas cytosine methiodide melts at 253.5° . F. S. K.

Aspergillin, a Vegetable Hæmatin. By G. LINOSSIER (*Compt. rend.*, 112, 489—492).—The spores of *Aspergillus niger*, when treated with very dilute ammonia, yield a dark-coloured solution from which a slight excess of hydrochloric acid throws down *aspergillin* as a black, bulky, flocculent precipitate. When dried over sulphuric acid at the ordinary temperature and powdered, it closely resembles hæmatin in appearance, and its general resemblance to this substance justifies the name “vegetable hæmatin,” although whether the two substances have similar functions has yet to be determined.

Aspergillin is almost insoluble in water, alcohol, and neutral solvents, and is insoluble in dilute mineral acids, but dissolves in dilute acetic acid. It dissolves easily even in dilute solution of alkaline hydroxides, alkaline carbonates, and certain salts which have an alkaline reaction such as borax and disodium hydrogen phosphate. As in the case of hæmatin, its ammoniacal solution is precipitated by barium hydroxide. When freshly precipitated, aspergillin forms a colloidal semi-solution with water, which is converted into a perfect solution by alkalis, but is precipitated by acids and certain neutral salts. Heat reduces the solubility in various solvents, and if heated for some hours at 180° , it becomes insoluble in alkalis. When heated in presence of air, aspergillin evolves an odour of burnt horn, and, like hæmatin, leaves a residue of ferric oxide.

Acid solutions are brown (green in thin layers) and alkaline solutions are reddish-brown; they exert a general absorption throughout the spectrum, increasing in intensity, though not continuously, from the red to the violet. An ammoniacal solution seems to undergo no change even after prolonged exposure to light. Sodium hyposulphite reduces solutions of aspergillin and the product absorbs oxygen with great energy when exposed to air, the colour very rapidly changing back from golden-yellow to brown. C. H. B.

Physiological Chemistry.

Effect of Certain Organic Acids on the Digestion of Proteids. By A. STUTZER (*Landw. Versuchs-Stat.*, 38, 257—261).—The action of hydrochloric and various organic acids on the digestion of proteids by pepsin has been carefully studied, the substance experimented on being cotton-seed meal; three different strengths of acid solution were employed, namely, 0.05, 0.1, and 0.20 per cent. The relative activities of acid of 0.1 per cent. as calculated on the amount of dissolved nitrogen was as follows:—Hydrochloric, 62; formic, 30; acetic, 7; propionic, 1; butyric, 7; lactic, 39; malic, 33; tartaric, 34; citric, 27. E. W. P.

Effect of Salt on Digestion. By A. STUTZER (*Landw. Versuchs-Stat.*, 38, 262—267).—The effects of sodium chloride on digestion known hitherto are, solution of albumin in aqueous liquids, increased excretion of stomach juices (pepsin), and the increased rapidity of the diffusion of liquids. The questions which the author strives to answer are: Will pepsin dissolve as much albumin when sodium chloride is present as when it is absent; and has sodium chloride a specific action on the pepsin, or on the hydrochloric acid, or on both? The solutions employed were: (1) water; (2) water and sodium chloride; (3) water and hydrochloric acid; (4) water, sodium chloride, and hydrochloric acid; (5) acidified stomach juice; (6) sodium chloride. The material acted on was cotton-seed meal soaked in chloroform-water, the temperature 40° , the time 30 minutes. Results: Salt alone has no appreciable action. Hydrochloric acid even in 0.05 per cent. solution has a very considerable solvent power, provided sodium chloride be present to the extent of only 0.25 per cent. Increase of sodium chloride means decrease of solvent action; increase of acid to 0.2 per cent. with small amount of salt, 0.25 per cent., is accompanied by increase of solvent power (53—71), but 1 per cent. of sodium chloride hinders the action of the acid. 1 per cent. of salt causes pepsin to dissolve more albumin than 0.25 or 0.5 per cent. of sodium chloride in the presence of acid. Pepsin solutions with salt added are capable of dissolving more albumin than when salt is absent; the most advantageous conditions under which salt acts are when 0.05 or 0.10 per cent. of hydrochloric acid is present. E. W. P.

Influence of Heat on the Digestibility of Fodder. By A. STUTZER (*Land. Versuchs-Stat.*, 38, 267—276).—Wheaten bran: A temperature of 100° reduces the solubility of the proteids; hydrochloric acid (without pepsin) has scarcely any action on boiled bran, whilst on bran heated in the dry state to 98° , its action is but slightly reduced. With reference to bread and meal, it appears that the process of baking the flour has but a small effect on the digestibility of the nitrogenous matter, this being rendered slightly less soluble, the proteids of the crust of bread being less digestible than those of the crumb. Hydrochloric acid readily dissolves the proteids of flour, but is almost without action on those contained in bread; whilst water alone dissolves four times the amount out of meal that it does out of bread.

The proteids of earth-nut cake become less soluble in water after having been exposed to a moist or dry heat. Hydrochloric acid (0.05 per cent.) has no solvent power on this meal when it has been boiled with water, but a dry heat has no influence on the solubility of the proteids. Dry or moist heat reduces the solubility in acid stomach juice. From these experiments, it would appear that fodders are not rendered more digestible by heat as regards the proteid matter, but possibly may be so as regards the cellulose.

E. W. P.

Influence of Oil or Fat on the Digestibility of Proteids. By A. STUTZER (*Landw. Versuchs-Stat.*, 38, 277—279).—The presence of fat or oil in fodders (cocoa-nut cake, &c.) appears to have but a very

slight reducing action on the solubility of proteids in water or hydrochloric acid (without pepsin), and the differences observed when pressed and unpressed meals are submitted to the solvent action of pepsin are so slight, that the author considers that these differences must be attributed to errors of observation.

E. W. P.

Effect of Increasing the Proteids in Food Rations of Grown Animals. By E. KERN and H. WATTENBERG (*Bied. Centr.*, 1891, 77—87).—The experiments described were conducted in the year 1879, and consisted in feeding two 3½-year-old sheep with an ordinary ration of hay and crushed barley, and in addition, during the first three periods (July 14—Sept. 24), with increasing quantities of proteid in the form of conglutin (70—210 grams), and in the following two periods (Sept. 15—Oct. 25) with decreasing quantities in the form of flesh meal (152—76 grams) from which all fat had been removed. The sheep were kept in Pettenkofer's respiration apparatus, and all excretion products were collected and measured.

The mean daily growths of crude wool were in the one case 11.33 grams, in the other 13.71; a table of digestion coefficients during all periods is given, and it is pointed out that the sum of the amounts of crude fibre and of non-nitrogenous extractive matters digested closely approaches to the amount of non-nitrogenous extractive in the *original* food. Period I, extractive in food, 472 grams; digested food fibre, 141 grams; digested extractive, 324 = 465 grams. Do. do. sheep II, 473 grams. In Period V, the results are respectively 459, 447.8, 455.

The percentage of hippuric acid was lowered as the proteids in the food were increased, but resumed its original quantity during the periods when the proteids were decreased; there was also an increase in flesh with increase of proteids ingested.

As regards products of respiration during Period I (no extra nitrogen), there was expired 727.4 grams of carbonic anhydride, of which 56.4 per cent. was produced during the day—this quantity rose as the food increased in richness; and in Period IV, we find 815.7 grams of carbonic anhydride expired, of which 56.6 per cent. appeared in the day-time. Finally, during the last period, when all additional nitrogen was withdrawn, the total carbonic anhydride was 676.0 grams, of which 56.7 per cent. was obtained during the day.

Although the results were not as satisfactory as could have been desired, yet the authors consider that an increase of proteids in food is accompanied by a decrease in the excretion of methane. Other points examined, such as the formation of fat and flesh from a known quantity of proteids, have not led to any satisfactory results.

E. W. P.

Oxygen in the Blood of Animals at Great Altitudes. By VIAULT (*Compt. rend.*, 112, 295—298).—The author has previously found that one of the first effects produced on animals which are transferred to great altitudes from the low levels to which they are accustomed is a considerable increase in the number of red corpuscles in the blood. He has now determined, at the place, the quantity of oxygen in the blood of animals on the upper slopes of the Cordilleras. Sheep, at a height of 4392 metres, and a pressure of 450 mm., gave 13.16 c.c.

and 13.30 c.c. of oxygen per 100 c.c. of blood. A dog, at a height of 3724 metres, and a pressure of 485 mm., gave 18.26 c.c. of oxygen per 100 c.c. The maximum absorptive power of the blood in these three cases was 16.0, 17.0, and 25 c.c. respectively. Similar results were obtained at the summit of the Pic du Midi, and it follows that at great altitudes the proportion of oxygen in the blood of animals is practically the same as at low levels. It would seem that the greater rarefaction of the oxygen is compensated by the greater degree of subdivision of the red corpuscles and their consequent greater absorptive activity.

C. H. B.

Increase in the Quantity of Hæmoglobin in the Blood according to the Conditions of Existence. By A. MÜNTZ (*Compt. rend.*, 112. 298—301).—Ordinary rabbits were taken from the plain in August, 1883, and were transferred to the summit of Pic du Midi, at a height of 2877 metres, and a pressure of 540 mm. They seemed to acclimatise at once, and fed and multiplied in a normal manner. In August, 1890, some of the rabbits, born on the Pic, and descendants of those transported from the plain many generations before, were killed, and their blood compared with that of rabbits living on the plain:—

	Sp. gr.	Solids per cent.	Iron in 100 grams.	Oxygen absorbed by 100 c.c.
Rabbits from Pic du Midi	1060.1	21.88	70.2 mgr.	17.28 c.c.
Rabbits from the plain..	1046.2	15.75	40.3 "	9.56 "

It follows that, after many generations, the blood of animals living at great altitudes becomes richer in hæmoglobin, and thus acquires a greater absorptive power which compensates for the rarefaction of the oxygen.

It seems, however, that a comparatively short time is required to bring about this change. The blood of sheep grazing at a height of 2300—2700 metres, to which they had been transferred from the plain six weeks before, was compared with that of similar sheep that had remained in the valley:—

	Sp. gr.	Solid matter per cent.	Iron in 100 grams.	Oxygen absorbed by 100 c.c.
Sheep on the mountain	1053.2	18.19	60.4 mgr.	17.47 c.c.
Sheep in the valley	1038.0	13.58	32.5 "	7.32 "

The blood undergoes the same change in the process of fattening:—

	Sp. gr.	Solid matter per cent.	Iron in 100 grams.	Oxygen absorbed by 100 c.c.
Fat sheep	1058.0	20.33	57.0 mgr.	16.4 c.c.
Ordinary sheep .	1038.0	13.60	33.0 "	7.7 "

C. H. B.

Effect of Medicines, and especially of Valerian Extract, on the Destruction of Dextrose in the Blood. By L. BUTTE (*Compt.*

rend. 112, 347—350).—The dextrose was estimated by the fermentation method with the use of a mercurial pump (Quinquand and Gréhant). Sodium hydrogen carbonate or morphine retards the destruction of dextrose in the blood, but curarine accelerates it. Valerian extract retards the destruction very considerably when added to freshly-drawn blood, and also when injected into the left femoral vein of a dog. C. H. B.

Isolation of the Glycolytic Ferment of the Blood. By R. LÉPINE and BARRAL (*Compt. rend.*, 112, 411—412).—Fresh dog's blood was defibrinated and placed in a powerful centrifugal machine; the serum thus separated was found to have very little glycolytic power. The separated corpuscles were treated with a volume of salt water equal to the original serum, and the process of separation was repeated; the salt solution contained much less albumin than the serum, but its glycolytic power was much greater. A second treatment with salt water gave a liquid with very little albumin, but with still greater glycolytic power. It follows, therefore, that the destruction of glucose is not due, as Arnaud has supposed, to some action of living blood albumin; the results point, in fact, to the existence of a soluble ferment. C. H. B.

Human Chyle and Lymph. By I. MUNK and A. ROSENSTEIN (*Virchow's Archiv*, 123, 230—279).—In the present research, a female patient, 18 years of age, suffering from elephantiasis of the left leg, was the subject of numerous observations. At varying periods, fistulous communications between the swollen lymphatics and the exterior were spontaneously established, and the lymph which escaped was collected. It was clear under ordinary circumstances, but after a fatty meal was milky, or, in other words, consisted of chyle; this was, no doubt, due to the insufficiency of the valves of the larger lymphatic channels. Previous cases in which it has been possible to collect human chyle or lymph are alluded to; this case seems, however, to be the first in which it has been possible to contrast the properties of the lymph and chyle of the same individual. Observations such as these are also more valuable than those performed on animals, as the period of observation can be more prolonged than in those cases.

The quantities of material available was very large, about 130 grams of chyle being collected per hour during digestion, and about half that quantity of lymph during periods of inanition. By availing themselves of religious fast days, the observers were able to make observations on the fluid collected throughout long periods (18 to 20 hours) of abstinence, and to compare it with that obtained in periods during which various diets were administered.

Hunger-lymph, collected at least 12 hours after a meal, is an almost clear, yellowish fluid, of alkaline reaction, of sp. gr. 1.016 to 1.023, faint odour, and saline taste. On standing, it coagulates, the clot consisting of fibrin and varying numbers of leucocytes.

Red blood-corpuscles and free hæmoglobin were absent on all occasions but one, which occurred during a menstrual period. The

lymph-serum contained 94 to 96 per cent. of water, and of the solids, albumin was the most abundant constituent. The following numbers were obtained in two analyses :—

	I.	II.
Total proteid per cent.	3.516	3.544
Albumin	2.818	2.489
Globulin	0.698	1.055
Globulin: albumin	1:4	1:2.4

The amount of extractive nitrogen was 0.135 per cent. The ethereal extract (fat, lecithin, and cholesterol) was 0.06 to 0.063 per cent. The alkalinity in terms of sodium carbonate was 0.152 to 0.183 per cent. In normal lymph, it is probably higher, as acids are formed during coagulation.

Chyle collected during digestion periods is milky two hours after the meal, and more markedly so three hours after. Fat droplets are scanty, the fat being present in the finest molecular state of subdivision. After a diet containing little fat, the percentage in the chyle is from 2 to 3 per cent. After a fatty meal, it rises to 4 or 5 per cent. The amount of water sinks in a corresponding degree. When the fistula was open, about 60 per cent. of the fat given was recovered in the chyle during the 13 hours following a meal. A comparatively small fraction must therefore have entered the blood stream, or been saponified, or escaped with the feces. The fact that little entered the blood stream was confirmed by analysis; during both hunger and digestion, the ethereal extract of the blood was approximately 0.17 per cent., if the fistula was open; whereas, during fat digestion, when the fistula was closed, the percentage rose to 0.43. From this it was judged that an examination of the chyle at repeated intervals after a meal would give a correct measure of the rate of absorption. Zawilski (*Arbeiten physiol. Anstalt Leipzig*, 1876, 147) stated that in dogs the absorption of fat began two hours, and reached its maximum about 10 hours, after a meal. In the present research, it was judged advisable to make experiments with different varieties of fat.

Olive oil, to which 6.4 per cent. of free oleic acid was added, was taken as an instance of fluid fat. The chyle was analysed hourly. About 60 per cent. was recovered in 13 hours. Absorption began, as indicated by the rise in the percentage of fat in the chyle, between two and three hours, and reached a maximum from four to six hours, after the meal. The fat separated from the chyle had the characters of the fat in the food, except that it contained only 2.4 per cent. of free oleic acid. The soaps in the chyle corresponded with about 4 per cent. of the fat given. About one-fourteenth of the ethereal extract consisted of lecithin, and one-fourteenth of cholesterol. The proportion of lecithin:cholesterol:fat = 1:1:12. Hoppe-Seyler, in a case of chylo-thorax, gives the proportion 1:1.6:96; Hasebroek, in a case of chylo-pericardium, as 1:1.9:6.1 (*Abstr.*, 1888, 736).

Other researches were similarly made with mutton suet; about 55 per cent. was recovered in the chyle. The maximum was reached in the fifth hour, but the percentage of fat in the chyle remained

high until the eighth hour after the meal, or about two hours longer than in the case of olive oil.

Fatty acids were then given, pure erucic acid being selected. About 45 per cent. of this was recovered in the chyle, not, however, as the free acid, but in the form of the glyceride, erucin; the synthesis probably occurs in the epithelial cells of the intestinal mucous membrane; only a trace of soap was found in the chyle.

Lastly, spermaceti was given; again the chyle had the usual milky appearance. The fat appears to be broken up in the intestine into palmitic acid and cetyl alcohol; the former is absorbed, about 15 per cent. being recoverable in the chyle. It is not, however, absorbed as the free acid, but appears in the chyle as palmitin, the synthesis with glycerol occurring as before in the epithelial cells. This experiment thus furnishes the key to the *modus operandi* of the fact so often previously observed, namely, that animals will lay on normal fat even when fed on spermaceti and other unusual forms of fat. In experiments on dogs, even more spermaceti is absorbed than in man.

W. D. H.

Synthesis of Fatty Acids in the Animal Organism. By WATHER (*Chem. Centr.*, 1891, i, 189—190; *Centr. Physiol.*, 4, 590—591).—The author's experiments, the results of which support Munk's views, were made with dogs, some of which were fed on egg albumin and starch, whilst others had fatty acids in addition to this food, and the results showed that the lymph of the former contained very little either of fatty acids or fats, whereas the lymph from the latter contained little fatty acids but much fat, and since the mucous membrane of the stomach did not in any case contain any large amount of fats or fatty acids, whilst, on the other hand, that of the intestinal canal contained very considerable quantities of fat, the author concludes that it is here that the fats are synthetically formed from the fatty acids.

The author also found in the intestinal canal a crystalline substance, soluble in ether, which contains lecithin. The amount of lecithin found in the stomach and canal was too small to account for the glycerol in the fat formed.

J. W. L.

Butter Fat. By M. SCHRÖDT and O. HENZOLD (*Lamulo. Versuchs-Stat.*, 38, 349—371).—The object of the experiments was to ascertain the variations in the amount of insoluble and of volatile fatty acids in butter fat, and the relation of these variations to the period of lactation and to the feeding. The experiments, which extended over a year, were made with 10 cows (3 varieties). The winter feeding was meadow hay (6 to 7.5 kilos.), oat-straw (1.5 to 2.5 kilos.), beetroot (5 kilos.), wheat bran (3 to 4.5 kilos.), cotton cake (1 to 1.5 kilos.), and salt (20 grams). The cream was removed from the milk after 24 hours. The filtered butter fat was kept in well-closed bottles, and several samples examined together. Besides estimating the volatile and insoluble acids, the behaviour towards iodine and the refractive-exponents were observed. The volatile fatty acids were determined in 5 grams of fat by Wollny's method, and the insoluble fatty acids by Hehner's method (also in 5 grams). The amount of acid found is

expressed in c.c. of decinormal alkali; the "iodine numbers" are grams of iodine capable of being absorbed by 100 grams of fat. With regard to the volatile fatty acids, the results confirm those obtained by Nilson (*Bied. Centr.*, 18, 171); the amount depends on the period of lactation and not on the feeding. The amount of olein also depends on the period of lactation. The refractive exponent is a fairly constant number. Leaving out of account the four days subsequent to calving, the numbers vary as follows: volatile fatty acids, 21.70 to 34.33; iodine number, 27.38 to 43.46; refractive exponent, 1.458 to 1.463. The results are given in tables. The amount of volatile fatty acids is greatest about two months after calving, after which it decreases as the period of lactation progresses. The amount of olein, on the other hand, increases; and the amount of insoluble fatty acids is higher in late than in early periods of lactation. (Compare Mayer, *Abstr.*, 1889, 173, and Vieth, this vol., p. 507).

N. H. M.

Influence of Alkalis on the Glycogen of the Liver. By E. DUFOURT (*Chem. Centr.*, 1891, 188—189; from *Centr. Physiol.*, 4, 589—590).—The author has made seven parallel experiments, six with dogs, and one with a guinea-pig, on the action of sodium hydrogen carbonate on the amount of glycogen formed in the liver. The dogs were allowed to fast for four days, then fed with meat for 8—15 days, the amount being the same for each pair of dogs, and to one of each pair 2—5 grams of sodium hydrogen carbonate per day was given in addition. The dogs were then killed, and the amount of glycogen determined from the difference between the amounts of sugar present as such and that obtained after heating with hydrochloric acid. The following table gives the results:—

	Dog 1.		Dog 2.		Dog 3.		Dog 4.		Dog 5.		Dog 6.	
	No alk.	With alk.	No alk.	With alk.	No alk.	With alk.	No alk.	With alk.	No alk.	With alk.	No alk.	With alk.
Weight in kilograms ..	7.55	9.87	8.5	7.0	8.5	8.0	6.0	6.0	6.8	6.5	9.5	8.2
Weight of liver in grams ...	300	383	215	189	148	190	192	229	271	250	230	190
Sugar.....	1.64	3.06	1.5	2.52	1.35	2.43	2.49	3.01	1.62	2.16	2.93	2.56
Glycogen	1.39	5.18	1.5	1.60	0.62	2.28	0.15	3.78	0.09	2.33	1.36	1.43
Total sugar .	2.88	7.91	2.55	4.80	1.83	4.23	2.89	6.49	2.47	4.12	2.99	4.06
Total sugar per 100 of liver.	0.96	2.06	1.32	2.27	1.23	2.22	1.24	2.83	0.91	1.64	1.30	—

The experiment with guinea-pigs was carried out on similar lines, and the result was an increase in the amount of glycogen formed in the liver in every instance.

J. W. L.

Urea. By K. A. H. MÖRNER and J. SÖOQUIST (*Skandinav. Archiv Physiol.*, 2, 433—487).—In view of Schöder's hypothesis (*Arch. exp.*

Path. u. Pharm., 15, 364) that the liver cells form urea from ammonium salts, it was judged necessary to examine the amounts of urea and ammonia excreted in various liver diseases. In cases of cirrhosis, syphilis, and cancer of the liver there was an increased amount of ammonia, and lessened amount of urea found. The amount of extractive nitrogen was in some cases markedly increased, in others not. Also in cases where no liver disease was present, an increase of ammonia in the urine was sometimes noted; for instance, in a case of fatty heart, one of pyopneumothorax, and especially in a case of tetanus. In a case of ascites and pleurisy, the amount of extractive nitrogen was not increased, and the amount of ammonia was less than normal.

The various methods at present in vogue for the estimation of urea are discussed, and the following new one, ultimately adopted in carrying out the investigation:—

5 c.c. of urine is mixed in a flask with 5 c.c. of a saturated barium chloride solution, to which 5 per cent. of barium hydroxide has been added. To this was added 100 c.c. of a mixture of two parts of 97 per cent. alcohol, and one part of ether, and the whole allowed to remain in a closed flask until the next day. The precipitate is then filtered off and washed with the alcohol and ether mixture. The alcohol and ether are then distilled off from the filtrate (*plus washings*) at 55°. When the volume of the fluid reaches 25 c.c., a little water and magnesia are added, and the distillation continued until the steam has no longer an alkaline reaction, and the volume of the fluid is 10—15 c.c. Some drops of concentrated sulphuric acid are then added, and the whole placed in a flask on the water-bath. The nitrogen is estimated by Kjeldahl's method, and the amount of urea calculated from the nitrogen found.

W. D H

Schreiner's Base (Spermine). By A. JÜRGENS (*Chem. Centr.*, 1891, i, 193—194; from *Pharm. Zeit. Russ.*, 29, 726—732).—Owing to the uncertainty as to the identity of Pöhl's specimen of this base with that of Schreiner, the author has examined both specimens.

From the genital organs of the steer the author has isolated about 0.0003 per cent. of Schreiner's base, and his results substantiate Schreiner's. He considers that the characteristic odour of semen obtained from the aurochloride of the base after treatment with magnesium has only a negative value, since the mother liquors, from which the phosphate of the base had been separated, gave the same smell after like treatment.

From the spermine, after treatment with magnesium, a derivative is obtained which is also present in the testicles, and which must, therefore, be already formed in the semen. Pöhl's specimens, prepared during May, June, July, and August, contained no spermine. Ammonium phosphate and ammonia produced no crystalline precipitate, auric chloride precipitated an amorphous substance, platinic chloride gave cubical and not prismatic crystals. Calculated on the dry substance, the author found 54 per cent. of mineral matter and 43 per cent. of sodium chloride in a July specimen, in an August specimen 59.35 per cent. of mineral matter and 56.8 per cent. of salt,

whilst the dry substance contained in the "2 per cent." solutions amounted to 2.3 and 2.1 per cent. respectively, so that of the so-called spermine only about 1 per cent. was present. The biuret reaction for peptone was positive. J. W. L.

Diastatic Ferment in Urine. By ROSENBERG (*Chem. Centr.*, 1891, i, 185; from *Centr. Physiol.*, 4, 587—588).—The author found varying quantities of a diastatic ferment in human urine, the greatest quantities occurring a few hours after taking food. The ferment was detected both directly and indirectly after extraction with fibrin, by adding a little starch paste at the body temperature, and then testing for sugar with 5 per cent. potash or by Trommer's test.

Experiments with animals showed that ligaturing the ductus Stenoniani only increased the diastatic ferment in the case of herbivore, not with the carnivore, which only show traces of the ferment in the urine.

Trypsin and fat ferment were never detected in fresh human urine or in that of carnivore; in rabbits only when the ductus Wirsungianus was ligatured; with herbivore, after this procedure the diastatic ferment appeared in the urine. J. W. L.

Artificial Preparation of Sphæroliths of Uric Acid Salts. By W. EBSTEIN and A. NICOLAÏER (*Virchow's Archiv*, 123, 373—376).—If some uric acid be dissolved on a microscope slide in a dilute alkaline solution, and watched with the microscope, there is, after slight concentration, a formation of round particles of urates varying in diameter from 2 to 100 μ . These are mixed with needles, either singly or in bundles. As solvents, sodium hydroxide, potassium hydroxide, lithium carbonate, borax, ammonia, and piperazine were used; the best results were obtained by using the uric acid sediment from human urine.

With the polarising microscope between crossed Nicols, the sphæroliths showed a right-angled, black interference cross, the arms of which lay parallel to the polarisation planes of the Nicols, and, concentric with the middle point of this cross, coloured interference rings were seen.

Similar sphæroliths were obtained with sodium hydrogen carbonate, so that they may consist either of acid or normal urates.

The interest of such an observation as bearing on the formation of urinary calculi is pointed out.
W. D. H.

Pathology of Proteïds. By S. MARTIN (*Brit. Med. J.*, 1, 1891, 159—161).—The changes in structure that occur in a diseased tissue or organ are associated with chemical changes, and it is to certain changes in the proteïds, the most abundant constituent of most living structures, that attention was chiefly directed in the present research.

Although peptones and albumoses are formed in the alimentary canal, their presence elsewhere in the body is pathological, as during normal absorption they are regenerated into the blood proteïds. The action of micro-organisms during putrefaction is, first, similar to that of pepsin, namely, it forms albumoses and peptones, but, subsequently, ptomaines may make their appearance. Putrefaction (using the word in the wide sense of the changes due to microbes) is, moreover, a frequent factor in pathological processes, and albumoses and peptones are poisonous substances. If these poisons are formed in decomposing collections of cells, as in abscesses, empyema, phthisis, &c., they pass into the lymph and blood-stream, passing ultimately from the body by the urine, constituting what is generally termed peptonuria, but which should be more properly called albumosuria, the proteïd which is present being deuterio-albumose. Illustrative cases are quoted which show the amount of albumose in the pus and in the urine before and after the evacuation of the abscess, the albumose in the urine varying with the amount of accumulated pus.

One of the most striking features of pus-formation which is common to it and albumose poisoning is fever. It is possible that other factors have also to be considered; thus leucine, often found in pus, is a fever producer; alkaloids, if they do exist, have yet to be isolated.

In ordinary pus, the agent which forms the albumoses is probably not an enzyme, but the *Staphylococcus pyogenes aureus*; in tubercle, it may be the tubercle bacillus.

But the presence of albumoses in disease cannot always be ascribed to micro-organisms, as in glycosuria and osteomalacia. In osteomalacia the diseased bones contain an albumose similar to that excreted in the urine, and perhaps due to the rapid breaking down of lowly-organised cells. In the puerperal state, the origin of the albumose may be the degenerating cells of the hypertrophied uterus which is undergoing involution. The origin of albumoses in other cases, such as measles, is at present involved in obscurity.
W. D. H.

Specific Gravity of Blood in Disease. By S. M. COPEMAN (*Brit. Med. J.*, 1, 1891, 161—163).—The method used differs from that of Roy (*Abstr.*, 1887, 608), by the fact that the standard solutions of glycerol and water used contained considerable quantities of boroglyceride and magnesium sulphate, and a small amount of corrosive sublimate. These solutions keep perfectly.

A number of observations on the specific gravity of the blood, in cases of disease chiefly of an anæmic character, are recorded. It was

found that when a rise of density of the blood is produced artificially, as by a ligature round a limb, it is accompanied by a corresponding rise in corpuscular richness; and in cases of disease also, it appears that the number of corpuscles is an important factor, if not the most important. But in some cases, the specific gravity of the plasma must vary also, particularly in one case of pernicious anæmia, in which the specific gravity of the entire blood was only as high as that of normal plasma.

W. D. H.

Idiosyncrasy of certain Animals with respect to Phenol. By ZWAARDEMAKER (*Uumpt. reud.*, 112, 492—493).—Quantities of phenol insufficient to produce any evil effects on dogs and rabbits, throw cats and rats into violent convulsions, terminating in death from respiratory paralysis. As little as 11 milligrams per kilo. of body weight was sufficient to produce slight convulsions in an adult cat. This idiosyncrasy is probably due to a peculiar excitability of the nervous centres.

C. H. B.

Physiological Action of Thebaine, Narcotine, and their Derivatives. By R. STOCKMAN and D. B. DOTT (*Brit. Med. J.*, 1, 1891, 157—159).—In continuation of a previous research (*Abstr.*, 1890, 1178), certain opium alkaloids and some of their derivatives were studied, and the results confirm the conclusion previously arrived at, that the addition or substitution of certain radicles modifies very superficially the original action of the alkaloid.

Thebaine (vinyl ether of morphine, $C_{17}H_{19}(C_2H_3O)NO_2$, Grimaux) in physiological action belongs to the morphine group. It stands, however, at its extreme limit, and more closely resembles strychnine than morphine; a slight preliminary narcotic stage, observed after small doses, stamps it, however, as somewhat different from strychnine.

Methylthebainium sulphate, $(C_{15}H_{21}NO_3CH_3)_2SO_4$, is obtained by adding methyl iodide (1 mol.) to thebaine, and decomposing the iodide formed with silver sulphate. Its crystals are colourless, and freely soluble in water. From experiments on frogs and rabbits, the conclusion is drawn that the physiological action of the drug is not very different from that of thebaine; its tetanising power is, however, diminished, and its paralyzing action on cord and motor nerve terminations is increased.

Narcotine, $C_{23}H_{25}NO_7$, *cotarnine*, $C_{12}H_{13}NO_3$, and *hydrocotarnine*, $C_{12}H_{15}NO_3$, were also examined. These also all belong physiologically to the morphine group, their chemical differences altering their action in degree but not in kind.

Chemistry of Vegetable Physiology and Agriculture.

Cultivation Products of the Tubercle Bacillus. By E. M. CROOKSHANK and E. F. HERROUN (*Brit. Med. J.*, 1, 1891, 401—403).—In cultivations of the tubercle bacillus in glycerol broth, albuminous

substances of the nature of albumose and peptone were identified, and also a substance which gives the reactions of an alkaloid. The latter was, however, obtained in too small a quantity for more than a qualitative analysis. Injected into animals, symptoms similar to those produced by Koch's "tuberculin" were obtained.

Bacterial Decomposition of Cane-sugar with Formation of a New Lactic Acid. By F. SCHARDINGER (*Monatsh.*, 11, 545—559).—See this vol., p. 666.

Conversion of Starch into Dextrin by the Butyric Ferment. By A. VILLIERS (*Compt. rend.*, 112, 435—457).—See this vol., p. 659.

Formation and Migration of Carbohydrates in Leaves. By W. SAPOSCHNIKOFF (*Chem. Centr.*, 1891, i, 93—94; from *Ber. deut. bot. Ges.*, 8, 233—242).—1. *The Migration of the Carbohydrates out of the Leaves.*—The results of the author's experiments show that the carbohydrates pass out of the leaves much more quickly when on the plant, than when cut off and laid in water; that they pass from the leaves the more quickly, the fewer the number of leaves; and that this rate depends on the rapidity of growth. In spring and summer all the starch disappears in 1—2 days or less, whilst in winter the process occupies from 7—14 days. The starch is probably transformed into glucose previous to passing out of the leaf, and the rate at which this change takes place depends on the rate at which the soluble product, glucose, passes away. The starch contained in leaves cut off and placed in water remains for a week or more unchanged, whilst that in leaves on the plant frequently disappears in 12 hours.

2. *Formation of Carbohydrates.*—In order to determine the rate of formation of carbohydrates in the leaves, the amount actually present was determined, and the rate of migration was allowed for. The following figures, expressing the weight of carbohydrates in grams formed per square metre of leaf per hour, were obtained in this way for the varying states of the weather.

Plant—*Helianthus annuus*, sky-clear = 0.729 and 0.481; clear, but a few clouds = 0.594 and 0.428; clear, with frequent white clouds = 0.379; beclouded = 0.140, 0.147, and 0.141. For *Cucurbita pepo*, the following were found: clear sky = 0.403, and cloudy = 0.298, showing a more rapid formation under a clear sky.

In the case of leaves cut off the plant, the amount of carbonic anhydride assimilated is limited, probably owing to the collection of assimilated substance. A leaf, containing no starch, and which had been kept for two or three days in darkness, was better able to assimilate carbonic anhydride than one which had not been kept from the daylight, but which contained starch. From experiments on the assimilation of carbonic anhydride, it was found that there was not so much glucose formed in the leaf as corresponded with the amount of carbon absorbed, and the author concludes that some other substance is formed besides glucose.

J. W. L.

Assimilation of Nitrogen from the Air by Robinia pseud-acacia. By B. FRANK (*Chem. Centr.*, 1891, i, 93; from *Ber. deut. bot. Ges.*, 8, 292—294).—One seed of *Robinia pseudacacia* was allowed to germinate in each of a series of pots containing sterilised, nitrogen-free quartz sand, mixed with a non-nitrogenous nutrient solution. To the sand was added a small quantity of earth, taken from where old *Robinia* were growing. The germination and growth proceeded normally, and at the end of 125 days the plants were 22 cm. high, and had from 5—7 leaves each, which measured from 9—18 cm. in length. On the roots of each plant, a number of nodules had formed, varying in size from that of mustard seeds to that of a pea. Some of these were entirely empty, whilst others had commenced to undergo this process. The dry substance of four of the plants weighed 4.411 grams, and contained 0.092 gram of nitrogen; the nitrogen contained in the seeds of these plants amounted to 0.0024 gram. J. W. L.

Analysis of Milk of Ripe and Unripe Cocoanuts. By L. L. VAN SLYKE (*Amer. Chem. J.*, 13, 130—131).—The milk of the unripe nuts was transparent like water, containing in suspension a little cloudy-white substance, which was readily removed by filtration. In the ripe nut, the milk was quite turbid in appearance, and did not filter clear. The specific gravity was determined by a picnometer, water by drying at 60°, and proteids by Gunning's modification of Kjeldahl's method. Hammerbacher's analysis probably refers to ripe cocoanuts.

Analyses of Beetroot Seed. By N. LASKOWSKY (*Landw. Versuchs-Stat.*, 38, 317—319).—The analysis of the seeds gave the following results:—Water, 10 per cent.; proteids, 20.13; fat, 17.05; crude fibre, 4.54; ash, 3.74; cellulose free from nitrogen, 44.54. Various

samples were examined with regard to the quantity of fat contained in the seed; the percentages found varied from 23·09—20·76.

E. W. P.

Composition of Drainage Waters. By P. P. DEHÉRAIN (*Compt. rend.*, 112, 465—469).—Experiments were made with soils from different parts of France, two from the north and two from the district of Limagne, in the Auvergne. The experimental pcts contained 50 kilos., and the results are calculated to kilos. per hectare; from March to December, 1890, the quantity of nitric nitrogen lost in the drainage waters was as follows:—

Soil from—	
Wardrecques (Pas de Calais)	152·4
Blaringhem (Nord)	128·1
Marmilhat (Puy de Dome)	62·5
Palbost (Puy de Dome)	45·2

The soils from the north lose a much greater quantity of nitrates, although they are poorer in nitrogen than the soils of Limagne. No definite relation could be traced between the quantity of nitrates formed in the soil and the quantity of water retained. The smaller quantity of nitrates in the soils of Limagne is probably due to the fact that they contain a large quantity of organic matter, which, as Warington and Winogradski have shown, retards nitrification. The two soils from the north lose their fertility rapidly, owing to the great loss of nitrates in the drainage, and they require constant manuring, whilst the soils of Limagne require much less constant attention.

The quantity of nitrates in soils is usually deficient in spring, but nitrification proceeds rapidly in the autumn, and after harvest there is often great loss of nitrogen in the drainage. During October, 1889, soils at Grignon lost 72·2 kilos. of nitric nitrogen per hectare. The author has previously proposed to sow, after harvest, some rapidly growing plant, such as mustard, rape, or colza, in the hope that these crops would retain the nitrates, and when worked into the soil in the late autumn, or in spring, would restore to the soil the nitrogen which would otherwise have been lost in the drainage, besides providing a useful organic manure. Experiments in this direction were made in the autumn of 1890, and, although the season was unfavourable, the results were satisfactory. From July to November there was very little rain, and the consequent dryness of the soil retarded nitrification, so that the loss in the drainage of bare soils was much below normal. From November 1st to 7th, 1890, the loss of nitric nitrogen in kilos. per hectare from bare soils was as follows:—

Beet-root gathered in October	7·5
Maize gathered in August	14·5
Hemp gathered in August	10·5

With a protective crop, the loss during the same period was very small indeed.

Colza, after oats	0·37
Rape, after peas	0·51

If the protective crop is killed by frost before it has been worked into the soil, its efficiency disappears. Colza, however, will live through the winter in comparatively mild climates, and in severe climates, since the loss by drainage during December is always very small, the crop may be worked into the ground in November.

Whether the nitrogen retained will repay for the cost of seed and of labour depends on circumstances, and especially on the actual value of the loss by drainage. It seems to be better to use *Leguminosæ* with *Cruciferae* for the protective crop, instead of *Cruciferae* alone, but the author will report subsequently on experiments in this direction.

Analytical Chemistry.

Reactions for Microchemical Mineral Analysis. By H. BEHRENS (*Jahrb. f. Min.*, Beilage 7, 434—470).—By the investigations of Haushofer and of Streng the employment of the microscope in chemical investigations has been greatly extended. The method was originally confined to the identification of the rock-forming minerals. At the present time, it forms a valuable aid to qualitative analysis. The saving of time, of material, and of working space presents such great advantages for the microchemical method, that anyone who has had practice with this method would invariably use the microscope for certain reactions, such as for potassium, calcium, and magnesium. The author has, therefore, prepared this paper, which is too lengthy to admit of complete abstraction, giving complete instructions for conducting microchemical mineral analyses. After giving details as to the mode of dissolving the material to be examined, he deals with decantation and filtration, sublimation, evaporation, instruments, and reagents, and finally devotes 28 pages to an enumeration of the microchemical reactions of the various elements, arranged in alphabetical order.

B. H. B.

Apparatus for the Estimation of Water in Mineral Analysis. By T. M. CHATARD (*Amer. Chem. J.*, 13, 110—113).—Many minerals lose the whole of their water only when heated for a considerable time at a temperature at which glass softens; for such, the author employs a platinum tube. A figure in the original paper represents a convenient form of tube, and an air-bath specially adapted for the preliminary drying before the ignition. The tube is 250—300 mm. long, and 16 mm. external diameter; it tapers at one end into a tube 80 mm. long and 5 mm. diameter, to which is sealed a glass adaptor, for connection with the absorption apparatus. The other end of the larger tube is fitted with a collar of phosphor-bronze, into which fits a perforated stopper of the same metal. That portion of the tube which is to be heated, is rendered impervious to the gases of the flame, and at the same time protected from injury, by a wrapping of asbestos-paper soaked with a saturated solution of borax; this is in

its turn covered with a sheet of platinum foil, and then highly heated and slowly cooled. The platinum boat containing the substance is placed in a cylinder of platinum foil, closed at the end nearest the stopper by a cap, in which there is a small hole to allow of the passage of the air current; this cylinder, whose object is the prevention of loss by spurling, is thrust into the coated portion of the large tube, together with two rolls of platinum gauze, one at each end of the cylinder.

A. G. B.

Detection and Estimation of Hydrochloric Acid in Gastric Juice. By A. FAWIZKY (*Virchow's Archiv*, 123, 292—309).—Hydrochloric acid is usually detected in the gastric juice by means of certain colour reactions. It is well known that proteids form, with hydrochloric acid, loose combinations, and the presence of these substances may, therefore, interfere with tests for the acid. These substances, or their digestive products, conveniently grouped under the heading peptone, are apt to occur in the stomach; hence the necessity of ascertaining correctly the value of these colour reactions in their presence. Ewald (*Zeit. Klin. Med.*, 1, 619) pointed out that the presence of peptone interferes with the methyl-violet and tropeolin reactions. Seemann (*ibid.*, 5) made some qualitative experiments in the same direction; and Moritz (*Deutsch. Arch. Klin. Med.*, 13), from observations on two healthy persons, found that the reactions with congo-paper and tropeolin did not succeed when the proportion of peptone to acid exceeded 8 or 12 to 1. In the present research, attention was particularly directed to the most delicate of these colour tests, namely, the methyl-violet reaction, and Günsburg's phloroglucinol reaction, with the result, similar to that obtained by Moritz, that the reactions did not succeed when the proportion 9 : 1 was exceeded.

The acidity of gastric juice may be due to hydrochloric acid, lactic acid, and fatty acids; and the question next investigated was whether an approximate estimation of the hydrochloric acid might be made by simply titrating with standard alkali, supposing that lactic acid, as tested for by Uffelmann's reaction, was absent; it was found that such a simple method gives fallacious results.

The best method is considered to be that of Sjöquist (*Abstr.*, 1889, 302); the end reaction is, however, rather obscure, and several modifications have consequently been suggested. Thus, v. Jaksch (*Sitzungsber. Wien. Akad.*, 98, Abth. 3, 1890) estimates the barium chloride, gravimetrically, as the sulphate. Salkowski suggested to the author a modification which would not be so lengthy as this, and a series of experiments on artificial mixtures of hydrochloric and lactic acids, and peptone shows that it is equally delicate. The method consists in adding excess of barium carbonate to 10 c.c. of the test liquid, evaporating to dryness, and burning off the organic residue. The barium chloride is extracted with hot water, filtered, and sodium or ammonium carbonate added to the filtrate, until the barium is completely precipitated as carbonate. The precipitate is collected, washed with water until the washings give no reaction with silver nitrate; it is then dissolved in hydrochloric acid, evaporated

to dryness, dissolved in water, and the chlorine titrated with a standard silver nitrate solution, with potassium chromate as indicator. The solubility of barium carbonate in water is so slight as to make no practical difference in the result.

Bourget's modification (*Arch. Med. exper. Anat. Pathol.*, p. 444) is very similar. He dissolves the barium carbonate in a known quantity of hydrochloric acid, and then titrates with normal soda.

W. D. H.

Mode of Combination of Sulphuric Acid in Plastered Wines, and the Detection of Free Acid in Wines. By L. MAGNIER DE LA SOURCE (*Compt. rend.*, 112, 341—343).—The author criticises the paper of Roos and Thomas, and considers that when a wine has been thoroughly plastered, some of the potassium must necessarily be present as hydrogen sulphate when a formation of potassium hydrogen tartrate has taken place.

Sulphuric acid added to wine in quantity exceeding 1 gram per litre cannot be detected in the ash, unless potassium carbonate is added before evaporation. This is the limit at which the presence of the acid can be distinctly recognised by the taste.

C. H. B.

Separation of Titanium, Chromium, Aluminium, Iron, Barium, and Phosphoric Acid in Rock Analysis. By T. M. CHATAUD (*Amer. Chem. J.*, 13, 106—110).—The author asserts that success with this process, which is a combination of several methods, depends on careful attention to numerous details, for which the original must be consulted. The following gives an outline of the process. Silica is eliminated by evaporation with sulphuric and hydrofluoric acids. The residue is treated with hydrochloric acid, which leaves barium sulphate and unattacked minerals; fusion with sodium carbonate decomposes the latter, and enables the barium to be determined. The original hydrochloric acid solution and the various secondary solutions obtained during the fusion and the precipitation of the barium, all of which should contain the chromium and iron as sesquioxides, are mixed, precipitated with ammonia, the precipitate redissolved, and again precipitated to eliminate magnesium. The precipitate is once more dissolved, the solution evaporated, and the residue fused with sodium carbonate and nitrate. The melt is dissolved in water, and the titanium determined in the insoluble portion by Gooch's method (*Proc. Amer. Acad.*, 12, 435; *Abstr.*, 1886, 492). The solution containing chromic and phosphoric acids is heated with ammonium nitrate as long as aluminium phosphate and hydroxide are precipitated; the phosphoric acid is determined by the molybdate method. The filtrate is precipitated with ammonia and ammonium sulphide; the precipitate is dissolved, the solution oxidised, evaporated, treated with sodium hydrogen carbonate, and filtered after some hours; this eliminates any remaining alumina, after which the chromium is reduced, and precipitated with ammonium sulphide.

A. G. B.

Quantitative Estimation of Pentaglucooses (Pentoses) in Vegetables. By G. DE CHALMOT and B. TOLLENS (*Ber.*, 24, 694—695).—The authors have improved the method of Günther and

Tollens (Abstr., 1890, 1352). The decomposition of the substances is effected as before, with hydrochloric acid, but the furfuraldehyde, instead of being titrated, is precipitated with phenylhydrazine acetate, and the hydrazone weighed. The distillation is conducted on a bath of Rose's metal, with hydrochloric acid of sp. gr. 1.06 (100 c.c.), fresh portions of the latter being added until the distillate no longer gives the furfuraldehyde reaction. It is then made faintly acid with acetic acid, and in a determinate volume, precipitated with phenylhydrazine acetate, the hydrazone being collected in an asbestos filtering tube, dried in a special drying apparatus in a vacuum at 50–60° and weighed; a correction is applied for its solubility.

Arabinose, when small quantities (0.2 gram) are taken, yields 52.7 per cent., and with larger quantities (0.5 gram), 47.7–50.2 per cent.; and xylose, 56–59 per cent. of furfuraldehyde. The mean yield is: Arabinose, 48.72 per cent.; xylose, 56.25 per cent.; and pentaglucofoses (pentoses), generally 52.5 per cent. of furfuraldehyde.

Quantitative estimations of pentaglucofoses (pentoses) in the under-mentioned substances (of which 2–5 grams were taken), by this method gave the following results:—

Cherry gum	45–46 per cent. Arabinose.
Wheat-straw	24.9 „ xylose.
Oat-straw.....	22.6 „ „
Beech-wood.....	19.7 „ „
Fir-wood	7.8 „ „

Duplicate estimations of the above gave a maximum difference of 0.6 per cent. of furfuraldehyde. It is thus established that pentaglucofoses (pentoses) are very widely distributed in nature.

A. R. L.

Estimation of Invert-sugar in Molasses. By STRIEGLER (*Chem. Centr.*, 1891, i, 211–212; from *Zeit. Vereins Rubenzuckerind.*, 1890, 418, 964–975).—The author prefers Soldaini's reagent to that of Nessler for the determination of the invert-sugar in molasses, and he also prefers clearing with sodium carbonate and "blood-charcoal" to lead acetate. He recommends the following method:—10 grams of molasses is weighed and dissolved in a 100 c.c. flask with 70 c.c. of water, precipitated with sodium carbonate, and warmed at 90–95°, until the precipitate becomes dense, then cooled by immersion in cold water, diluted to 100 c.c., and shaken with 1–2 grams of blood-charcoal. 50 c.c. of the filtrate is added to 100 c.c. of Soldaini's reagent, which must be in a state of ebullition; the liquid is heated further until boiling again commences, boiled for four minutes, and allowed to rest for one minute. It is then filtered through a double filter, and after one-half or two-thirds of the filtrate has passed through, it is returned to the filter again, after which the precipitated cuprous oxide is washed with potassium hydrogen carbonate solution, until free from cupric sulphate, and then finally washed with hot-water.

From the author's results, 50 milligrams of invert-sugar reduce

from 140.5 to 144.5 milligrams of copper; Herzfeld found 133.8 milligrams; Bodenbender and Scheller found 141—142 milligrams.

J. W. L.

Estimation of Free Fatty Acids in Fodder. By G. LOGES and C. CLAESSEN (*Landw. Versuchs-Stat.*, 38, 314—316).—Four methods of estimating the free fatty acid in fodders were compared for accuracy. The methods were:—(1) to extract with ether, and titrate after previous drying for three hours; (2) after three hours' drying, to add alcohol to the ethereal extract, and then titrate; (3) without previous drying, to extract and treat as in (2); (4) to digest for three hours in cold ether, and titrate aliquot portions of the filtrate, with addition of alcohol; an alcoholic solution of sodium hydroxide was employed, and phenolphthaleïn used as indicator. Results:—(1) gives too low values, as in estimating the fat of many fodders a loss occurs by volatilisation during drying, and also the drying of the ethereal extract results in loss by volatilisation. Methods (3) and (4) yield results which agree well together, and these two methods are the only ones which can be recommended to produce trustworthy results.

E. W. P.

Alterability of some Food-fats. By O. REITMAIR (*Landw. Versuchs-Stat.*, 38, 373—400).—The acidity, behaviour towards iodine, and the behaviour when saponified, of several fats was investigated. The following are the most important results:—Earth-nut fat is very changeable. When fresh it is nearly clear and thin, with a slight and agreeable taste and odour; it contains no free fatty acids, and its saponification number is the least, and the iodine number the highest, of any observed.

The expressed earth-nut oil changes slowly; only when much exposed to light it becomes, after a long time, viscous and rancid, and has then a lower iodine number and a higher saponification number.

The fat in earth nuts changes slightly when the outer shells remain uninjured. The fat of earth-nut cake changes most, and especially when the cake is poor in fat. The "acid number" of the fat rises quickly after the pressing out. The iodine number may sink to one-third of its original value, especially in the case of old and bad nuts.

To judge of the freshness of earth-nut cake from the character of the fat, the appearance of the fat is the first thing to be considered. If solid at the ordinary temperature, much free fatty acid is present, and the less there is of fatty acid the softer the fat will be. The high iodine number of the fat is the best criterion for the freshness of the cake, and of the seed from which it was prepared.

N. H. M.

Detection of Tannin in Plants. By T. WAAGE (*Chem. Centr.*, 1890, ii, 1030; from *Apoth. Zeit.*, 5, 685—686).—The author considers a solution of perfectly anhydrous ferric chloride in ether to be the best reagent for tannin in plants, since the aqueous solution reacts with other substances besides tannin. Iodine and zinc chloride has the objection that it reacts with gallic acid. Potassium di-

chromate is a very delicate reagent, but reacts also with hydroxy-aromatic substances. The author discusses the values of the reagents recommended by Loew and Bokorny, Gardiner, Darwin, Moll, and Klercker. Pfeffer's reaction, the fixing of aniline dyes, applies not only to tannin, but to phloroglucinol also. J. W. L.

Estimation of Urea. By K. A. H. MÖRNER and J. SJÖQUIST (*Skandinav. Arch. Physiol.*, 2, 438—487).—See this vol., p. 758.

Determination of Nicotine in Presence of Ammonia. By A. PIZZOLATO (*Gazzetta*, 20, 780—798).—The method proposed by the author is based on the neutral reaction of a solution of nicotine in 96° alcohol to litmus and alizarin, and on the insolubility of normal ammonium sulphate in alcohol of the same strength. The substances containing the nicotine and ammonia must be distilled in a current of steam with some alkali, which does not decompose nicotine, and the distillate collected in a known volume of normal sulphuric acid sufficiently large to yield the acid salts of the base. The best alkali for distilling with the materials from which the nicotine is to be separated is magnesia, as this has no action on either nicotine or the associated proteid matters. The distillate is then reduced by evaporation to a volume of 50—100 c.c., coloured with a drop of litmus or alizarin, titrated with a decinormal or normal solution of potash or soda, and evaporated to dryness on the water-bath; the residue, which consists of the sulphates of nicotine, ammonium, and potassium or sodium, is taken up with 60 c.c. of alcohol (98—99°), which dissolves only the nicotine sulphate. The solution is titrated in presence of the insoluble salts with an alcoholic decinormal solution of potash or ammonia (prepared by mixing 100 c.c. of a normal aqueous solution with 900 c.c. of absolute alcohol), finishing as soon as the suspended salts become slightly coloured. For every 30 c.c. of the decinormal solution used, an addition of 20 c.c. of 98—99 per cent. alcohol must be made to maintain the alcoholic strength of the solution. The partial dissociation (1.3 per cent.) of the ammonium sulphate, on evaporating to dryness, renders a slight correction necessary. The amount of acid found to represent the ammonia present must be multiplied by 1.013 to obtain the real figures, and the difference must be subtracted from the quantity of acid representing the nicotine. The necessity for making this correction may be avoided by re-acidifying the sulphuric acid solution after titration, and before evaporating to dryness, and adding to the dry residue a quantity of alkali corresponding exactly with the amount of acid added; taking care that the strength of the alcoholic solution titrated does not fall below 96—97°.

A large number of experiments are given to prove the accuracy of the above methods. S. B. A. A.

Estimation of Morphine. By G. LOEFF (*Chem. Centr.*, 1890, ii, 1034; compare *Abstr.*, 1890, 1349, and Dietrich, this vol., p. 511) - - Replying to Dietrich's criticisms on his method, the author contends that the employment of potassium carbonate has its advantages;

that since he has found calcium sulphate in morphine extracts, the precipitation as oxalate is not unnecessary; that a concentrated extract of opium contains a larger quantity of colouring matter than a dilute one: and that it is better to evaporate the ether layer, because morphine has been found in it after ten minutes' shaking.

J. W. L.

The Assay of Quinine Sulphate by the Ammonia Process. By L. PRUVIER (*J. Pharm.* [5], 23, 163—170).—After an examination of the whole process, the following procedure is recommended. The sulphate is dried at 100°, and an amount is weighed off equivalent to 2 grams of the original sample, agitated with 35 parts of water (calculated on the anhydrous salt) boiled for one or two minutes to complete solution, and, after replacing the water boiled off, the solution is allowed to cool to 15°, and filtered at that temperature. 5 c.c. of the filtrate is measured into each of three flasks, and ammonia of 0.96 sp. gr. is run steadily in to the first one until a slight precipitate remains undissolved; this, for example, may take 7.5 c.c. The second flask, with 8 c.c., may yield a slight opalescence. Finally, the third receives 8.5 c.c., and gives a transparent liquid; if this remains transparent for about a quarter of an hour, the assay indicates 8.5 c.c. But if the second flask becomes clear after some minutes, and remains limpid, then 8 c.c. is the definite result.

J. T.

Toxicological Observations. By F. CIOTTO and P. SPICA (*Gazzetta*, 20, 619—631).—After pointing out the indecisive character of the tests hitherto proposed for vegetable alkaloids in presence of ptomaines, the authors describe some observations of cases of suspected poisoning with atropine, and their experiments with animals and solutions of atropine, from which they draw the following conclusions:—(1.) Vitali's reaction for atropine is only slightly less sensitive than the mydriatic action, 0.0000002 gram being the smallest amount that can be distinctly detected by the former method; rabbits dosed with slightly less than this amount should be kept under observation for at least half an hour. (2.) The changes which an aqueous solution of atropine undergoes (Flückiger, *Pharm. Chem.*, 1888, 542) are accelerated by exposure to light, and probably by dilution and a moderately high temperature; free atropine is more readily altered than its salts, and the product in any case does not respond to either the chromatic or the physiological test. (3.) In the extracts from two human bodies, obtained by the Stas-Otto method, Vitali's reaction was obtained in the absence of atropine; some ptomaine capable of giving this reaction must therefore exist in putrefied animal remains. (4.) It appears that purification of the extracts, whilst removing a considerable portion of the atropine when present, only partially removes this ptomaine.

The authors hold that in medico-legal investigations evidence of the presence of a poison cannot be considered conclusive unless its characteristic chemical reactions, together with its physiological effects, are severally and satisfactorily exhibited.

General and Physical Chemistry.

Relations between the Lines of Various Spectra. By W. N. HARTLEY (*Phil. Mag.* [5], 31, 359—363).—A reply to some criticisms on the author's work by J. S. Ames (this vol., p. 2). J. W.

Absorption Spectrum and Colour of Liquid Oxygen. By K. OLSZEWSKI (*Ann. Phys. Chem.* [2], 42, 663—665).—In his former examination of the absorption spectrum of liquid oxygen (Abstr., 1887, 625), the author found bands corresponding with the wave lengths 628, 577, 535, and 480. Liveing and Dewar (Abstr., 1891, 1), on examining the absorption spectrum of gaseous oxygen under high pressure, found the same four absorption bands in the visible part of the spectrum, and also two bands in the extreme red corresponding with the Fraunhofer lines A and B.

The author has lately had occasion to prepare liquid oxygen in some quantity and has repeated his examination of the absorption spectrum, more particularly in the extreme red. The column of liquid oxygen obtained had a thickness of 30 mm., and was 50 mm. in height. It was contained in a thin glass vessel surrounded by three glass beakers, in order to protect it, as far as possible, from outside heat. In this condition it was found possible to keep a sufficient quantity for the purpose in view, under atmospheric pressure and at its boiling point -181.4° , for over half an hour. The observations gave the four absorption bands before obtained, and also a fifth corresponding with the Fraunhofer line A. This band is of less intensity than those of wave-lengths 628, 577, and 480, but stronger than the band 535. An absorption band corresponding with the Fraunhofer line B was not observed.

Liquid oxygen, as first obtained in small quantity in 1883, was described as being colourless. Since then the author has repeatedly had under examination liquid oxygen in larger quantities, and he has invariably noticed that a layer of greater thickness than 15 mm. has a distinctly blue colour by transmitted light. In the above experiments, in which liquid oxygen was employed in larger quantity than had hitherto been the case, the pale-blue colour of the liquid was particularly noticeable. As special precautions were taken in purifying the gas, and the absence of ozone was ascertained by special tests, there seems no reason to doubt that the colour observed is characteristic of oxygen in the liquid state. In the author's opinion, the blue colour of the sky is therefore probably due to the oxygen in the atmosphere, since this element, at any rate in the liquid condition, is blue in colour. H. C.

New Method of Investigating Faint Bands in Spectra; Spectra of Hydrocarbons. By H. DESLANDRES (*Compt. rend.*, 112, 661—663).—The bands λ 438.19, λ 437.13, and λ 436.5 observed,
VOL. LX. 3 f

together with the ordinary bands of hydrocarbons and of cyanogen, in the electric arc and in the combustion of cyanogen, have been variously attributed to cyanogen and to hydrocarbons. The application of the method of calculation previously described (Abstr., 1888, 637), shows that from the known 16 bands of hydrocarbons the positions of the three bands in question can be accurately calculated, and hence the author concludes that they really belong to the hydrocarbons. Calculation indicates the presence of bands at λ 408.35 and λ 408.17, but they will be very feeble, and will be more or less hidden by the intense bands of cyanogen.

C. H. B.

Refraction and Dispersion of Fluorobenzene and Allied Compounds. By J. H. GLADSTONE and G. GLADSTONE (*Phil. Mag.* [5], 31, 1—9).—The following table contains the index of refraction of fluorobenzene, as determined by the authors, for the principal lines of the solar spectrum, together with the customary optico-chemical values deducible from these numbers. The temperature of observation was 22.8°:—

	A.	C.	D.	F.	G.	H.
Refractive index, μ	1.4563	1.4606	1.4646	1.4751	1.4819	1.4933
Molecular refraction, $\frac{\mu-1}{d} M$	42.92	43.33	43.70	44.68	45.61	46.40
Atomic refraction of fluorine	0.63	0.63	0.53	0.48	0.44	0.35

It thus appears that the atomic refraction of fluorine in organic compounds is very small compared with that of chlorine, bromine, and iodine, the values for which are 10.00, 15.23, and 25.20 respectively for the line A. The atomic dispersion of fluorine, too, is anomalous, the refraction being less at the blue end of the spectrum than at the red. A consideration of various inorganic fluorides served to confirm the above results with regard to the optical properties of fluorine.

J. W.

Dispersion of Carbon Compounds: Ethereal Salts. By P. BARBIER and L. ROUX (*Compt. rend.*, 112, 582—584; compare Abstr., 1890, 1353).—In the ethyl salts of acids of the acetic series, and in the acetates of the radicles of the methyl series, allyl, and benzyl, the specific dispersion increases with the molecular condensation. The mean difference between the molecular dispersive powers of two consecutive homologues is practically constant, and is equal to 7.5. The molecular dispersive power of the alkyl salts is equal to the algebraic sum of the molecular dispersive powers of its components. Isomerides, such as ethyl formate and methyl acetate, have very different dispersive powers.

C. H. B.

Relations between Dispersion and Chemical Constitution. By J. W. BRÜHL (*Zeit. physikal. Chem.*, 7, 140—193).—After giving a short historical survey of the work already done on the optical

dispersion of organic substances, the author proceeds to discuss the merits of the various dispersion constants which may be adopted. He rejects the expression for the specific dispersive power used by Barbier and Roux, namely, $\frac{B}{d}$, where B is the second member of

Cauchy's dispersion formula, and d the density (Abstr., 1890, 673), on the ground that it is theoretically without foundation and inexact in practice; and prefers to follow the example of Gladstone, who simply subtracts the specific refractive powers for two different wavelengths in order to obtain the specific dispersive power. Instead however, of employing the empirical refraction constant, $\frac{n-1}{d}$, used

by Gladstone, he takes the "theoretical" constant $\frac{n^3-1}{(n^2+2)d}$, so that his expression for the molecular dispersive power becomes

$$\left(\frac{n_v^3-1}{n_v^3+2} - \frac{n_a^3-1}{n_a^3+2} \right) \frac{M}{d};$$

the light used being H_α and H_γ (Fraunhofer, C and f). This formula is practically independent of the temperature, and varies only very slightly even when the substance passes from the liquid into the gaseous state, which gives it the preference over Gladstone's formula.

From the data available for isomeric substances of the fatty series with similar distribution of valencies, it follows that the position of the atoms in the molecule has little, if any, influence on the dispersive power: on the other hand, if the distribution of the valencies is different in two isomeric substances (for example, allyl alcohol and propaldehyde) then the specific and molecular dispersive powers are also different.

The following homologous series of C_nH_{2n+2} or paraffinoid derivatives were investigated:—alcohols, ethers, bromides and iodides, aldehydes, ketones, acids, ethereal salts, and acid chlorides. It was found that in all these series there is a constant difference in molecular dispersive power for a difference in composition of CH_2 : the value ranges from 0.104 (aldehydes) to 0.119 (iodides), and is in the mean 0.110.

In the case of the olefins and benzene derivatives, the difference is not constant, but as the data here are limited no safe conclusion can be drawn.

The author, from the material he has collected, revises the values for the atomic refractive powers to be attributed to the elements, and also gives numbers for the atomic dispersion. He distinguishes between oxygen united to 2 atoms of carbon (ether oxygen) and oxygen united to 1 atom of carbon and 1 of hydrogen. The following table contains his results (p. 776).

It is thus apparent that the dispersive power is essentially additive in character, but profoundly modified by structural influences. A glance at the table further shows that there is no simple relation between the refractive and the dispersive power of substances.

	Atomic refraction.		Atomic dispersion.
	Old values.	Revised values.	
Singly bound carbon	2.48	2.365	0.039
Hydrogen	1.01	1.103	0.036
Hydroxylic oxygen	1.58	1.506	0.019
Ether oxygen		1.655	0.012
Carbonylic oxygen	2.34	2.328	0.086
Nitrogen (singly bound to carbon only)	3.02	2.76	0.19
Chlorine	6.02	6.014	0.176
Bromine	8.95	8.863	0.343
Iodine	13.99	13.808	0.774
Ethylene linking	1.78	1.836	0.23
Acetylene linking	1.97	2.22	0.19

The data for the olefines and the derivatives of benzene throw no light on the distribution of the bonds in the latter: one can only say that the nucleus is certainly not held together by nine ordinary fatty bonds. A few cinnamyl compounds were investigated. These substances have an abnormally high dispersive power, and this the author is inclined to attribute, with Gladstone, to the presence in them of an unsaturated carbon atom directly bound to the benzene nucleus. When a carbonyl group is linked to an unsaturated carbon atom, as in acraldehyde, the dispersive power is here also unusually great.

J. W.

Optical Properties of α -Bromonaphthalene. By B. WALTER (*Ann. Phys. Chem.* [2], 42, 511—512).— α -Bromonaphthalene, in addition to having a strong dispersive power, is very transparent to ultra-violet rays. This combination of optical properties makes the substance an important one in researches on fluorescence, phosphorescence, &c. The coefficient of refraction alters comparatively little with the temperature.

J. W.

Phosphorescence of Minerals under the Influence of Light and Heat. By H. BECQUEREL (*Compt. rend.*, 112, 557—563).—Various forms of fluor spar from various sources were excited by light, heat, and the electric spark, and the spectrum of the phosphorescence was examined. Measurements of the wave-lengths of the bands are given. In the phosphoroscope, the bands that are visible or have the highest intensity vary with the speed of rotation of the disc, a result due, according to the author, to differences in the persistence of the phosphorescence of the various substances that are present in the fluor spar and give rise to the different spectra. The electric spark excites phosphorescence in the same way as sunlight, and the spectra are the same; the effect is more intense with the spark than with sunlight, probably because of the high proportion of rays of high refrangibility in the former. When the fluor spar is

heated, a limited quantity of energy is set free in the form of luminous vibrations, but if the heating is continued, the phosphorescence ceases. It can, however, be restored by exposing the substance to light or the electric spark. The bands in the spectrum when the substance is heated, have the same positions as in the phosphroscope, but they have different relative intensities. The relative intensities also vary with the temperature. Phosphorescence under the influence of heat belongs in fact to the same class of phenomena as phosphorescence excited by light. C. H. B.

Experiments with Selenium Cells. By S. BIDWELL (*Phil. Mag.* [5], 31, 250—256).—Selenium cells made in the manner suggested by the author (*Nature*, 23, 58) gradually lose their great resistance and also their sensibility to light. Only one cell out of 13 retained its original sensitiveness over a space of 10 years. A current from a 26-volt battery, passed through a selenium cell with copper electrodes for two days, deposited amorphous selenium and an oxide of selenium at the anode. The resistance of the cell was then different, according as the current passed from anode to cathode or from cathode to anode. When a piece of magnesium ribbon was burnt near this cell, a current from anode to cathode was indicated by the galvanometer, which ceased when the light was extinguished. The current was proved not to be due to thermoelectric action.

J. W.

Chemistry of Secondary Batteries. By J. H. GLADSTONE and W. HIBBERT (*Phil. Mag.* [5], 31, 42—44).—Frankland (*Abstr.*, 1890, 842) has contended that the lead compounds which play the chief part in the chemical reactions taking place on the charging and discharging of secondary cells are subsulphates. The authors have already shown that one of these is not a definite compound (this vol., p. 3), and now prove that the second substance, $Pb_3S_2O_{10}$, derived from sulphuric acid and red lead, may be decomposed by a solution of ammonium acetate, which dissolves out lead sulphate and leaves behind lead peroxide.

An analysis of the residue left by the action of pure dilute sulphuric acid on spongy lead during a period of five months, gave the composition 82 per cent. lead sulphate, and 18 per cent. metallic lead. Only 11 per cent. of metallic lead remained when the acid in a similar experiment was mixed with sodium sulphate.

J. W.

Electrical Phenomena Developed in the Formation of Solid Carbonic Oxide. By G. HAUS-KNECHT (*Der.*, 24, 1031—1032).—Solid carbonic oxide is easily obtained by allowing the liquid compound contained in an iron cylinder to evaporate rapidly into a bag of sail cloth. When a bag of 1—2 litres capacity is employed, and the experiment conducted in the dark, a pale, greenish-violet light is observed in the bag, and electric sparks of 10—20 cm. in length shoot out through the pores of the bag. If the hand is brought in contact with these sparks, the same pricking sensation is felt as is produced by an electrical machine. The cause of these electrical phenomena is probably the same as in Armstrong's gas electric

machine. The carbonic oxide as it rushes out from the cylinder is pressed rapidly through the fine openings in the sides of the bag, and thus is strongly rubbed, and also causes small quantities of the liquid and solid to rub together. An essential condition for success is the absence of air in the carbonic oxide employed. The phenomenon of light is first developed when a crust of solid carbonic oxide of 0.5—1 cm. has formed in the bag. The author is engaged in investigating the nature of the phenomena and determining the quantity of electricity developed. E. C. R.

Specific Inductive Capacity of Electrolytes. By E. B. ROSA (*Phil. Mag.* [5], 31, 188—207).—The author studied the specific inductive capacity of water and alcohol by measuring the force exerted between a fixed and a movable electrode in an electrolytic cell. The following is a summary of his results:—

(1.) The expression for the force between two electrodes having a homogeneous medium between them is of the form $F = AKV^2$, where F is the force, A a constant, K specific inductive capacity of the medium, and V potential. For a given liquid and given electrodes at a constant distance, F is proportional to V^2 . This holds for electrolytes as well as dielectrics through a range of potential from 1 to 60 volts.

(2.) When the potentials and medium are constant, and the distance between the electrodes is varied, F is independent of the nature of the medium, depending only on the capacity of the condenser.

(3.) When the rate of alternation of the current changes, the force is but slightly altered, unless the electrolyte is a fairly good conductor. In the latter case, the force is diminished if the speed is reduced, owing to polarisation.

(4.) When the conductivity of distilled water is increased by the addition of tap water, or of minute quantities of acid or of copper sulphate, the force is not greatly altered, although the current increases many times. The slight decrease observed is probably due entirely to polarisation.

(5.) With rise of temperature, the conductivity increases while the force diminishes, the rate being practically constant within the range of experiment. This diminution is not due to polarisation, for the increase of conductivity is comparatively small, and a slight fall of temperature conditions an immediate and full restoration of the force.

The electrolytes considered behave therefore very much as dielectrics. The following values of K were obtained at 25° C:—For water, $K = 75.7$; for alcohol, $K = 25.7$. These determinations agree with the work of Colin and Arons and others. J. W.

Electrolysis. By F. BRAUN (*Ann. Phys. Chem.* [2], 42, 450—464).—Grothius (*Gilbert's Annalen*, 61, 65) passed an electric current through two solutions of silver nitrate, communicating with each other only by means of a crack in the glass tube containing one of them. The positive pole was immersed in the external vessel. He observed that silver was deposited on the outside of the crack, whilst

oxygen was given off on the inside. The author has now made a series of experiments which confirm this observation. He finds that the silver is only deposited when the intensity of the current has attained a certain minimum value which depends on the strength of the solution.

The corresponding phenomenon was not observed with manganese and nickel salts, but salts of lead, gold, palladium, cobalt, and iron showed it distinctly. Formation of a peroxide which might conduct as a metal seems to be without influence in producing the electrolysis.

As the current passes, bubbles of gas may be seen in process of formation in the crack, which pulsates as the bubbles increase in size and are liberated on reaching the surface. This may be also noticed with acids and alkaline salts. In the dark, sparks may be observed within the crack. The breadth of the crack need not be very small, as the phenomena of electrolysis were observed at a slit of 0.06 mm. breadth cut in a mica plate.

The author considers the sparks to be due to the recombination of the oxygen and hydrogen liberated on the passage of the current. Further experiments on the subject are promised. J. W.

Influence of Temperature and the State of Aggregation on the Behaviour of Bismuth in the Magnetic Field. By P. DRUDE and W. NERNST (*Ann. Phys. Chem.* [2], 42, 568—580).—The Hall phenomenon of the rotation of the equipotential lines by a galvanic current, in the case of bismuth is found to be less marked at a temperature just below the melting point than at the ordinary temperature. Above the melting point the effect is so slight as to have become scarcely measurable. On allowing the bismuth to solidify and cool down again, it did not return exactly to its initial condition as measured by the Hall effect. The increase in the resistance of bismuth in the magnetic field also becomes smaller with rising temperature. The increase in this case already becomes very slight at a temperature much below that at which bismuth melts. The bismuth does not return to its initial resistance on cooling.

Antimony was also examined with somewhat similar results, the effect of change of temperature being, however, far less marked than in the case of bismuth. In the case of mercury, the Hall effect could not be measured, and although a distinct increase of resistance was noticed, the influence of temperature was not ascertained.

Bismuth, as far as could be ascertained, undergoes no change in optical properties in the magnetic field. H. C.

Determination of Critical Temperatures and Pressures, especially that of Water. By L. CAILLETET and H. COLARDEAU (*Compt. rend.*, 112, 563—565).—In order to eliminate the action of water or other liquids on glass, and to avoid the necessity for observing the meniscus, the liquid is placed in a metal tube connected with a manometer. Varying quantities of the liquid are used, and the apparatus is heated to definite temperatures and the pressure observed. If the quantity of liquid is insufficient to fill the apparatus

even when it has expanded, but is sufficient to furnish a saturated vapour. the pressure of the saturated vapour is the same at any given temperature below the critical point, whatever may be the weight of the liquid in the apparatus. Beyond the critical point, however, the pressures are different for each particular weight of liquid in the apparatus. The determination of the critical point, therefore, resolves itself into a determination of the temperature at which the curve of pressure with different quantities of liquid in the apparatus ceases to be independent of this quantity. Details of the measurements in the case of water will be published after the manometer has been verified by means of a special manometer at the Eiffel tower.

Specific Gravity of a Liquid a Function of its Boiling Point and Molecular Weight. By A. E. RICHARDSON (*Chem. News*, 63, 58—60).—The boiling point of a liquid has been shown to be to some extent dependent on its molecular weight, but hitherto between specific gravity and the temperature of ebullition no definite relations seem to have been observed. In this paper, the author endeavours to show the existence of such relations, considering only those liquids which have a specific gravity greater than unity.

Imagine the case of a liquid heated to temperatures far above its boiling point. Also conceive that ebullition has by some means been prevented. Under such circumstances it is palpable that the specific gravity of the liquid will have much decreased, taking it for granted that the liquid would continue expanding. At some temperature, constant for each liquid, the specific gravity would at last assume unit value. Here, then, is a new condition of liquid matter, namely, the temperature at which each given liquid attains unit specific gravity. To arrive at these temperatures, two measurements are required for every liquid. We must know the specific gravity at some given temperature, and the rate of expansion between 0° and the boiling point.

From existing data, the values of T , the unit specific gravity temperature, and of T_z , the absolute temperature of unit specific gravity, are calculated for a number of liquids. Plotting these values as ordinates against the specific gravities as abscissæ, regular curves are obtained, showing that specific gravity is a function of the temperature of unit specific gravity. The values of T/m , where m is the molecular weight, are very uniform, and many of them closely approximate to the number 2. Hence, since T/m approaches constant value, the temperature of unit specific gravity varies as the molecular weight, and the specific gravity is therefore a function of the molecular weight. Lastly, there is a greater uniformity between the values of T_a/t_a , where t_a is the absolute temperature of boiling, than between those of T/m , and consequently all that has been said with regard to the values of the latter applies with even greater force to values of T_a/t_a .

Laws of Dissociating Gases. By A. J. SWART (*Zeit. physikal. Chem.*, 7, 120—139).—The fundamental equations for ideal gases are put into the following form, in order to take into account the volume of the molecules and their attraction for each other :—

$$\text{I. Physical equation.... } \left(p + \frac{n}{v^2}\right)(v - b) = T\Sigma R.$$

$$\text{II. Chemical } \quad \quad \quad K - \frac{q}{T} = \Sigma n \log_e C.$$

R is the gas-constant for each constituent of the dissociating mixture, n the number of molecules of each constituent that participate in the reaction producing equilibrium, C the corresponding concentration, q the internal heat transformation per half kilogram molecule, and K a constant of integration.

The case of nitrogen peroxide is first studied, the proper values being inserted in the above equations, and the law for the dissociation deduced from them. Natanson's experimental results compared with the calculated values show a fair agreement.

The equation obtained is then applied to the investigation of the coefficient of tension, the coefficient of expansion, the critical temperature, the specific heat, and the velocity of sound in dissociating nitrogen peroxide. In these cases also the accordance of theory with experimental results is satisfactory. Applications to other dissociating gases are also made.

J. W.

Constant Vapour Pressure. By J. L. ANDREAE (*Zeit. physikal. Chem.*, 7, 241—273).—It is a well-known fact that the vapour pressure of any hydrated crystalline salt alters with the amount of water the salt contains, that of $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$ being greater than that of $\text{CuSO}_4 \cdot 1\text{H}_2\text{O}$, and that of the latter in its turn greater than CuSO_4 with less than 1 mol. of water. Whether the alteration is more or less gradual, or whether it takes place in an abrupt manner as the proportion of the water to that of the salt is increased, has not yet been ascertained, and the object of the present paper was to obtain an answer to this question.

Two methods of observation were employed, the one statical, and the other dynamical. In the statical method, two samples of the same salt in different degrees of hydration were enclosed in vacuum bulbs connected by means of a U-tube filled with oil, which served as a manometer for indicating and measuring an excess of pressure in either bulb. By means of this apparatus, experiments could be conducted at various temperatures. In the dynamical method, two bulbs were taken, and, as before, filled with different samples of the hydrated salt. Each was weighed separately, and the two then so connected as to allow a free passage of water vapour from the one bulb to the other, both being perfectly shut off from the outside air. Under these circumstances, water passes from the salt of higher to that of lower tension, this continuing until equilibrium is established, a change which is readily ascertained by disconnecting and weighing the bulbs from time to time. When the weights become constant, the salts in each bulb are analysed, and the change which has taken place determined quantitatively.

Three salts were examined, strontium chloride, copper sulphate, and sodium carbonate. With the first of these salts, three experiments were first of all conducted by the dynamical method. The two

bulbs contained in the three cases $\text{SrCl}_2 \cdot 5\text{H}_2\text{O}$ and $5 \cdot 0\text{H}_2\text{O}$, $\text{SrCl}_2 \cdot 5\text{H}_2\text{O}$ and $3 \cdot 4\text{H}_2\text{O}$, $\text{SrCl}_2 \cdot 5\text{H}_2\text{O}$ and $2 \cdot 6\text{H}_2\text{O}$. They were left connected with one another for 66 days, and weighed from time to time. No change of weight in any of the bulbs was noticed during or at the end of this time. The conclusion is that no unequal exchange of water had taken place between the above salts, and that their vapour pressures are therefore the same. Two experiments were now conducted in which the bulbs contained $\text{SrCl}_2 \cdot 5\text{H}_2\text{O}$ and $1 \cdot 65\text{H}_2\text{O}$, and $\text{SrCl}_2 \cdot 5\text{H}_2\text{O}$ and $0 \cdot 6\text{H}_2\text{O}$. These bulbs were left connected in all for 200 days. In the first pair, a passage of water from the salt of higher to that of lower hydration took place during the first 19 days, and after this no further change occurred. In the second pair, a similar change took place, and was completed in about 50 days. On analysing the salts at the end of the experiments, they were found to have the composition $\text{SrCl}_2 \cdot 5 \cdot 12\text{H}_2\text{O}$ and $2 \cdot 01\text{H}_2\text{O}$, and $\text{SrCl}_2 \cdot 4 \cdot 01\text{H}_2\text{O}$ and $2 \cdot 01\text{H}_2\text{O}$. From this it appears that $\text{SrCl}_2 \cdot 5\text{H}_2\text{O}$ has a greater tension than a salt containing less than $2\text{H}_2\text{O}$; but from what has gone before it appears that its tension is not greater than that of any salt containing more than $2\text{H}_2\text{O}$. Between $\text{SrCl}_2 \cdot 2\text{H}_2\text{O}$ and $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$ no increase, therefore, in the vapour pressure of the hydrated salt takes place, but salts of all intermediate compositions have the same vapour pressures. This result was confirmed by the statical method, in which case salts of composition between those above quoted were enclosed in the two bulbs of the apparatus, and the pressure in the two was found to remain equal. Variation in temperature made no difference in the result as long as the heating of both bulbs was the same. On the other hand, when a salt containing more than $2\text{H}_2\text{O}$ was enclosed in one bulb, and a salt containing less than $2\text{H}_2\text{O}$ in the other, a very distinct excess of pressure was noticed in the former bulb, the difference becoming more pronounced as the temperature was raised. Experiments were also made to ascertain whether $\text{SrCl}_2 \cdot 2\text{H}_2\text{O}$ has a greater tension than $\text{SrCl}_2 \cdot \text{H}_2\text{O}$, but with negative result.

The investigation of the behaviour of the other two salts was carried out in a perfectly similar manner. It was found that the tension of $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$ was greater than that of $\text{CuSO}_4 \cdot 1\text{H}_2\text{O}$, and that the latter is greater than that of CuSO_4 with less than 1 mol. of water. Between the limits given here, however, the vapour pressures remain constant, so that the pressure does not change gradually, but undergoes an abrupt alteration at $\text{CuSO}_4 \cdot \text{H}_2\text{O}$ and $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$. In the case of sodium carbonate, there is no change in the vapour pressure between $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$ and $\text{Na}_2\text{CO}_3 \cdot 4 \cdot 5\text{H}_2\text{O}$, as also between $\text{Na}_2\text{CO}_3 \cdot 6 \cdot 95\text{H}_2\text{O}$ and $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$. The experiments do not serve, however, to determine the exact composition of the intermediate hydrate.

From the above it is evident that the vapour pressures of salts of different hydration are equal when the salts contain an amount of water which is either above or below a certain limit. In the cases considered the limits are $\text{SrCl}_2 \cdot 2\text{H}_2\text{O}$, $\text{CuSO}_4 \cdot \text{H}_2\text{O}$, and $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$, $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$, and probably $\text{Na}_2\text{CO}_3 \cdot 6 \cdot 7\text{H}_2\text{O}$. On the other hand, the vapour pressures of salts of different hydration are unequal when one salt contains an amount of water which is greater, and another

salt an amount of water which is less, than a certain limit. It is, therefore, obvious that the vapour pressure of any hydrated salt will not change regularly with the degree of hydration, but that the change will be abrupt and occur at certain intervals. H. C.

Vapour Pressure of Copper Potassium Chloride and its Solutions. By J. G. C. VRIENS (*Zeit. physikal. Chem.*, 7, 194—220).—This research is supplementary to those of Meyerhoffer (Abstr., 1889, 819, and 1890, 564), who investigated the reciprocal transformations of the various compounds of cupric chloride with potassium chloride, and the solubility of the systems composed of these substances. The author has now made a complete set of corresponding determinations of the vapour pressures of the solid compounds and of their saturated solutions. He finds, in confirmation of Meyerhoffer's work, that the vapour pressure at the temperatures of transformation of one system into another is always the same, irrespective of the composition of the mixture; and has succeeded in many cases in pursuing the curves of vapour pressure into the unstable region beyond the point of transformation.

In order to compare his results with the deductions from thermodynamical theory, he determined the heat of combination of the water of crystallisation in the compounds, and calculated the vapour tensions by means of the formula $\frac{d \log_e F}{dT} = \frac{Q}{2T^2}$, where F is the ratio of the maximum pressure of the vapour from the water of crystallisation to that of pure water; T the absolute temperature, and Q the heat developed by the combination of 18 kilos. of water. The theoretical and experimental numbers are in satisfactory agreement. J. W.

Vapour Pressures of some Aqueous Salt Solutions at 0°. By C. DIETERICI (*Ann. Phys. Chem.* [2], 42, 513—536).—In a former paper (Abstr., 1890, 207), it has been shown that saturated water vapour at 0° obeys the ordinary gaseous laws and the pressure which it exercises was calculated from measurements of the density. The vapour pressures of some salt solutions have now been determined in like manner, and the reduction of the vapour pressure of the water by the addition of the salt thus ascertained. The method used was, as before, calorimetrical, the weight of water converted into vapour and occupying a certain known volume being determined by measuring the heat of vaporisation.

The salts examined were sodium chloride and nitrate, potassium chloride, bromide, and iodide, and lithium chloride. In the case of the potassium salts, the reduction in the vapour pressure of the water was found to be very nearly proportional to the amount of salt present. With sodium nitrate, the vapour-pressure reduction decreases; with sodium chloride, and still more with lithium chloride, it increases more rapidly than the amount of salt. It is, therefore, evident that the alteration of vapour pressure with the amount of dissolved salt is different for different salts at 0°, as has already been shown to be the case for other temperatures by Tamman and Emden (Abstr., 1887, 764). Since the ratio of a vapour pressure of the solution to that of

pure water should, according to Babo's law, remain unchanged by temperature, a comparison of the author's results for 0° with those of Tamman for 100° is made, and the above law is found to hold good with remarkable accuracy.

According to the Van't Hoff theory, the vapour-pressure reduction should be proportional to the amount of salt present, or accepting the dissociation hypothesis of Arrhenius, should decrease with increasing concentration. The results with sodium and lithium chlorides are, however, in direct opposition to the latter view, which only those obtained with sodium nitrate support. The author calculates the values of Van't Hoff's coefficient i from his results, and compares them with those obtained by Arrhenius from the electrical conductivities and the reduction of the freezing point. The agreement is far from satisfactory. Two non-electrolytes, cane-sugar and urea, were also examined, and for these values for i of 1.08 and 0.84 were obtained.

H. C.

Apparatus for Freezing Point Determinations. By K. BECKMANN (*Zeit. physikal. Chem.*, 7, 323—330).—The apparatus, of which a sketch is here given, is a slightly modified form of that described by the author in a former paper (*Abstr.*, 1889, 11). It consists of the inner vessel A, surrounded by the air-jacket B, and placed in a cooling solution or mixture in the outer vessel C. Into A a weighed quantity of the solvent is introduced. This is done by weighing the liquid in a Sprengel U-tube, transferring it to A through the side tube on the right, and then weighing the empty Sprengel tube. After the freezing point of the solvent has been ascertained in the usual manner, a weighed quantity of the substance which is being experimented with is introduced through the side tube into A, and after it has all been dissolved by the solvent, the freezing point of the solution is ascertained. The difference between this and the former determination gives the freezing point reduction.

The thermometer D registers only in all about 6° and is graduated to $\frac{1}{100}^{\circ}$. As absolute measurements are not required, it can be adjusted for use with any solvent by means of a small reservoir at the top, to or from which some of the mercury can be removed at will, so that the readings shall fall on suitable portions of the scale. A stout piece of platinum wire, introduced through a glass tube in the cork carrying the thermometer, serves as a stirrer. When a very hygroscopic substance is used as the solvent, it is advisable to pass a stream of air, dried by being passed through sulphuric acid in the bulbs F, through the space between the stirrer and the glass tube. The india-rubber tube E, fastened to the upper portion of the stirrer, enables the operator to secure a firm grasp of the latter. When dealing with hygroscopic substances, the apparatus should be closed with tightly-fitting india-rubber stoppers. On introducing the material experimented with into the apparatus, it sometimes happens that a portion remains adhering to the side tube, the thermometer, or the stirrer. The inner tube should then be removed from the vessel B, and inclined, so that the solvent enters the side tube, and, after dissolving the substance remaining in this, is made to wash the stirrer and thermometer when the tube is returned to its original position.

In liquids which do not readily crystallise, crystallisation may be induced by introducing a small quantity of the previously crystallised solvent. In the tube A of the sketch, a small quantity of the solvent is placed, and after being drawn into the tube B, closed at the top by means of the pinch-cock C, it is submitted to a temperature sufficiently low to cause crystallisation. On withdrawing B from A, and warming slightly, the solid becomes sufficiently detached to allow a small portion to fall from the tube on opening the pinch-cock. B is then replaced in A, and left in the freezing mixture until again required.

The above apparatus may be employed not only with substances solidifying at low temperatures, but also with solvents which are themselves solid at ordinary temperatures. The author quotes experiments with phenol and with naphthalene as solvents in illustration of this, in which cases the outer vessel C was replaced by a beaker filled with water and by means of a thermostat kept constantly at a temperature a little below that at which the solvent melts.

H. C

Thermal Potential for Dilute Solutions. By E. RIECKE (*Ann. Phys. Chem.* [2], 42, 483—501).—The author, taking the fundamental equation of Gibbs as his basis, calculates the potential for the components of a dilute solution; and then applies his results to the consideration of various phenomena that such a solution exhibits. He thus deduces the laws regulating the lowering of vapour pressure, the depression of the freezing point, dissociation of electrolytes, the distribution of a substance between two solvents, osmotic pressure, diminution of solubility, and the absorption of gases. The results he obtained are identical with those got experimentally, or derived theoretically by other methods (compare Planck, *Ann. Phys. Chem.* [2], 32, 485). J. W.

Discussion on the Theory of Solution (*British Association Report*, 1890, 311; *Chem. News*, 62, 185, 194; 63, 147, 157, 169; and *Zeit. f. Physikal. Chem.*, 7, 378—426).—S. U. PICKERING (who opened the discussion with a paper on the "Present Position of the Hydrate Theory of Solution") said: When a definite solid hydrate crystallises from a solution, the existence of some molecules of this hydrate in the liquid can scarcely be denied, but it does not follow that every liquid hydrate can be obtained in the solid condition. Evidence of such uncrystallisable compounds must be sought in the existence of irregularities in the properties of the solution when its composition is varied regularly. The author's work on sulphuric acid (*Trans.*, 1890, 338) and other substances, has shown that such irregularities, consisting of definite changes of curvature in the figures representing the various properties, exist, that the position at which they occur is the same whatever property is examined, and, moreover, that this position corresponds wherever it can reasonably be expected to do so, with simple molecular proportions. Similar irregularities are noticed with very weak solutions, indicating the existence of hydrates of great complexity. The lowering of the freezing point of several solvents must, even on the physical theories, lead to the conclusion that liquid molecules are often very complex. A careful examination of the freezing points shows that the molecular depression (that produced by one molecule dissolved in 100 molecules of solvent) is by no means a constant, but varies with the nature of the solvent and of the dissolved substance, and also varies irregularly with the strength of the solution, even when this is very small, and when the dissolved substance is not an electrolyte. Such variations and irregularities can only be attributed to the existence of disturbing causes (such as hydrates), and they are inconsistent with any purely physical theory of solution. The depression with very strong solutions is generally abnormally large, whereas according to the physical theory the reverse should be the case. With every solvent there are instances of substances which on dissolution produce only half the normal depression of the freezing point, this abnormal action being attributed to the acting molecule consisting of two fundamental molecules; in the case of water the smaller values are regarded as normal, and the larger as abnormal, their abnormality being due to the dissociation of the molecule into two or more

ions. This view is irreconcilable with Raoult's constant of 0.63° for the molecular depression, for the smaller value in the case of water is $1^{\circ}.03$, and this would necessitate the acting molecule of water being $\frac{1.03}{0.63}$, or $1\frac{1}{2}\text{H}_2\text{O}$. Other objections are raised against

the dissociation theory; thus, the stability as evinced by the heat of formation as well as by the chemical properties of many of the substances said to be dissociated, is contrasted with the instability of many of those which are represented as remaining intact: again, the heat evolved in the dissolution of hydrochloric acid cannot be attributed to dissociation into ordinary atoms (for such a dissociation must absorb heat), and it has, therefore, to be attributed to the combination of electric charges with the atoms, a view which endows an electric charge with an attribute possessed, as far as we know, by matter only. Ostwald's experiment of producing electrolysis by a current of electrostatic origin cannot prove the pre-existence of free ions in solution, for, if the conservation of energy is to hold, energy in some form must have been expended on the solution, and there is nothing to show that it has not been utilised in bringing about the decomposition of the molecules. An outline is then given of the views which the author has propounded as to the freezing points of solutions, according to which, by taking into account the existence of hydrates as well as the mechanical effect produced by introducing foreign molecules into a solvent, the depression of the freezing point of water by sulphuric acid may be calculated as far as -34° , or 30 per cent. (Proc., 1889, 149); the concordance is so good that the composition of the hydrates may be calculated from the observed freezing points, and these hydrates are found to agree with those indicated by the study of the curves representing the various properties of the solutions. In the case of weak solutions, the lowering which can be attributed to chemical causes alone is but a small portion of the total lowering, and this accounts for the approximate regularity and constancy observed with such solutions, and the approximate validity of calculations based on purely physical views, even though solutions may be truly chemical in their origin and nature.

J. H. GLADSTONE said that substances generally have the same molecular refraction in whatever solvent they are dissolved, and a solution has the same specific refractive energy as the mean of those of the solvent and the dissolved substance: ammonia dissolved in alcohol has, moreover, the same value as gaseous ammonia. Water as a solvent behaves anomalously; the haloïd salts exhibit a higher refraction and dispersion in water than that given by calculation; in water, also, the refraction increases with dilution up to a certain extent and then becomes constant, whilst in other solvents dilution has no effect; this difference the speaker considered was evidently not dependent on the dissolved substance being an electrolyte or not. With hydrochloric acid, he had obtained results analogous to W. H. Perkin's magnetic rotation results; in isoamyl oxide, the acid gives the theoretical value (11.25); in water, it gives a value 3.15 higher; as free chlorine and hydrogen would give a smaller value than the

compound, and as the addition of water of hydration would probably not affect the value at all, no conclusions in favour of either the dissociation or the hydration theory can be drawn from these results, and the speaker could only infer that some profound and at present unknown change is effected on the constitution of many substances by dissolving them in water.

S. ARRHENIUS communicated a statement to the effect that a decrease in the molecular depression of the freezing point with an increase of concentration was not a consequence of the law of osmotic pressure. Yet Beckmann's and Eykman's determinations show that such a decrease occurs in the majority of cases. Owing to electrolytic dissociation, the molecular depression should not be a constant independent of concentration in the case of weak solutions of electrolytes. Taking a certain value for the conductivity of an infinitely dilute solution of sulphuric acid, he showed that the calculated depression agrees with Pickering's observed values within experimental error as far as a strength of 1 per cent., or a depression of 0.4° , and fairly well as far as 4 per cent., or 1.6° .

J. WALKER said that Arrhenius' objection, that electrolytic dissociation had not been taken into consideration, applied to almost all of the instances tabulated by Pickering.

W. RAMSAY suggested that it was not inconceivable that complexes of the dissolved substance, compounds of the latter with the solvent, and also the ions resulting from its dissociation, might all coexist in solution.

H. E. ARMSTRONG said that the dissociationists regarded the neutralisation of an acid by an alkali as consisting solely of the formation of water from some of the ions constituting the reagents. Water and hydrochloric acid are thus regarded as being compounds of a totally different order, the former undissociated, the latter nearly entirely dissociated, a proposition opposed to known facts of chemistry, and also to the behaviour of these substances at high temperatures. He considered that the numerical agreements between theory and practice did not prove the correctness of the dissociation theory; electrical resistance was, no doubt, a measure of the activity of a substance, and it could, therefore, be successfully used in applying a correction for the superior activity of compounds in various cases, but this superior activity might be either chemical or physical in its nature.

G. FITZGERALD said that there must necessarily be a connection between many physical properties. The connection between electric conductivity and osmotic pressure was a very important one, and he proposed that the quality measured by the former should be termed the "measure of ionisation" instead of the "ratio of dissociation" or the "measure of affinity." He objected to the use of the term "dissociation" on the ground that the ions supposed to be present were still held together somehow, so that they could not diffuse away from each other. He considered that the ions could not be independently mobile in the liquid, and that the rôle of the solvent is not merely to give the ions space to resolve themselves, for different solvents act differently towards the same substance. Van't Hoff's

argument that osmotic pressure is due solely to the kinetic pressure of the molecules or ions does not necessitate the conclusion that the forces between these are small, but merely that the space within which they are bombarding is small compared with the space rate of variation of these forces. He regarded, however, the whole of Van't Hoff's argument as fallacious, for according to it one salt molecule could never produce osmotic pressure in its own neighbourhood by any forces of attraction between it and the solvent; this he considered to be erroneous, for if the semipermeable membrane were affected by the salt to a smaller degree than the water, there would be a difference of pressure in the solvent near and far from the salt, and this would act on the semipermeable membrane even though it were permeable to the solvent. He considered that there were other explanations preferable to that given by Van't Hoff. The mobility of the ions required by the laws of electrolysis is not greater than that required by osmotic pressure, and does not necessitate true dissociation. The continual interchange of atoms in contiguous molecules, which Williamson's and Clausius' theories alone require, is sufficient for this purpose, and such interchange may be effected by the formation of complex molecules followed by tautomerism. He considered it undoubted that solution is a true chemical combination. He thought that the energy required for dissociation might be supplied by assuming an affinity of the element for electricity, or supposing the ions to be allotropic atoms with different internal energy from that possessed by ordinary atoms; on the former assumption, however, the atom with its electrical charge combined would not be acted on by electrical forces required in the manner to explain electrolysis, and he thought that the facts of solution might be explained more simply by chemical combination than by the idea of allotropic atoms. He did not consider that the explanation offered by the dissociationists as to the heat of neutralisation explained anything. A rough calculation led to the estimate that an atom would acquire its ionic velocity in 10^{-15} of a second and 10^{-10} of a centimetre, in which case Ohm's law would not fail owing to the smallness of the intermolecular bombardment differences until the rate of the alternating current is comparable with that of light.

O. LODGE thought that the moment during which molecules are changing partners (a change proved by the existence of double decomposition) afforded an instant of potential dissociation sufficient to account for electrolysis; if, however, this instant were not long enough, we might fall back on the outlying atom stragglers of gross complex molecules without admitting that extreme state of dissociation which the physicists maintain. He had objected to Ostwald's experiment of producing electrolysis by an electrostatic charge on the ground that the experiment was an imaginary one (see Ostwald's remarks below), but even if it could be performed, the accepted laws of electrolysis would enable us to predict what would happen, the results being the same as if the current were derived from a battery.

W. OSTWALD said that if a current from a battery is led into two beakers containing copper sulphate solution, connected by a siphon

with its ends covered by a membrane, and filled with potassium ferrocyanide solution, a deposit of copper ferrocyanide is formed on the membrane, and through this no copper salt can pass; after a time, a deposit of metallic copper forms on the positive side of the membrane, showing that the latter is impermeable to the copper ions; these get filtered off, the electric charges with which they were combined alone pass through the membrane. K and Cl ions pass through a ferrocyanide membrane, Ba and FeC_6N_6 ions do not. In a salt which consists of one ion which can pass and one which cannot, such as barium chloride, the former passes to a certain extent, but is prevented from going far by the negative charge on it being attracted by the positive charge on the other ion which remains on the other side of the membrane. This explains why the ions cannot be separated by diffusion. The addition of an ion which can pass, such as K, to the barium chloride allows the chlorine of the latter to pass freely; but this might be due to previous double decomposition, potassium chloride being formed; but the free passage of the Cl ions may also be effected by placing other positive ions capable of passing on the *other* side of the membrane, as, for instance, copper nitrate; the Cl ions then pass freely in one direction and the NO_3 ions in the opposite direction: here no double decomposition is possible and the results can only be explained by free migrating ions. He considered that the energy required to dissociate a compound into its ions might be much less than that required to dissociate it into ordinary uncharged atoms. It was impossible to deny that the facts could be explained by theories other than Arrhenius' dissociation theory, but the latter is consistent with a very great number of facts. The experiment which Pickering and Lodge had referred to had actually been successfully performed, and no more involved the creation of energy than the production of a spark from bodies charged by induction. He considered that the opposition of chemists to the dissociation theory was merely a matter of feeling similar to that which led them for a time to oppose the idea of the dissociation of ammonium chloride by heat. The dissociation theory explains the difference between the behaviour of electrolytes and organic compounds as analytical reagents. The law of constant proportion is no argument against the theory, for the ions are charged with equal quantities of opposite electricities, and, for the solution to be electrically neutral, these electricities, and, consequently, the different ions, must be present in equivalent proportions. In answer to Armstrong, he pointed out that pure hydrochloric acid, like pure water, was a non-conductor, and the latter, like the former, would be a conductor in a suitable solvent: there was already some evidence that water was dissociated to a small extent.

J. VAN'T HOFF said that in dilute solutions a law corresponding with Avogadro's existed, and dissociation into ions was a necessary consequence of this. The action on the semipermeable membrane is due to the shock of the dissolved molecules and also to the difference of the forces acting on them (? on it) from the solvent on one side, and from the solution on the other. The result of the shock is directly proportional to the concentration, while that of the attraction is pro-

portional to its square, so that the latter vanishes in dilute solutions, and the shock is alone the origin of pressure. Although these views are intended more to popularise than to prove the laws in question, Van der Waals' investigation of the kinetics of the action leads to a precisely similar result. According to his own theory, the depression of the freezing point is not independent of the nature of the solvent, and Raoult himself has abandoned his empirical constant in favour of Van't Hoff's formula.

W. N. SHAW took objection to some of the substances, such as the monohydrate of sulphuric acid, which Pickering quoted as solvents. He considered that a solvent could not be considered as inert if it caused the dissociation of the dissolved substance. He alluded to stannic chloride (*Phil. Mag.*, 1890, 383) as a substance which is converted into an electrolyte by the addition of alcohol or water, but not by the addition of chloroform or hydrogen sulphide, chemical action accompanying the change in the former case.

S. PICKERING pointed out* that none of the positive arguments in favour of the existence of hydrates in solution had been refuted. There were difficulties in applying Kohlrausch's conductivity values for the calculation of the freezing points of sulphuric acid, and, even if we can correct the irregularities of the freezing points by the irregularities of the conductivities, this does not explain the existence of these irregularities; and their existence is inconsistent with any purely physical theory; moreover, non-electrolytes exhibit similar irregularities. The concordance exhibited by Arrhenius' calculations extended to 0.4° only, the total depression to 80°: an extension of the calculations to stronger solutions exhibits errors of different signs in different parts, and these finally attain a magnitude of 60°. Calculations on his own theory agreed with the observed values as far as a depression of at least 34°. Although Van't Hoff's equation represented the molecular depression to be independent of the nature or amount of the dissolved substance, yet both these affected it. The conservation of energy could not be said to be in open contradiction to the dissociation theory if sufficient hypotheses were made respecting the energy of the ions, yet these hypotheses themselves appeared to be in practical contradiction to the conservation of energy. They involve either the introduction of electric charges from nowhere capable of combining with matter to generate heat, or else they hypothecate a new form of atom which shall be *minus* that free energy which an ordinary atom possesses.

S. U. P.

Deduction from the Gaseous Theory of Solution. By O. MASSON (*Nature*, 43, 345—349; *Zeit. physikal. Chem.*, 7, 500—510).—In every simple solution the dissolved substance may be regarded as distributed throughout the whole bulk of the solution. Its total volume is therefore that of the solution, the solvent playing the part of so much space; and its specific volume is the volume of that quantity of the solution which contains 1 gram of the substance. To avoid confusion it is best to speak of this as the specific solution

* The whole of Pickering's answer appeared in the *Chemical News* only.

volume of the substance. It is obviously in inverse ratio to the concentration.

Imagine a soluble solid in contact with water at a fixed temperature. The substance exercises a certain osmotic pressure, in right of which it proceeds to dissolve. This pressure is analogous to the vapour pressure of a volatile substance in space, the space being here represented by the solvent; and the process of solution is analogous to that of vaporisation (Nernst, *Abstr.*, 1890, 3). If there is enough water present, the whole of the solid will go into solution, just as the whole of a volatile substance will volatilise if the available space is sufficient. If the solvent is present in excess, the solution formed will be unsaturated, and the dissolved matter will be in a state comparable to that of an unsaturated vapour; but if there is not excess of the solvent present, a saturated solution will be obtained in presence of undissolved solid, just as we may have a saturated vapour in the presence of its own liquid or solid.

Suppose now that the temperature, in place of being fixed, is allowed to vary, a rise of temperature will disturb equilibrium, and its re-establishment would necessitate increased solution or vaporisation, as the case may be. In the case of a volatile liquid, it will become more volatile as the temperature rises, until when the critical temperature is reached it becomes infinitely volatile, and for higher temperatures can no longer exist in the presence of its own vapour, no matter how great the pressure may be. And from the analogy between solution and vaporisation, we may expect for every substance and its solvent a definite temperature, above which the substance cannot exist in presence of its own solution. This may be spoken of as the critical solution temperature.

The solution of a solid substance has here been compared to the vaporisation of a volatile liquid, but for purposes of a stricter analogy volatile solids, such as camphor or iodine, may be taken. A volatile solid will not reach its critical point without having first melted at some lower temperature, and a similar change should be exhibited in the solution process. At some definite temperature below that of infinite solubility, we may expect the solid to melt. This solution melting point will not be identical with, but lower than, the true melting point of the solid, owing to solution of the solvent in the liquid, which will take place in accordance with the rule of reciprocal solubility.

The above hypothesis demands that increase of solubility with rise of temperature shall be as general a law as increase of vapour pressure. It seems to demand some connection between the true melting points of salts and the rates of their increase of solubility, a relation established in a general way by Tilden and Shonstone (*Abstr.*, 1884, 254). Further, whilst no case is known of a solid substance having as such infinite solubility in any simple solvent, several cases are known of liquids of infinite solubility, and also of solids which, after they have melted in presence of their own solutions, become at some higher temperature infinitely soluble. The observations of Alexéeff (*Abstr.*, 1886, 847) more particularly show that two liquids become one homogeneous solution at a temperature which

depends on the ratio of the original ingredients. There is one ratio which demands a higher temperature than any other; this is the critical solution temperature, above which either ingredient is infinitely soluble in the other.

From the observations of Alexéeff on the solubility of aniline in water and of water in aniline at different temperatures, the author deduces experimental evidence in favour of the above views. He also calculates the specific solution volumes of aniline in water at different temperatures, and plots the values against the temperature. The curve so obtained is strikingly similar to the curve given by Ramsay and Young for the specific volume of alcohol and its saturated vapour at different temperatures, thus affording additional support to the view that solution and vaporisation are perfectly analogous processes.

H. C.

Deductions from the Gaseous Theory of Solution. By S. U. PICKERING (*Nature*, 43, 488).—When water crystallises from a solution by cooling, the tendency of the water molecules to coalesce will, on the hydrate theory, be partly counterbalanced by the attraction of the other substance present, so that the freezing point will be lower the more of the other substance, say salt, there is present. Similarly, the temperature of crystallisation of the salt from strong solutions must be lower the more water there is present. The curve formed by the latter temperatures gives what is generally termed the solubility of the salt in water, and the solubility is thus seen to increase with temperature. At a temperature above that of the solidifying point of the salt, no salt will be able to crystallise, and the solubility of it in water will be infinite; whilst at temperatures above the solidifying points of both salt and water, the mutual solubility of these will be infinite, and a homogeneous liquid will be produced. Similar results will be obtained if the two substances separate in the liquid, instead of the solid, condition, and hence the existence of a "critical solution temperature" may be deduced from the hydrate, as well as the gaseous, theory of solution (see preceding abstract). The author considers that the fact that osmotic pressure is numerically equivalent to what the gaseous pressure of the dissolved substance would be, does not prove that this substance is a gas when dissolved. The osmotic pressure has not yet been proved to be measured by $\frac{1}{2}mv^2$, and existing evidence is strongly opposed to the idea that the solvent only "plays the part of so much space." The only explanation yet offered by the supporters of the gaseous theory as to the cause of a solid dissolving at all is that it "exercises a certain pressure, in right of which it proceeds to dissolve," and the author calls on them to substantiate the existence of a pressure which has not yet been recognised.

S. U. P.

Some Ideas about Solution. By W. RAMSAY (*Zeit. physikal. Chem.*, 7, 511—513).—The curves constructed by Masson (this vol., p. 791) for the specific solution volumes are isobaric curves. The data of Alexéeff are not sufficient to serve for the construction of the isothermal curves, but were it possible to determine the osmotic

pressures of the different mixtures, isothermal curves could then be obtained analogous to those of Andrews and others for gases. Such solution isothermals should be similar in form to the isothermals for gases.

If we imagine the isothermal curve for solutions to be of similar form, say, to that of Andrews for carbonic anhydride, the continuous passage of gas to liquid in the latter case would be replaced by a continuous change from the one solvent to the other in the former. In that portion of the curve which represents the period of transition from gas to liquid, we may have represented certain labile conditions which it is possible to realise, such as that in which the gas exists at a pressure above that required for liquefaction, and that in which the liquid exists at a pressure below that under which vaporisation usually takes place. In the case of solutions, the first of these conditions would find its analogue in the phenomenon of supersaturation, as for example in the case noticed by Nicol, of the dissolution of anhydrous sodium sulphate in a saturated solution of the same salt. The second condition may perhaps correspond with that in which a syrup is formed, as when at high temperature water dissolves in cane-sugar, and the liquid on cooling remains viscid without crystallising.

The suggestion is also made of the possibility of determining the specific heats for constant osmotic pressure and for constant concentration, and of studying the isentropic relations in the case of solutions.

H. C.

Solubility of some Substances in Mixtures of Water and Alcohol. By G. BODLÄNDER (*Zeit. physikal. Chem.*, 7, 308—322).—Although many experimental data exist with reference to the influence on the solubility of a substance in water exercised by the presence of a third substance, no generalisations have up to the present been effected, with the exception of the laws which Nernst has shown (*Abstr.*, 1890, 3) hold in the case of electrolytes. In accordance with Nernst's deductions, a third substance, if a non-electrolyte, should exercise no influence on the solubility, and should itself dissolve in an aqueous solution, just as in pure water. Hence the solubility of a substance in water should be in no way altered by the addition of alcohol to the water, provided that the substance itself is quite insoluble in alcohol.

Experiments on the solubility of a number of substances, both electrolytes and non-electrolytes, in mixtures of alcohol and water, prove, however, that this is not the case. If in 100 c.c. of the alcoholic solution there are contained S grams of dissolved substance, and W grams of water, and the alcohol exercises no influence on the solubility, the proportion of salt to water, S/W, should remain constant whatever variation takes place in the amount of alcohol present. But it was found in all cases, that as the amount of alcohol was increased, the ratio S/W decreased, so that water which contains alcohol in solution will not dissolve any third substance to the same extent as pure water, and the solubility will decrease as the amount of alcohol present increases.

Two assumptions may be made with reference to this behaviour.

A given amount of water may be able to dissolve only a certain amount of alcohol or of any other substance, but not the two together, so that if to a saturated solution of the one a quantity of the other be added, the water will be divided between the two, to the exclusion of a certain portion of the substance which it originally held in solution. Or, on the other hand, it might be that the addition of alcohol to water effected a decrease in its solvent action on other substances, comparable with the reduction which it effects in the freezing point. Both these assumptions, and the further deductions which they involve, are fully considered by the author, but neither appears to hold in the cases studied.

The only explanation remaining of the influence exercised by the alcohol is that it is a purely mechanical one, and simply due to the dilution of the water, and consequent distribution over a larger space. Theoretical considerations have led the author to the conclusion that if this is so in saturated solutions of a substance in water containing different amounts of alcohol, the ratio of the amount of water, W , to the cube root of the amount of the dissolved substance should be approximately constant. This relation is, as a matter of fact, found to hold experimentally in those instances which have been quoted above.

The experimental data given include the solubility of sugar, potassium and sodium chlorides and nitrates, and ammonium sulphate. In all these cases the ratio $W/\sqrt[3]{S}$ is approximately constant. With potassium chloride and nitrate and sodium nitrate, the values at first increase slightly with increasing amounts of alcohol, and then decrease, a behaviour which may be due to dissociative or associative changes. In the case of sodium chloride, a marked increase in the values of the ratio takes place throughout with increasing amounts of alcohol. But if the assumption is made of the existence of a hydrate, $\text{NaCl}\cdot 2\text{H}_2\text{O}$, and the results calculated on this basis, the values so obtained are perfectly similar in character to those with the other salts just mentioned. With ammonium sulphate, difficulties were experienced, owing to the separation of alcoholic solutions of this salt into layers (see Traube and Neuberg, *Abstr.*, 1888, 783), but by considering the upper and lower layers in each case separately, normal results were obtained. H. C.

Solubility of Mixed Salts in Water. By G. BODLÄNDER (*Zeit. physikal. Chem.*, 7, 358—367).—In a former paper (preceding abstract), the author studied the solubility of various substances in mixtures of water and alcohol, the compounds chosen being soluble in water, but insoluble in alcohol. He now investigates the effect produced on the solubility of one salt in water by the addition of another. The salts chosen were sodium nitrate and chloride, and potassium nitrate and chloride. The conditions of experiment differ from those of Nernst and Noyes (compare *Abstr.*, 1890, 3; and this vol., p. 142) in so far as the above-mentioned salts are all easily soluble in water, and not merely slightly soluble. As in the case of the addition of alcohol, the addition of a second salt diminishes the solubility in such a way that the quotient

of the quantity of water present in the solution by the cube root of the quantity of original salt is approximately constant. The numbers obtained when sodium chloride was added to sodium nitrate solution would appear to indicate that the chloride exists as $\text{NaCl} \cdot 2\text{H}_2\text{O}$. J. W.

Determination of Affinity Coefficients. By M. CONRAD and C. BRÜCKNER (*Zeit. physikal. Chem.*, 7, 274—282 and 283—305).—The first of these papers deals with the action of alkyl iodides on the sodium compounds of phenols and cresols. The methods of investigation have been described in former papers (compare Abstr., 1889, 931; 1890, 4, 327, and 1046). The action of methyl, ethyl, and propyl iodides on sodium phenoxide dissolved in ethyl and methyl alcohols was studied. The action takes place more rapidly in the former than in the latter solvent. As in former cases, methyl iodide is found to have the greatest, and propyl iodide the least, activity, that of ethyl iodide being intermediate. The action of methyl iodide only on the sodium compounds of the cresols was examined. The action is more rapid than in the case of the phenol compound. It is also most rapid with paracresol, and least with orthocresol, metacresol occupying exactly a mean position between the two.

In the second paper, the action of alkyl iodides on ethereal salts of acetoacetic acid and its derivatives in the presence of sodium ethoxide is considered. In this case also, methyl iodide is found to exceed the other alkyl iodides in activity. The action in the case of methyl acetoacetate is, on the other hand, slower than in that of the ethyl salt. If the affinity coefficient for ethyl acetoacetate be taken in each case as 100, those of the other ethereal salts will be:—

	Methyl iodide.	Ethyl iodide.	Propyl iodide.
Ethyl acetoacetate	100	100	100
Methyl acetoacetate	56·7	70·1	86·6
Ethyl methylacetoacetate	—	357	—
„ ethylacetoacetate	291	343	421
„ heptylacetoacetate	273	290	—
„ allylacetoacetate	174	197	—
„ benzylacetoacetate	—	159	—
„ benzoylacetoacetate	61·6	70	—

If potassium is substituted for sodium ethoxide, the action in the case of ethyl acetoacetate is found to be more rapid. Propyl bromide acts less rapidly than propyl iodide. H. C.

Rate of Decomposition and Stereochemistry of Chlorhydrins. By W. P. EVANS (*Zeit. physikal. Chem.*, 7, 337—357).—From the mode of formation of various chlorhydrins, the author assigns to them appropriate stereochemical formulæ. These formulæ fall into four classes when considered with respect to the distance between the summits of the carbon-tetrahedra occupied by the chlorine atom and the hydroxyl group. It is assumed that the

reaction $\text{Cl}\cdot\text{R}''\cdot\text{OH} + \text{KOH} = \text{R}''\text{O} + \text{KCl} + \text{H}_2\text{O}$ will take place the more readily, the nearer the chlorine and the hydroxyl are to each other in the molecule. Corresponding to the stereochemical formulæ, then, the rates of decomposition of the chlorhydrins by potassium hydroxide solution should also be capable of being arranged in four groups. Measurements were made at different temperatures to test the validity of these considerations. The following table contains the coefficients of velocity found by the author:—

	24.5°.	34°.	43.6°.
1. { Trimethylethylene chlorhydrin....	1.93	5.00	9.40
{ Dimethylethylene chlorhydrin....	1.73	4.70	11.00
{ α -Dichlorhydrin.....	0.76	2.27	6.70
2. { β -Dichlorhydrin.....	0.32	0.54	0.96
{ Methylethylene chlorhydrin.....	0.049	0.147	0.31
3. Ethylene chlorhydrin.....	0.0068	0.019	0.052
4. Trimethylene chlorhydrin.....	0.0000	0.000	0.000

The agreement with the deductions from the stereochemical formulæ is satisfactory. J. W.

Action of Water on Normal Salts of Amines of the Paraffins. By A. COLSON (*Compt. rend.*, 112, 619—622).—If a hydrochloride of an amine is dissociated by water, the acid, as Berthelot has shown, will form a stable combination with the water, whilst that portion of the base which is free from chemical affinities will dissolve in the liquid in the same manner as a gas, and will have a definite tension at a given temperature. If air is passed slowly through the solution, the air saturated with aqueous vapour will form a mass of gas in which the amine will have a tension proportional to its tension in the liquid.

Air was passed into solutions of equivalent quantities of diisobutylamine and triethylamine hydrochlorides respectively for six hours, and the acidity of the liquid was then determined. With solutions containing 1 gram-mol. per litre, the ratio of the loss of amine at 100° was diisobutylamine : triethylamine :: 25 : 13; at 56—58°, the loss was less than one-third of that at 100°, but the ratio was 7 : 3, or practically the same. The ratio of the loss from a solution containing 1 gram-mol. per litre to that from a solution of half the strength was as 1.4 : 1, and the ratio between $\frac{1}{2}$ gram-mol. and $\frac{1}{4}$ gram-mol. was likewise 1.4 : 1. It follows that the tension of dissociation diminishes considerably as the concentration of the liquid decreases. A very slight excess of acid prevents any sensible loss even after six hours at 100°. C. H. B.

Inorganic Chemistry.

Coefficients of Volatility for Aqueous Hydrochloric Acid. By R. B. WARDER (*Chem. News*, 63, 17—18).—100 c.c. of hydrochloric acid of known strength was submitted to fractional distillation in a flask of 250 c.c. capacity, placed in a cylindrical air-bath, and covered with a conical hood of sheet copper heated in such a way as to keep the temperature of the upper part of the flask from 40—50° above the boiling point of the liquid. By this means the condensation of moisture upon the sides of the flask was prevented, and the distillate obtained really represented the vapour escaping from the surface of the boiling liquid. Successive portions of the distillate were collected in receivers, which in the case of strong acids contained 10 c.c. of water to absorb acid fumes. The several fractions, after weighing in well-stoppered vessels, were titrated against sodium hydroxide, or against centinormal silver solution after evaporating with excess of ammonia. The amount of water present in any fraction was determined by deducting the weight of the acid from the total weight of the fraction; and the weights of water and acid thus found in each fraction were subtracted successively from the water and acid taken to find the composition of the residue after removal of this fraction. The mean composition of the boiling liquid during the removal of each fraction was expressed in the form $H_2O + nHCl$, the composition of the distillate being $H_2O + n'HCl$ or $H_2O + vnHCl$. The coefficient v was then found by dividing n' by n . Four distillations gave 25 pairs of values (see original) which could not be all expressed by one equation. When dilute acid ($n = 0.07$ to 0.11) was boiled rapidly (about 1 gram distilling over per minute), the results agreed with the equation $v = 445n^2$. When strong acid was boiled rapidly, the values of v were somewhat greater than would be indicated by the equation last given, and were approximately represented by $v = 3063n^4$. These two empirical curves, which occupy different parts of the field, are entirely consistent with each other, but must be regarded as a first approximation only of the function sought. When the dilute acid was boiled from 20 to 60 per cent. more slowly, the values of v were about 10 to 30 per cent. less than those indicated by the equation given, and it therefore appears that v is a function of the rate of boiling, as well as of the composition of the liquid.

G. T. M.

Is it Possible to Form Ozone by Lowering the Temperature of a Flame? Is there Ozone Near to a Flame? By L. ILOSVAY (*Bull. Soc. Chim.* [3], 4, 707—714).—The author's statement that ozone is not formed during rapid combustion has been traversed by Loew (*Abstr.*, 1890, 330) and Cundall (*Proc.*, 1890, 26). Both these writers indicate methods of detecting ozone formed by flames, using the odour and taste of the ozone for the purpose. Considering these tests unsatisfactory, the author has re-examined the question. Repeating the experiments of Loew and Cundall, the products of com-

bustion in the first case, and the air taken from around the flame in the second, have not been found (1) to give the odour of ozone, (2) to render thalious oxide paper brown, (3) to permanently decolorise a solution of sulphophenylazo- α -naphthylamine so that naphthylamine no longer restores the colour. It is concluded, therefore, that the experiments of these chemists were insufficient to prove the formation of ozone in the special cases given. After the gas used had been carefully deprived of sulphur compounds, in one experiment the reaction with thalious oxide paper was obtained in about seven hours, but in several others failed. A new series of experiments, made with special precautions to keep the temperature of the flame low and with the aid of a special collecting apparatus, yielded the thalious oxide reaction in about 4—5 minutes, and the other ozone reaction in 10—15 minutes. By this modified method, the methane flame gives less, the hydrogen and carbon monoxide flames more ozone than the flame of illuminating gas.

The relative amounts of nitrous acid and ozone formed by the flame depend (*a*) on the temperature of the latter, ozone formation being favoured by a low temperature; (*b*) possibly on its surface.

Experiments made with oxygen in place of air did not yield such good results; the author intends to repeat them.

It was found impossible to obtain the reactions of ozone by Cundall's method even after 10 to 12 hours; the nitrous acid reaction was, however, very characteristic.

The author maintains that the partial conversion of oxygen into ozone, obtained by blowing a current of air or oxygen on to a flame, does not contradict his statement that "ozone is not formed during rapid combustion."

The above results agree with those obtained by Dewar, who ozonised oxygen by causing it to pass over white-hot platinum, and also with the experiments of Elster and Geitel. It is concluded that combustion is not the source of the ozone of the air, as the conditions found to be essential for its production are absent in ordinary combustion.

W. T.

Conversion of Sodium Pyrophosphite into Phosphite. By L. AMAT (*Compt. rend.*, 112, 614—616; compare this vol., p. 641).—The change is more rapid the more concentrated the solutions, but the effect of dilution becomes smaller and smaller as the concentration diminishes. With solutions so dilute that the concentration is without influence, the rate of change is proportional to the quantity of acid present. Nitric and hydrochloric acids exert the greatest effect, sulphuric acid somewhat less, and phosphorous acid still less, whilst acetic acid has only a very slight effect.

The change in presence of alkali is subject to similar laws, the rate of change at each instant being proportional not only to the quantity of pyrophosphite present in the solution but also to the quantity of free alkali.

C. H. B.

New Form of Silicon. By H. N. WARREN (*Chem. News*, 63, 46).—A form of silicon, crystallising in perfect and well developed

oblique octahedra, was obtained on subjecting potassium silicofluoride to an intense heat in contact with impure aluminium. On separating the graphitoidal silicon thus formed by the aid of dilute acids, small quantities of the new variety were obtained. Larger yields were procured, with varying success, by introducing pieces of metallic aluminium, about the size of a walnut, into a clay crucible containing a mixture of 4 parts of potassium silicofluoride with 1 part of potassium carbonate and 2 parts of potassium chloride, in a state of fusion. After the violent action attending the introduction of the aluminium had subsided, the crucible was urged to whiteness for about 5 minutes; after cooling, a button containing 80 per cent. of silicon was obtained. This was placed in a plumbago crucible with 12 parts of aluminium and 2 parts of tin, and the whole covered with a layer of sodium silicate. The crucible was heated at the highest temperature obtainable for about 2 hours; after cooling the crucible and breaking the piece of aluminium contained therein, the new modification was obtained in large, perfect crystals, having a full metallic lustre and resembling the crystals of cast iron, which are sometimes seen on breaking a pig of that substance; it is infusible and insoluble in all acids except hydrofluoric.

G. T. M.

Action of Hydrogen Iodide on Silicon Chloride. By A. BESSON (*Compt. rend.*, 112, 611—614).—Dry hydrogen iodide has no action on silicon chloride at the ordinary temperature, but at a high temperature products of partial substitution are obtained; the determining cause of the reaction being the difference between the heats of formation of hydrogen chloride and hydrogen iodide, and the partial dissociation of the latter at the temperature of the experiment. Hydrogen iodide mixed with vapour of silicon chloride is passed somewhat rapidly through a glass tube heated to redness; the product is agitated with mercury to remove free iodine, and is then fractionated.

Silicon iodochloride, SiCl_2I_2 , is a colourless liquid which boils at 113° — 114° , and does not solidify, even at -60° . It is not affected by light alone, but when exposed to air it becomes brown from separation of iodine, and this change is accelerated by light. It fumes in the air, is decomposed by water, and combines with ammonia to form a white, amorphous solid, $2\text{SiCl}_2\text{I}_2 \cdot 11\text{NH}_3$, which is also decomposed by water; it does not form a compound with hydrogen phosphide, even under pressure and at a low temperature. Silicon iodotrichloride can also be obtained by heating silicon chloride with iodine in a sealed tube at 200° — 250° .

Silicon diiododichloride is obtained only in small quantity; it boils at 172° , does not solidify even at -60° , and rapidly becomes brown, owing to separation of iodine. It fumes in the air, burns with liberation of iodine, and is decomposed by water; when dissolved in carbon tetrachloride, it combines with ammonia to form a white, amorphous solid, $\text{SiCl}_2\text{I}_2 \cdot 5\text{NH}_3$, which is decomposed by water. The diiododichloride is also obtained by saturating the iodotrichloride with hydrogen iodide at -22° , and heating the solution for 24 hours in sealed tubes at 250° .

The *chlorotri-iodide*, SiClI_3 , was obtained in very small quantity; it fumes in the air, rapidly becomes red, gives a combustible vapour, and combines with ammonia. It boils at about 220° , and when strongly cooled remains in superfusion, but on agitation forms a white solid which melts at about -30° . C. H. B.

Action of Heat on Carbonic Oxide. By BERTHELOT (*Compt. rend.*, 112, 594—597).—Carefully purified and dried carbonic oxide, when heated in glass tubes at 500 — 550° , always yields a small quantity of carbonic anhydride, without any separation of carbon. The quantity of anhydride formed is practically the same as at high temperatures, but in the latter case there is separation of carbon. The formation of carbonic anhydride at 500 — 550° is probably accompanied by the formation of a suboxide, as, for example, $10\text{CO} = \text{C}_2\text{O}_3 + 2\text{CO}_2$. C. H. B.

Reaction of Carbonic Oxide. By BERTHELOT (*Compt. rend.*, 112, 597).—Carbonic oxide reduces ammoniacal silver nitrate, the liquid becoming brown even in the cold; when heated, an abundant black precipitate separates. The reaction is very sensitive, and can be obtained with an aqueous solution of the gas; the presence of even a large quantity of air does not interfere with the reaction. C. H. B.

Reduction of Oxygen Compounds by Magnesium. By C. WINKLER (*Ber.*, 24, 873—899).—The author has examined the reducing action of magnesium, and of magnesium in the presence of hydrogen, on the elements of the fourth group, and gives a detailed account of the experiments. The following results were obtained:—

Carbon.—Magnesium burns at a red heat in carbonic anhydride to form amorphous carbon; when heated with carbonates, however, an explosive action takes place. The reduction is generally accompanied with the formation of magnesium carbide and carbon monoxide. Carbon monoxide at a higher temperature is reduced to carbon. The carbon so obtained always contains magnesium, even after prolonged treatment with hydrochloric acid. When the experiment is conducted in the presence of hydrogen, no compound of carbon and hydrogen is formed.

Silicon.—Magnesium and silicon have a decided tendency to combine chemically with one another. The two elements combine with a faint evolution of light when gently heated together. Silica, when heated with magnesium, is converted, with evolution of light and scattering of the mixture, into a mixed product. The product in the cooler parts of the tube has the bluish-grey colour of magnesium silicide, that in the hotter part of the tube the brown of amorphous silicon. When the product is mixed up and again heated, a mixture of silicon and magnesia is obtained. If excess of silica be employed, no magnesium silicide is produced, but only silicon. Silicates are also reduced by magnesium. Silicon is without action on silica at a high temperature. When the reduction was conducted in an atmosphere of hydrogen, no compound of silicon with hydrogen was obtained.

Titanium.—Titanic anhydride, when heated with magnesium, is not reduced to titanium, but titanium monoxide and magnesium titanate are produced. The latter is not capable of further reduction. With a limited quantity of magnesium, other oxides of titanium, together with magnesium titanate, are formed. Magnesium titanide is not obtained. A compound of titanium and hydrogen does not appear to exist.

Zirconium.—The reduction of zirconic anhydride by magnesium takes place at high temperatures with evolution of light, but is usually incomplete. If the experiment is performed in an atmosphere of hydrogen, the latter is rapidly absorbed with the formation of black *zirconium hydride*, ZrH_2 . Zirconium hydride is inflammable, and is not attacked by acids. Magnesium zirconide could not be obtained.

Cerium.—Cerium dioxide is reduced at high temperatures by magnesium, according to the proportions of the latter, either to cerium or cerium sesquioxide, with evolution of light. Cerium monoxide and magnesium ceride do not appear to exist. When the reduction is effected in hydrogen, the latter is rapidly absorbed, and *cerium hydride*, CeH_2 , is formed. Cerium hydride is inflammable, is brownish-red, and is decomposed by acids. Lanthanum behaves in the same way as cerium, which points to its being a quadrivalent element, and to having a position in the natural system of elements different from that usually assigned to it.

Thorium.—Thorium dioxide is reduced to thorium on heating it with magnesium. When the experiment is conducted in hydrogen, the latter is absorbed, and thorium hydride, ThH_2 , is formed. A monoxide of thorium does not appear to exist.

Germanium.—The oxide is reduced to germanium with a violent report and scattering of the mass.

Tin.—The oxide is violently reduced to metal with evolution of light and explosion, resulting in the violent shattering of the tube.

Lead.—The oxide is reduced to metal with a violent explosion and evolution of light.

The author points out that, like carbon and silicon, all the other members of the *main* sub-group of quadrivalent elements are capable of forming compounds with hydrogen, with the exception of titanium. The existence of a hydrogen compound of lanthanum points to its having a different position in the system of elements, as stated above. The hydrogen compounds obtained correspond with the hydrocarbons C_4H_{10} , and the authors think that there can be no doubt that compounds will be obtained from them corresponding with the derivatives of the hydrocarbons and so-called organic compounds.

E. C. R.

Rubidium Barium Dithionate. By G. BODLÄNDER (*Chem. Zeit.*, 14, 1140—1141).—While preparing rubidium dithionate from rubidium sulphate and barium dithionate, tufts of interlacing, very slender, white, hair-like needles were observed to separate, and when isolated by repeated recrystallisations, these crystals were found to suffer no loss of weight at 100° , but at higher temperatures an evolu-

tion of sulphurous anhydride and water occurred, leaving a residue of rubidium and barium sulphates. Analysis indicates the composition $(\text{S}_2\text{O}_6)_2\text{BaRb}_4 + \text{H}_2\text{O}$ for this substance. The crystals are doubly refracting, and show extinction parallel and at right angles to the long axis; they are more soluble in warm than in cold water, and readily from supersaturated solutions. The solubility is diminished by the presence of excess of the rubidium sulphate, but increased when the barium dithionate is present in excess; but the composition and the physical characters of the double salt remain unaltered under these circumstances.

D. A. L.

Allotropic Silver. By M. C. LEA (*Amer. J. Sci.* [3], 41, 179—190, and 259—267; *Phil. Mag.* [5], 31, 238—250, and 320—329).—Gold-like allotropic silver (Abstr., 1890, 213) behaves in a characteristic manner with strong acids. Hydrochloric acid has no action on normal reduced silver, but when it is added to the allotropic silver some silver chloride is always formed, although the amount is small because of the immediate conversion of the silver into the ordinary form. If the acid is diluted with 50 vols. of water, this last change is much slower, and about one-third of the metal is converted into chloride. Even when the acid is diluted with 100 vols. of water, the metal is changed into the ordinary white form, whilst a considerable quantity is converted into chloride. Sulphuric acid diluted with 50 vols. of water has no action on ordinary silver, but converts the gold-like modification into the normal form, and dissolves a small quantity. Sulphuric acid mixed with 4 vols. of water, and allowed to cool, converts the gold-like form, in a few seconds, into the intermediate modification described below; if the acid is mixed with 2 vols. of water, and applied hot, the metal changes instantly into the normal light-grey form. The action of strong acids on allotropic silver is not accompanied by any evolution of gas. Oxalic, citric, and tartaric acids have no action on the moist precipitated allotropic silver, but dry films, on paper, are converted by the same solutions into the ordinary white metal. Ammonia dissolves a small quantity of allotropic silver, but does not change it into the ordinary form.

Gold-like silver behaves with potassium ferricyanide, ferric chloride, &c., in the same manner as ordinary silver, but is more active.

An intermediate gold-like modification, D, has a bright-yellow instead of a deep-yellow colour, is harder, and can be burnished, is not converted into the white form by shearing stress, and gives no colour reactions with potassium ferricyanide or ferric chloride, which only cause a slight deepening of the colour. It is obtained by heating films of the gold-like modification C, on glass or paper, at a temperature just below that at which the paper begins to carbonise. No similar change is produced by merely drying the gold-like variety.

If the precipitated gold-like variety is subjected to prolonged washing, it dries with a deep copper colour. The washing is accomplished much more easily if a 2 per cent. solution of sodium potassium tartrate is used instead of water, until the process is nearly

finished. Silver tartrate and stannous nitrate yield gold, blue, and other modifications of silver, but the products always contained considerable quantities of tin. Similar results were obtained with silver citrate.

High-tension electricity changes gold-like silver C into ordinary white silver, even with a moderately powerful discharge. If several films on paper are put together, and held between the conductors, there is a transference of some of the silver from one sheet of paper to the next. The parts which have been affected by the discharge no longer give any colour reaction with potassium ferricyanide.

Dry films of gold-like silver on glass, change to the white form when heated. After 9 hours at 100°, the edges of the film have become white, whilst the centre is completely changed into the intermediate variety D; at 180°, conversion into the intermediate form is complete in 10 minutes; at 200°, the edges become white in 10 minutes, and the conversion into ordinary white silver is complete in half an hour.

The dried precipitate, in mass, undergoes a similar change at 180—190°. A film of gold-like silver on pure paper is converted into the intermediate form in half an hour, if immersed in water heated at 99—100°; a similar film on glass passes completely into the normal silver in 24 hours, without disintegration of the film.

The application of the slightest friction or shearing stress immediately changes the gold-like silver C, into white silver. If this change is partially produced by friction, and the substance is left at rest, the change spreads spontaneously through the whole mass. All solid specimens of allotropic silver change spontaneously into white silver, even in the dark. Films on paper or glass alter more slowly.

Gold-like silver on glass or paper seems unchanged on exposure to light, but reacts less readily with potassium ferricyanide, and after exposure to one or two days of summer sunshine it is completely converted into the intermediate form D. Exposure for several months is insufficient to change it into ordinary metallic silver. Exposed under glass in a printing frame, however, it changes into the white form, because the glass becomes much hotter than the films that are freely exposed, and the change is brought about by heat rather than by light.

Of all the reagents which give colour reactions with allotropic silver (Abstr., 1890, 335), the best are potassium ferricyanide in 5 or 10 per cent. solution, which gives brilliant purples, blues, brownish-reds, and browns, and ferric chloride, which gives rose-colour. The colours are those of thin films.

It seems probable that the gold-like, intermediate, and normal varieties represent respectively atomic, molecular, and polymerised forms of the metal. Light, high-tension electricity and shearing stress affect silver haloids in much the same way as they affect the allotropic forms of the metal. Heat also affects silver bromide (on paper), and makes it reducible by the ferrous oxalate developer, the change being slow at 100°, and very rapid at 140°. Since, however, the paper is not quite dry, the result must be regarded as an effect of the simultaneous action of heat and moisture. When heated with

water at 100° for 3 or 4 hours, silver chloride darkens without evolution of any gas, and the water acquires a slight alkaline reaction, doubtless because of its action on the glass. Silver bromide, under similar conditions, changes only from yellow to greenish-yellow, and, finally, to dirty grey.

Sulphuric acid diluted with 2 vols. of water has no visible effect on silver bromide paper, but in one case, after washing with water and treatment with ferrous oxalate, the part that had been touched with acid was whiter than the rest. If the paper, after treatment with acid, is well washed, treated with very dilute ammonia, again washed, and treated with ferrous oxalate, those parts which have been touched with the sulphuric acid appear as brown marks on a white ground.

Silver photochloride, which, beyond a certain point, undergoes no further change when exposed to light, the author regards as analogous to the intermediate allotropic silver D.

Since the silver haloids are affected by the same agents as allotropic silver, and always in the same direction (that is, towards condensation), the author considers that silver probably exists in its haloid salts in one of its allotropic forms. C. H. B.

New Method of Making Alloys. By W. HALLOCK (*Chem. News*, 63, 17; compare Spring, *Abstr.*, 1882, 921).—When the metals of which Wood's alloy is composed are filed to fine grains and intimately mixed in the ratio of 1 part of cadmium (m. p. 315°), 1 part of tin (m. p. 280°), 2 parts of lead (m. p. 325°), and 4 parts of bismuth (m. p. 267°), and the mixture is tightly packed in a glass tube heated at 98–100° in a water-bath, in the course of some hours (generally a day or two) a homogeneous, liquid globule of the alloy is formed.

On the same principle, lead and tin may be melted together at 190–200° by simply laying a piece of tin on a carefully cleaned strip of lead, and placing the whole in an air-bath kept at the required temperature. Sodium and potassium readily form a liquid alloy at ordinary temperatures, when freshly-cut surfaces of the metals are placed in contact.

The author is of opinion that the method of making alloys here described will prove to be of general application, and suggests the following law as being highly probable:—An alloy can be produced out of its original constituents without considerable pressure (Spring, *loc. cit.*), if the temperature be above the melting point of the alloy, even though it be far below the melting point of the most easily fusible constituent. G. T. M.

Atomic Weight of Copper. By T. W. RICHARDS (*Chem. News*, 63, 20–23, 34–36, 43–44).—Cupric bromide was prepared by the action of a slight excess of pure bromine on pure copper in presence of water. After completion of the reaction, the excess of bromine was expelled, by gentle evaporation to dryness in a glass dish, the nearly normal cupric bromide dissolved in a small amount of water, and the solution filtered through asbestos contained in a perforated

crucible. The filtrate was barely acidified with pure hydrobromic acid, and concentrated to the consistency of syrup, the containing vessel being left wholly undisturbed in a vacuum for 36 hours. On agitation and cooling with ice, the resulting, odourless, black, super-saturated solution immediately crystallised to a mass of brownish-green needles, which were collected on a perforated crucible, and washed three times with a very little water. The dilute solution of these crystals deposited only an insignificant amount of the insoluble, basic bromide when allowed to remain for more than a week, and was, undoubtedly, a pure solution of cupric bromide. In it the ratio of copper to bromine was determined in the following way:—The copper, in 50–60 grams of the solution, was deposited, electrolytically, in a platinum dish, previously coated inside with a thin film of copper, so that the external conditions, before and after the analysis, might be the same. Slightly more than half a gram of the metal was obtained in each case. In determining the bromine in fresh portions of the solution, not only was the resulting silver bromide weighed, but also the silver required to form it; and this last value was determined according to two distinct methods. In the first place, the amount of silver required for a given weight of the copper bromide was calculated, and somewhat less than this quantity was weighed out, converted into nitrate, and the cupric bromide cautiously added to the warm, dilute solution. The deficiency of silver was made up by titration with a solution containing 1 gram of silver to the litre (compare Cooke, *Proc. Amer. Acad. Arts Sci.*, 17, 18). After noting this first value for the amount of silver required, a slight, known excess of the standard solution was added, and the silver bromide was washed and weighed. The excess of silver in the filtrate was determined by means of ammonium thiocyanate; solutions containing an equivalent amount of pure copper nitrate and small, known amounts of silver nitrate being used as a standard of colorimetric comparison. This second method of determining the amount of silver required to precipitate the bromine is not so accurate as the first, but is of value as a check.

Assuming the ratio $\text{Ag} : \text{Br} = 108.00 : 80.007$, the mean atomic weight of copper, as given by the eight final and most trustworthy determinations, = 63.645, with a maximum of 63.664, a minimum of 63.628, and a variation from the mean of ± 0.018 . This value for the atomic weight is considerably higher than that until now accepted, but agrees closely with the numbers obtained by the author in his previous investigations (*Proc. Amer. Acad. Arts Sci.*, 23, 180). If lower values for Ag are accepted, the following ratios are obtained:— $\text{Ag} : \text{Cu} = 107.93$ ($\text{O} = 16$): 63.60; $\text{Ag} : \text{Cu} = 107.675$ (Clarke): 63.45; $\text{Ag} : \text{Cu} = 107.66$ (Meyer and Seubert): 63.44; $\text{Ag} : \text{Cu} = 107.06$ ($\text{O} = 15.87$): 63.09.

G. T. M.

Artificial Cryolite and the Dissociation of Aluminium Fluoride. By A. v. ARSÓTH (*Chem. Zeit.*, 14, 868–869).—By fusing together sodium chloride, aluminium fluoride and zinc, and heating strongly for 15 minutes, or by adding aluminium fluoride to molten sodium chloride and fusing until the evolution of chlorine

ceases, a mass is obtained which, on treatment with water, leaves a pink, insoluble, amorphous powder, containing cryolite, to the amount of 46.88 per cent. by the first method, in which case zinc and aluminium chlorides are also formed, and amounting to 42.52 per cent. by the second method, the rest of the powder consisting of alumina, aluminium fluoride, iron oxide, and sulphuric acid. The powder at a high temperature approaching fusion, becomes granular and white.

D. A. L.

Carburation of Iron by the Diamond. By F. OSMOND (*Compt. rend.*, 112, 578—580).—Electrolytic iron, when heated in contact with diamonds at a temperature exceeding 1035° , but not exceeding 1065° , and, therefore, below the melting point of pure white iron (1085°), is attacked superficially, and carburated at those points where it is in contact with the diamonds. At a temperature of 1085° — 1125° , under the same conditions, the iron melts, the diamonds are dissolved, and a regulus of white cast iron is obtained. With a higher proportion of diamonds, some of the latter remain undissolved, but have been converted into a form resembling graphite, and have taken up a certain quantity of iron. The results show that the diamond, as such, cannot effect cementation: but in contact with iron it undergoes molecular change, and afterwards carburates the iron. The diffusion of the carbon into the iron is accompanied by a diffusion of iron into the altered diamond.

When cooled in hydrogen from 1200° to 600° , the diamond shows no abnormal development or absorption of heat. Graphite seems to show a retardation of cooling between 725° and 685° : and carbon from sugar shows a somewhat more marked retardation between the same temperatures. The variations are not much greater than the errors of observation, but it is noteworthy that the temperature, 725° — 685° , approaches closely to the temperature of the recalcrescence of steel: and this agreement can scarcely be a mere coincidence.

C. H. B.

Formation of Coloured "Lakes." By L. VIGNON (*Compt. rend.*, 112, 580—582).—The heats of neutralisation of stannic acid and metastannic acid respectively by potassium hydroxide are in the ratio 32.7 : 2.3, and these numbers may be taken as measuring the relative energy of the acid functions in the two cases.

If the two acids are boiled with phenosafranine in presence of sodium sulphate and the precipitates are washed until the washings are colourless, it is found that stannic acid has formed an intensely red lake, whilst the metastannic acid has acquired only a very pale rose tint. With stannic acid, 74 per cent. of the safranine in the solution is precipitated, whilst with metastannic acid the quantity removed is too small to estimate. In this case, the absorption of a basic colouring matter is coincident with the existence of a strongly marked acid function in the absorbent.

C. H. B.

Bromonitro-compounds of Platinum. By M. VÉZES (*Compt. rend.*, 112, 616—619).—When a concentrated solution of potassium platonitrite is gently heated with bromine, the compound $K_3Pt_4NO_3Br_2$ is obtained as a bright-yellow powder, consisting of microscopic, yellow

prisms which act strongly on polarised light. No gas is evolved in the formation of the compound, and it undergoes no loss of weight at $100-110^{\circ}$; it is an additive product from the platonitrite, and may be called *potassium platibromonitrite*. It is only slightly soluble in cold water, but more soluble in hot water, from which it crystallises in orange-yellow crystals, provided that it has not been heated too long above 80° .

If an aqueous solution of the platibromonitrite is heated for a long time at about 80° , nitrogen oxides are evolved and the liquid becomes red. When concentrated at a gentle heat, or in a dry vacuum, it deposits red, prismatic crystals of potassium platibromonitrosanitrite, $\text{Pt,Br}_3\text{,NO,2NO}_2\text{,K}_2$, which remains unaltered at $100-110^{\circ}$. It is much more soluble than the platibromonitrite, especially in hot water; by prolonged heating with water it is decomposed, with evolution of nitrogen oxides and formation of potassium platinobromide.

Hydrobromic acid acts more slowly on potassium platonitrite, and the product is a mixture of the platibromonitrite and the platibromonitrosanitrite, which can be separated by means of their different solubilities in water.

If potassium platinobromide, or one of the bromonitro-compounds, is heated with excess of potassium nitrite, the whole of the bromine is removed and the platonitrite is formed. The series of the bromonitro-compounds is, therefore, $\text{K}_2\text{Pt,4NO}_2$, $\text{K}_2\text{Pt,4NO}_2\text{,Br}_2$, $\text{K}_2\text{Pt,NO,2NO}_2\text{,Br}_3$, K_2PtBr_6 .

The author was unable to obtain a compound, $\text{PtBr}_3\text{,NO,K}_2\text{Br}_2$, analogous to the nitrosoplatinochloride, $\text{PtCl}_3\text{,NO,K}_2\text{Cl}_2$. He has verified the composition of the salt $\text{K}_2\text{Pt,4NO}_2\text{,Cl}_2$, described by Blomstrand.

C. H. B.

Double Nitrites of Rhodium. By E. LEIDIE (Bull. Soc. Chim. [3], 4, 809—814; see Abstr., 1890, 1382).—Claus and Lang have attributed contradictory properties to the double nitrites of the platinum metals, particularly to those of rhodium. Again, doubt is cast on Gibbs' method of separating these metals by means of the double nitrites, owing to the known inaccuracy of his statements concerning the solubility of the sulphides of the platinum metals in alkaline sulphides. To aid in the elucidation of the questions involved, the author has studied particularly the double nitrites of rhodium.

Contrary to the statements of Claus, there is but one potassium rhodium nitrite, $\text{Rh}_2(\text{NO}_2)_6\text{,6KNO}_3$. When prepared according to the method given in detail by the author, this salt forms white, microscopic crystals, without action on polarised light. It is almost insoluble in cold water, and insoluble in an excess of potassium nitrite, a 30 per cent. solution of potassium chloride, a 50 per cent. solution of potassium acetate, or in alcohol. Hot concentrated hydrochloric acid converts it into the double chloride, $\text{Rh}_2\text{Cl}_6\text{,6KCl} + 3\text{H}_2\text{O}$, obtained by Claus. This salt is very insoluble in water, which decomposes it into potassium chloride and the more stable chloride, $\text{Rh}_2\text{Cl}_6\text{,4KCl}$, the salt produced on mixing solutions of the two chlorides.

Sodium rhodium nitrite resembles the potassium salt in composition, and the method of preparation differs only in detail from that employed for the latter. It forms white, rather bulky, crystals, which act on polarised light. It is soluble in $2\frac{1}{2}$ parts of water at 17° , and in an equal weight of boiling water, but is insoluble in alcohol. Hydrochloric acid readily attacks the sodium salt with the production of the double chloride, $\text{Rh}_2\text{Cl}_6, 6\text{NaCl} + 18\text{H}_2\text{O}$.

The ammonium salt is prepared from the sodium rhodium nitrite by the addition of ammonium chloride.

Ammonium nitrite cannot be employed directly, on account of its ready decomposition by heat. In solubility and reactions, ammonium rhodium nitrite closely resembles the potassium salt.

Barium rhodium nitrite is prepared in much the same way as the potassium salt. It crystallises with 12 mols. H_2O , forming white, bulky crystals, which act on polarised light. The anhydrous salt is soluble in 50 times its weight of water at 16° , and in $6\frac{1}{2}$ times its weight of boiling water. Hydrochloric acid converts it into a mixture of barium and rhodium chlorides, forming no definite double salt. The barium may be precipitated from the mixture by the calculated quantity of sulphuric acid, and the rhodium chloride in this manner obtained free from alkali chlorides.

The soluble double salts of rhodium and sodium or barium yield no precipitate with sodium hydroxide or carbonate, or with barium hydroxide, and give the insoluble double nitrites of potassium or ammonium with potassium hydroxide or carbonate, or ammonium carbonate or ammonia, respectively. Hydrogen sulphide or sodium sulphide precipitates rhodium sulphide slowly in the cold, more rapidly on heating to 100° . The properties of its double nitrites may be utilised for the extraction of rhodium, for its separation from other metals of the platinum group, and for its quantitative estimation.

W. T.

Organic Chemistry.

Halogen Derivatives of Amylene. By J. KONDAKOFF (*Ber.*, 24, 929—933).—Hell and Wildermann, in a paper on the halogen derivatives of amylene (this vol., p. 533), state that for 60 years scarcely anything has been published on this subject. The author draws attention to the fact that since 1885 he has published a series of papers, in the *Journal of the Russian Chemical Society*, on this subject, and obtained the following results:—

Ordinary amylene consists (Flawitzky, Wischnegradsky, Eltekoff, &c.) of a mixture of isopentane with small quantities of trimethylethylene, unsymmetrical methylethylethylene, and propylethylene; according to Eltekoff, it consists of isopentane, trimethylethylene, unsymmetrical methylethylethylene, symmetrical methylethylethylene, and isopropylethylene. Both Gutrie and Bauer, and Hell and

Wildermann worked with this mixture. The author, however, employed amylenes of known constitution.

Trimethylethylene, treated with gaseous chlorine at $+16^{\circ}$ and -20° , gave the compounds C_5H_8Cl and $C_5H_{11}Cl$, and trimethylethylene chloride, $C_5H_{10}Cl$ (b. p. $133-135^{\circ}$). Besides these products, others, of higher boiling point, are obtained if excess of chlorine is employed, or if the trimethylethylene is cooled with calcium chloride and snow and treated with liquid chlorine. In the latter case, the action takes place with hissing and evolution of heat, and is very like the action of bromine. The product consists of $C_5H_{10}Cl$, $C_5H_8ClCl_2$, and $C_5H_8Cl_4$, together with an insignificant quantity of C_5H_8Cl and $C_5H_{11}Cl$.

Isopropylethylene, when treated with gaseous chlorine, yields almost entirely isopropylethylene chloride (b. p. $143-144.5^{\circ}$), and only a small quantity of α -ethylallyl chloride, $CH_3:CH:CH_2Cl$.

The mixed amylene, which consists chiefly of isopropylethylene and the unsymmetrical methylethylethylene, when treated with gaseous chlorine, gives isopropylethylene chloride and an unsaturated monochloride boiling at $102-103^{\circ}$, which is a derivative of methylethylethylene, and when warmed with potash yields an unsaturated primary alcohol. The latter consists of α -ethylallyl alcohol, $CH_3:CH:CH_2OH$, and probably $CH_3:CH:CH_2CH_2OH$.

With chlorine, symmetrical methylethylethylene yields, as chief product, methylethylene chloride, $CHMeCl:CHCl:CH_2Me$ (b. p. $138-139.5^{\circ}$), and a small quantity of the monochloride,

The latter, on treatment with water, is converted into the corresponding unsaturated secondary alcohol, $OH:CHMe:CH:CHMe$, which boils at $117-118^{\circ}$; with bromine, it forms a viscous bromide, $C_6H_{10}Br_2O$; and by the action of mineral acids is converted into methylpropylketone.

The author is at present engaged in studying the action of chlorine on the residual hydrocarbons obtained by treating commercial amylene with sulphuric acid. He believes that the difference in the action of chlorine and bromine is only apparent, and is determined by the temperature and different conditions of aggregation of the two agents.

When dry gaseous bromine is passed over the mixed amylenes in an atmosphere of carbon dioxide at 20° , bromo-compounds are obtained, which were separated into the fractions (1) $80-110^{\circ}$, (2) $110-120^{\circ}$, (3) $120-180^{\circ}$. On treatment with water they gave dimethylethylcarbinol, the unsaturated α -ethylallyl alcohol which changes into the isomeric aldehyde, an unsaturated alcohol which changes into the ketone, a glycol boiling at $207-212^{\circ}$, and the bromhydrin of this glycol. If dry bromine is added to trimethylethylene, cooled with snow and salt, additive compounds are obtained without any visible evolution of hydrogen bromide. If the mixture is not cooled, heat is evolved, hydrogen bromide comes off, and the bromides C_5H_8Br and $C_5H_{10}Br_2$ are formed. The former of these compounds is converted into $C_5H_8Br_2$, and then into $C_5H_8Br_3$ by the further addition of bromine.

On the evidence of the above observations, the author expresses the chlorination of amylene by the formulæ (1) $C_5H_{10} + Cl_2 = C_5H_9Cl$, (2) $C_5H_{10}Cl_2 - HCl = C_5H_9Cl$, (3) $C_5H_{10} + HCl = C_5H_9Cl$.

Hence, those amylenes and generally olefines which combine easily with mineral acids yield unsaturated monochlorides; those which do not combine easily with mineral acids give additive products with chlorine.

E. C. B.

The Complete Chlorination of Fatty Compounds of High Molecular Weight. By E. HARTMANN (*Ber.*, 24, 1011—1026).—The chlorination was conducted in a similar manner for all the compounds. The method for caprylene is as follows:—Caprylene is treated with a rapid stream of dry chlorine, first in the cold and then at the temperature of the water-bath, as long as hydrogen chloride is formed. The product, which is a colourless oil, is freed from hydrogen chloride and free chlorine by means of an air-pump, transferred to tubes, and iodine added; the tubes are well cooled, and then antimony pentachloride is added. A vigorous action takes place. When this action is ended, the tubes are sealed up and heated at 70° for 3 hours, then opened, and again sealed and heated for 3 hours at 120°, 170°, and 200°. They are again opened, and the antimony pentachloride regenerated by passing in dry chlorine, and the tubes heated finally at 320°. The product is slowly poured into a mixture of concentrated hydrochloric acid and ice, and the oil which is precipitated treated with hydrochloric acid, and then with soda solution to get rid of the antimony and iodine. The product is next fractionally steam-distilled. The residue is heated with iodine and antimony pentachloride at 380°, and the product steam-distilled. The residue is finally crystallised from ether or light petroleum.

The following results were obtained:—Caprylene chlorinated at 320° gave perchloromethane, perchlorethane, perchloromesole, C_4Cl_6 , and a brown compound, which, when further chlorinated at 380°, gave perchloromethane, perchlorethane, and perchlorobenzene.

Diisobutyl, chlorinated at 450°, gave perchloromethane, perchlorobenzene, and a trace of perchlorethane.

Diisoamyl at 360° gave about equal parts of perchloromethane, perchlorethane, and perchlorobenzene, and a trace of perchloromesole.

Cetyl iodide at 320° gave a large quantity of perchlorethane, together with some perchloromethane, perchloromesole, and a dark compound, which, on further chlorination at 360°, gave perchlorethane, perchlorobenzene, some perchloromethane, and a trace of a compound crystallising in small prisms and melting at 305·5°, which is probably perchlorodiphenyl.

Palmitic acid at 320° gave, as chief product, perchlorethane, together with a little perchloromethane and a dark compound, which, on further chlorination at 340°, gave, as chief product, perchlorethane and some perchloromethane and perchlorobenzene.

Pennsylvanian petroleum (commercial refined oil) at 350—360° gave perchlorethane and perchlorobenzene, small quantities of perchloromethane and perchloromesole, and a moderate quantity of residue, which, on chlorination at 450°, gave perchlorobenzene and perchloro-

methane. A specimen of petroleum boiling at 300—350° gave, on chlorination at a very high temperature, perchlorobenzene, as chief product, and perchloromethane.

Crude Galician ozokerite at 360° gave a large quantity of perchlorethane, together with perchloromethane, perchloromesole, perchlorobenzene, and a residue which on chlorination at 450° gave perchlorobenzene and a small quantity of perchloromethane. Ozokerite chlorinated at 450° gave perchloromethane and perchlorobenzene.

Bees'-wax at 450° gave a large quantity of perchloromethane, perchlorobenzene, and very little perchlorethane.

Perchloromesole, when heated for six hours at 450° with excess of antimony pentachloride containing iodine, is converted almost entirely into perchloromethane. Perchlorethane under similar conditions is also converted into perchloromethane.

Hence the hydrocarbons of the fatty series yield, as the final result of energetic chlorination, perchloromethane and perchlorobenzene, whilst perchlorethane and perchloromesole are obtained as intermediate products.

The author also describes the preparation of diisobutyl and diisomyl from isobutyl bromide and isoamyl bromide respectively. The bromides are mixed with dry ether, excess of sodium wire added, and the mixture allowed to remain for a day. The yield of diisobutyl amounts to 50 per cent. of that required by theory; the yield of diisomyl to over 90 per cent. This method is much cheaper than employing the iodides.

E. C. R.

Formation of Nitriles on Oxidation with Nitric Acid. By C. HELL and C. KITROSKY (*Ber.*, 24, 979—987).—When castor oil is oxidised with concentrated nitric acid, it yields a mixture of mono- and di-carboxylic fatty acids, and also various neutral compounds containing nitrogen, which are volatile with steam. Large quantities of capronitrile (b. p. 164—165°), considerable quantities of ceantho-nitrile (b. p. 180—185°), and small quantities of caprylonitrile (b. p. 200—205°) and valeronitrile (b. p. 140—143°) can be isolated from this neutral oil by fractional distillation, and probably also butyronitrile (b. p. 120—130°), but the quantity of the last-named compound is so small that it was not characterised with certainty; the other nitriles were identified by converting them into the corresponding fatty acids.

Fatty acids, such as caproic and ceanthyllic acids, or a mixture of the two, do not yield volatile nitriles on oxidation with concentrated nitric acid; ceanthaldehyde, on the other hand, yields about 1 per cent. of ceanthonitrile on treatment with nitric acid of sp. gr. 1.23 (3 parts).

Acetone gives about 1 to 1½ per cent. of its weight of hydrogen cyanide on oxidation with nitric acid, and methyl nonyl ketone yields octyl cyanide.

The above results may perhaps be explained by assuming that the nitric acid is reduced to ammonia, hydroxylamine, &c., and that condensation then takes place between the unchanged aldehyde or ketone and the reduction product; this view is, to a certain extent, borne out

by the fact that considerable quantities of ammonia are actually formed in the reactions. F. S. K.

Origin of the Higher Alcohols contained in Commercial Spirits. By L. LINDET (*Compt. rend.*, 112, 663—666).—Fermentation of sugar and of commercial "maltose" with a large quantity of yeast (80 per cent. of the sugar) yields a product containing a much smaller proportion of the higher alcohols than fermentation with a small quantity of the yeast (20 per cent. of the sugar). Acceleration of fermentation by addition of brewer's grains has a similar effect, the proportion of the higher alcohols being distinctly reduced. Previous experiments showed that the lower the temperature at which fermentation takes place, the lower the proportion of the higher alcohols, and the author considers that these results confirm the conclusions already published (this vol., p. 411). C. H. B.

Glucosoxime and Levulosoxime. By A. WOHL (*Ber.*, 24, 993—996; compare Jacobi, this vol., p. 644).—*Glucosoxime* is deposited in crystals when an alcoholic solution of anhydrous glucose and hydroxylamine is kept for 6 to 8 days at the ordinary temperature; it crystallises in small, anhydrous needles, melts at 135°, and does not decompose on prolonged heating at 100°. *Levulosoxime* can be prepared in a similar manner, but it is obtained in the form of a syrup which crystallises on keeping over sulphuric acid; it melts at 118° and resembles glucosoxime in appearance.

Ordinary reagents produce no precipitation in a solution of either of these oximes, and both compounds, even in presence of excess of alkali, prevent the precipitation of ferric hydroxide from solutions of ferric salts. Glucosoxime reduces ammoniacal silver solutions almost immediately, even in the cold, but levulosoxime does so only on warming; both compounds are feebly lævo-rotatory. On evaporating almost to dryness a solution of glucosoxime with concentrated soda, and then dissolving the yellowish residue in water, a solution which gives the Prussian blue reaction for hydrogen cyanide is obtained; the oximes of galactose, mannose, and levulose show a like behaviour.

When glucosoxime is dissolved in acetic anhydride containing a trace of zinc chloride, an energetic reaction takes place; on cooling, and pouring the solution into water, a thick oil is precipitated. This oil is readily decomposed by dilute alkalis, even in the cold, yielding a solution which contains hydrogen cyanide; when boiled with very dilute sulphuric acid, it is gradually decomposed into hydrogen cyanide and a substance which combines with phenylhydrazine yielding a yellow, crystalline compound which is not glucosazone.

F. S. K.

A Red Sediment formed in a Raffinose Solution. By F. G. WIECHMANN (*Chem. News*, 63, 5—7).—Whilst engaged in the isolation of raffinose from a low beet-sugar, the author obtained a small quantity of a substance having a bright-red colour. This substance contained iron, but was shown by spectroscopic examination not to

be hæmatin; it is remarkably fluorescent, and is insoluble in all ordinary solvents except concentrated mineral acids. No information is given as to its nature. G. T. M.

Action of Nitric and Sulphuric Acids on Vegetable Fibre. By J. LITSCHEURZ (*Ber.*, 24, 1186—1192).—Cellulose can be prepared in large quantities by the following process:—Fir-wood (1 part), free from bark, is cut into cubes 10—15 mm. in length, and heated at 45—50° with a mixture (10—15 parts) of concentrated sulphuric acid (1 vol.) and 25 to 30 per cent. nitric acid (3 vols.) for 14—16 hours; the light-yellow product is then separated from the warm solution, washed first with cold and then with hot water, and boiled with dilute soda until it is reduced to a pulp. The dark-brown liquid is run off and the pulp washed thoroughly with water (acidified with sulphuric acid if alkaline) until the washings are colourless. The cellulose obtained in this way is quite colourless, has a neutral reaction, and does not give the reactions of lignin; it is very strong and fibrous and contains 1.5—1.8 per cent. of ash, but is free from nitro-cellulose; the yield is 38—41 per cent.

The acid liquid, separated from the cellulose, contains considerable quantities of oxalic acid, small quantities of fatty acids, and substances, such as cellulosesulphuric acid, which reduce Fehling's solution; it is used again four or five times for treating fresh quantities of wood, the only difference being that, in each operation the mixture is raised to a temperature about 5° higher than that employed in the previous one. The nitric acid is then completely used up, and the clear solution, if left for about 24 hours, deposits a considerable quantity of oxalic acid; this product is nearly pure, and can be obtained in a state of purity by recrystallising once from water. In such a series of operations, the yield of cellulose is 38—40 per cent., and that of the oxalic acid 29—30 per cent. of the weight of the dry wood employed. The acid liquors remaining after separating the crystalline oxalic acid in the last operation contain about 30—32 per cent. of sulphuric acid, 1.5—2.0 per cent. of oxalic acid, and small quantities of cellulosesulphuric acid; after adding the proper quantity of nitric acid and a little sulphuric acid if necessary, a mixture is obtained which can be again used for treating a fresh quantity of wood. F. S. K.

Action of Phosphorus Oxychloride on Ethereal Silicates and their Chloro-derivatives. By H. N. STOKES (*Ber.*, 24, 933—936).—The action of phosphorus oxychloride on the trichlorhydrin of ethyl orthosilicate, SiCl_3OEt , was studied in the hope of obtaining silicon oxychloride, Si_2OCl_6 . The reaction, however, takes place in quite a different way. When the trichlorhydrin is heated with excess of phosphorus oxychloride in a sealed tube for 2 hours at 180°, ethyl chloride, a white, amorphous compound, and silicon tetrachloride are formed. The white, amorphous compound is freed from excess of phosphorus oxychloride by heating at 150—200° in a stream of dry air. On analysis, it gave numbers corresponding with the formula $\text{SiP}_2\text{O}_4\text{Cl}_2$. It is extremely hygroscopic, easily and completely soluble in absolute

alcohol, which proves the absence of free silicic acid, and is more soluble in water, but deposits silicic acid from the solution. On heating at 200° , phosphorus oxychloride is slowly evolved: at a red heat, phosphoric anhydride is given off, and a transparent glass remains, which contains lumps of silicic acid, and is probably the compound $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$. The author concludes that this white, amorphous substance is the chloride of a silicophosphoric acid. Neither the acid itself nor any of its salts could be isolated, as it is decomposed by water. When silver nitrate is added to the cold aqueous solution acidified with nitric acid and the silver chloride filtered off, the clear filtrate on addition of ammonia, deposits silver pyrophosphate, silver orthophosphate, and finally silicic acid. Phosphorus pentachloride at 100° easily converts it into silicon tetrachloride and phosphorus oxychloride.

The action of phosphorus oxychloride on the mono- and di-chlorhydrin of ethyl orthosilicate takes place according to the following equations:—

Ethyl orthosilicate is decomposed by phosphorus oxychloride according to the equation $\text{Si}(\text{OEt})_4 + 2\text{POCl}_3 = \text{SiP}_2\text{O}_6\text{Cl}_2 + 4\text{EtCl}$.

Hexethyl disilicate, $\text{Si}_2\text{O}(\text{OEt})_6$, is easily attacked by phosphorus oxychloride at 180° . Ethyl chloride is formed, together with a silicophosphoric chloride which is somewhat like the above, but has a different composition.

Ethyl disilicate chlorhydrin, when treated with phosphorus oxychloride, did not yield silicon oxychloride.

E. C. R.

Derivatives of Ethylamine. By S. GABRIEL (*Ber.*, 24, 1110—1121).—By the action of potassium hydrosulphide on bromethylphthalimide in alcoholic solution, the author has already found (*Abstr.*, 1889, 870) that ethylmercaptophthalimide,

is formed. Further investigation has shown that the corresponding monosulphide is always simultaneously formed. To prepare ethylmercaptophthalimide in the pure condition, an alcoholic solution of bromethylphthalimide and potassium hydrosulphide is heated at 100° under pressure; the product, when poured into water, solidifies almost immediately to a crystalline mass, which is separated from the monosulphide simultaneously formed by conversion into the mercury or lead salt, preferably the latter, which is then decomposed by dilute sulphuric acid. Ethylmercaptophthalimide separates out on evaporating the filtrate, and is purified by recrystallisation from alcohol; it becomes plastic at 76° , melts at $79-80^{\circ}$, and is converted by boiling 20 per cent. hydrochloric acid into phthalic acid and *amidomercaptan hydrochloride*, $\text{NH}_2 \cdot \text{C}_2\text{H}_4 \cdot \text{SH} \cdot \text{HCl}$, which crystallises in small, transparent needles.

Diphtalylamidoethyl sulphide, $(\text{C}_6\text{H}_4\text{O}_2 \cdot \text{N} \cdot \text{C}_2\text{H}_4)_2\text{S}$, is best obtained

by heating bromethylphthalimide with a slight excess of alcoholic potassium sulphide in a reflux apparatus. Hydrogen sulphide is evolved, and after half an hour the product is poured into water; the yellow oil thus precipitated gradually solidifies, and, on recrystallisation from alcohol, is obtained in slender, flat needles melting at $128-129^{\circ}$. The mercaptophthalimide is obtained simultaneously in small quantity. The monosulphide is not formed by the action of potassium sulphide, K_2S , on bromethylphthalimide, but may be obtained by treating sodium ethylmercaptophthalimide with bromethylphthalimide; the yield is, however, not good.

To eliminate phthalic acid from the monosulphide, either hydrochloric acid or potash may be employed; the *thioethylamine hydrochloride* thus obtained forms crystalline crusts or slender needles, melts at 181° , is hygroscopic and very soluble in water; its *aurrochloride* forms yellow, radial, spherical aggregates, its *platinochloride* yellow needles, and its *picrate* acute plates melting at 212° . By the action of aqueous soda and benzoic chloride, it yields a *benzoyl* derivative, which crystallises in scales and melts at $107-108^{\circ}$. The free *thioethylamine*, $S \cdot (CH_2 \cdot CH_2 \cdot NH_2)_2$, obtained by the action of solid potash on a concentrated solution of the hydrochloride, is a colourless oil, boils at $231-232^{\circ}$ under a pressure of 758 mm., and is miscible with water, forming a strongly alkaline solution.

When diphthalimidoethyl sulphide is oxidised with nitric acid of sp. gr. 1.25, nitrous fumes are evolved, and *diphthalimidoethyl sulphoxide*, $(C_8H_4O_2N \cdot CH_2 \cdot CH_2)_2SO$, is formed. The latter crystallises from alcohol or acetic acid in long, slender needles, melts at 189° , and is converted by hydrolysis with hydrochloric acid into *diamidoethyl sulphoxide hydrochloride*, $SO(CH_2 \cdot CH_2 \cdot NH_2)_2 \cdot 2HCl$, phthalic acid, and other products. The former crystallises in long, slender needles.

Under suitable conditions, ethylmercaptophthalimide may be oxidised to the corresponding bisulphide (see following abstract). The latter, on further oxidation with nitric acid of sp. gr. 1.25, yields *phthalyltaurine*, $C_8H_4O_2N \cdot C_2H_4 \cdot SO_3H + 1\frac{1}{2}H_2O$. This forms compact crystals and has a bitter taste; it becomes plastic at 85° , and at 100° melts to a milky liquid, which is completely transparent at $102-103^{\circ}$.

Gabriel and Heymann have previously shown (Abstr., 1890, 524) that thiazolines may be prepared by the action of alkylene dibromides on thioamides, hydrogen bromide being eliminated. The reaction does not, however, succeed with thiacetamide. The author has now found a new method of preparing mesophenylthiazoline (see following abstract), and has also succeeded in preparing mesomethylthiazoline in a similar manner. For this purpose, dithioethylamine hydrochloride was boiled with anhydrous sodium acetate and acetic anhydride; after removing the excess of the latter, the syrup, which is almost certainly the *diacetyl* compound, $(NHAc \cdot C_2H_4 \cdot S)_2$, was treated with phosphorus pentachloride, warmed for a few minutes, poured into water, the filtered solution made alkaline and distilled. The base comes over in the first portion, and is isolated by adding solid potash and extracting with ether. It boils at $144.5-145^{\circ}$ under a pressure of 769 mm., and has the expected composition, C_6H_7NS . On oxidation

with bromine-water, it yields taurine, and is converted by boiling hydrochloric acid into amidoethylamine hydrochloride and acetic acid; it must therefore be *mesomethylthiazoline*, $\begin{matrix} \text{CH}_2\cdot\text{S} \\ \text{CH}_2\cdot\text{N} \end{matrix} \gg \text{CMe}$. Its *picrate*, $\text{C}_6\text{H}_7\text{NS}\cdot\text{C}_6\text{H}_5\text{N}_3\text{O}$, forms long, flat needles, melting at 169 – 170° , and the *platinochloride* a pale-yellow, crystalline powder readily soluble in water.

When bromethylphthalimide is heated by itself, it blackens and evolves hydrogen bromide. On further heating, a portion distils over from which phthalimide and ethylphthalimide were isolated, and a large quantity of carbon remains behind.

Bromethylamine hydrobromide acts on ethyl acetoacetate in presence of aqueous soda forming *ethyl bromethylamido- α -crotonate*, $\text{C}_2\text{H}_4\text{Br}\cdot\text{NH}\cdot\text{CMe}\cdot\text{CH}\cdot\text{COOEt}$, which crystallises from light petroleum and melts at 48 – 50° . Bromethylphthalimide also combines with piperidine forming a syrup, which, on hydrolysis with hydrobromic acid and treatment with solid potash, yields *1-amidoethylpiperidine*, $\text{C}_6\text{NH}_{10}\cdot\text{C}_2\text{H}_4\cdot\text{NH}_2$. It is a colourless liquid, boils at 183 – 184° , and absorbs carbonic anhydride from the air, forming crystalline crusts; it is miscible with water and has an odour resembling, but much weaker than, that of piperidine. Its *hydrobromide*, $\text{C}_7\text{H}_{16}\text{N}_2\text{HBr}$, crystallises from absolute alcohol in acute needles; the *aurochloride* forms long needles, and the *platinochloride* rhombic tablets. Its solution in hydrochloric acid gives a deep-red coloration with potassium bismuthiodide.

H. G. C.

Dithioethylamine. By W. COBLENTZ and S. GABRIEL (*Ber.*, 24, 1122–1125).—When the crude alcoholic solution of ethylmercapto-phthalimide (see previous abstract) is treated with iodine or ferric chloride on the water-bath, it is converted into *diphthalylimidoethyl bisulphide*, $(\text{C}_8\text{H}_4\text{O}_2\text{N}\cdot\text{CH}_2\cdot\text{CH}_2)_2\text{S}_2$, which crystallises in small plates melting at 138 – 139° . When heated with hydrochloric acid at 190 – 200° , it is hydrolysed with formation of *dithioethylamine hydrochloride*, $(\text{NH}_2\cdot\text{C}_2\text{H}_4)_2\text{S}_2\cdot 2\text{HCl}$. The latter melts at 203° , and, on treatment with benzoic chloride and aqueous soda, yields *dibenzamido-diethyl bisulphide*, $(\text{NHBz}\cdot\text{C}_2\text{H}_5)_2\text{S}_2$, which crystallises from hot alcohol in needles and melts at 132° . When heated with phosphorus pentachloride at 100° , it yields a pale-yellow syrup, which is dissolved in a small quantity of dry chloroform and mixed with benzene. The crystals which separate are collected, washed with benzene, and placed over sulphuric acid. They become moist and ball together in the air, and are decomposed by soda with formation of an oil which may be driven over by steam, and is identical with the *mesophenylthiazoline* $\begin{matrix} \text{CH}_2\cdot\text{S} \\ \text{CH}_2\cdot\text{N} \end{matrix} \gg \text{CPh}$, described by Gabriel and Heymann (*Abstr.*, 1890, 524). The above hygroscopic crystals gave on analysis numbers agreeing with the formula $(\text{C}_8\text{H}_4\text{NS})_2\cdot 3\text{HCl}$, but the manner in which the reaction takes place is not yet fully ascertained.

H. G. C.

Action of Aqueous Ammonia on Isobutyl Chloride in Closed Vessels at 100° . By H. MALBOT (*Bull. Soc. Chim.* [3], 4,

693—697).—The author has endeavoured to determine the best conditions for the production of isobutylamine. From the results of nine experiments carried out under different conditions, he concludes that:—

(1.) It is not correct that an initial excess of ammonia always favours the formation of the primary amine to the exclusion of the secondary and tertiary products, but it considerably facilitates the transformation of the chloride. The rate of change of the isobutyl chloride augments very rapidly with the proportion of ammonia present. In two days, 31 per cent. is converted in the presence of two molecular proportions of ammonia, 50 per cent. with four; in three days 86 per cent. is transformed by six molecular proportions of ammonia, 95 per cent. by 10. Practically there is no advantage in using more than 10 molecular proportions of ammonia to one of isobutyl chloride.

(2.) Hofmann's hypothesis as to the formation of amines is inadequate to explain the results of these experiments, whereas the views put forward by the author in a previous paper (*Ann. Chim. Phys.*, March, 1888) account very well for the observed facts. W. T.

Hexamethylenamine. By Y. SCHWARZ (*Chem. Zeit.*, 14, 787).—*Hexamethylenamine tetrasilver bromide*, $C_6H_{12}N_4 \cdot 4AgBr$, is formed when an ammoniacal solution of silver nitrate is mixed with an ammoniacal formaldehyde solution containing ammonium bromide; as also when hexamethylenamine itself is used, and when metallic bromides act on hexamethylenamine silver nitrate. It is a curdy precipitate which partly dissolves, the other portion becoming rapidly crystalline. When heated strongly, hexamethylenamine passes off, leaving a mixture of silver bromide, metallic silver, and some charcoal. Nitric acid rapidly oxidises it, yielding pure silver bromide. The compound resembles the hexamethylenamine derivatives described by Horton (*Abstr.*, 1888, 1051). D. A. L.

Essential Oil of Mustard. By P. BIRKENWALD (*Chem. Centr.*, 1891, i, 266—267; from *Pharm. Zeit. Russ.*, 29, 785—787).—**Copper Compound of Allyl Thiocarbimide.**—A greenish-yellow, amorphous powder was found in the copper condenser when preparing allyl thiocarbimide. After washing it with alcohol, the colour changes to yellow; it dissolves in hydrochloric acid with evolution of hydrogen sulphide; it reacts with concentrated nitric acid, a strong odour of allyl thiocarbimide being emitted; it is blackened by potash, and allyl isothiocyanate is set free. The analysis agreed with a compound $CuS + C_3H_5NCS$.

Potassium Myronate.—The author has prepared potassium myronate from the seeds of *Brassica nigra* and *Sinapis juncea* by Will and Körner's method; both the specimens melted at 135° , and decomposed at 145° . The loss on heating at 100° during four hours amounted to 2.43 per cent. in the case of the specimen from *Brassica nigra*, and to 3.32 per cent. in that of the specimen from *Sinapis juncea*. The loss on heating should have been 4.3 per cent. to correspond with 1 mol. H_2O . The analysis of the specimen from *Sinapis juncea* gave results corresponding with those which Will obtained with a specimen from *Brassica nigra*. J. W. L.

Investigation of Crude Acetone. By L. WOLFES (*Chem. Zeit.*, 14, 1141—1142).—By fractionation, the crude oil boiling between 75° and 135° was separated into three fractions. From the first fraction, a substance boiling at 80° was obtained, which appeared to be methyl ethyl ketone. The second fraction yielded a substance boiling at 102—103°, which proved to be methyl propyl ketone; the absence of diethyl ketone was established. The third fraction, by repeated fractionation, yielded fractions of nearly equal amount; one boiling at 128—129° gave numbers between those required for methyl butyl ketone and allylacetone, the former substance being subsequently separated from its associates by means of sodium hydrogen sulphite. The oils not precipitated by this reagent were distilled from strong sodium hydroxide, and the indefinite substance (b. p. 128—130°) obtained was oxidised with nitric acid, evaporated to dryness, dissolved in water, and treated with barium hydroxide; the precipitate was found to contain succinic acid, the solution pyrotartaric acid. From the presence of the latter, the author infers that there is a ketone present containing a closed chain, probably identical with Kane's dumasine (*Annalen*, 110, 21).
D. A. L.

The Behaviour of Hexachlororthodiketohexene on Heating and towards Phosphorus Pentachloride. By T. ZINCKE and F. KÜSTER (*Ber.*, 24, 924—928).—Hexachlororthodiketohexene was prepared in a dry state by distillation under reduced pressure. The hydrate cannot be used in these experiments. The hexachlorodiketone when free from water forms a thick red oil, boils at 199° under 60 mm. pressure, solidifies when kept for some time, and absorbs water from the air with production of the hydrate. The red colour appears to be due to a little tetrachlororthoquinone.

When heated in a tube at 300—310° for some hours, colourless needles are obtained, mixed with liquid products. The needles are perchlorobenzene (m. p. 224°). The liquid also contains perchlorobenzene, which is separated by adding light petroleum. The filtrate, on remaining some time, deposits crystals of γ : γ -hexachloroketopentene

When the diketone is heated with phosphorus pentachloride (2 mols.) at 250°, it is completely converted into perchlorobenzene. When the reaction takes place at 200—210°, some perchlorobenzene is formed, together with a compound containing phosphorus. The compound obtained from the latter, after treatment with water, melts at 203°, forms shining plates, and is soluble in ether. As this compound was only obtained in small quantities from the diketone, which latter is difficult to prepare in the dry state, the authors attempted to prepare it from tetrachlororthoquinone.

Orthoquinone was heated with phosphorus pentachloride (2 mols.) for half an hour at 200—210°. On treatment with water, a mass of shining plates was obtained. The perchlorobenzene was extracted

from this with benzene, and the residue dissolved in ether and precipitated with benzene. Analysis showed that the compound was $C_6Cl_5O \cdot PO(OH)_2$. It forms white, silvery plates, melts at 203° with blackening, is soluble in ether, somewhat soluble in water, and is reprecipitated by hydrochloric acid, and dissolves in soda without decomposition. It is identical with the compound obtained from hexachlordiketohexene, and is also obtained from the para-derivatives $C_6Cl_5O_2$ and $C_6Cl_4O_2$. It is an intermediate compound in the production of perchlorobenzene. E. C. R.

Derivatives of Palmitic Acid. By C. HELL and C. JORDANOFF (*Ber.*, 24, 936—943).—The authors find that the most convenient material for the preparation of pure palmitic acid is Japanese wax, which yields one-half its weight of pure palmitic acid, whilst palm oil yields only one-fifth its weight. The acid was purified by distillation under reduced pressure, and melts at 62° .

α -Bromopalmitic acid is obtained by heating palmitic acid (175 grams) with phosphorus (7.1 grams) and bromine (65 c.c.). The product is purified by washing with water, when an emulsion is formed from which the acid is extracted with light petroleum. It crystallises in shining scales, melts at 51.5 — 52° , and solidifies in beautiful prisms or pyramids. It is insoluble, and when pure is incapable of forming an emulsion with water, dissolves easily in alcohol, benzene, ether, light petroleum, carbon bisulphide, and chloroform, and has no caustic action on the skin. The *ethyl* salt is obtained by passing hydrogen chloride into an alcoholic solution of the pure acid. It is a pale-yellow, fruity-smelling liquid, and boils at 241.5° under 38 mm. with slight decomposition.

α -Hydroxypalmitic acid is obtained by boiling the bromo-derivative with a slight excess of potassium hydroxide. When gently warmed with water, it forms an emulsion, and on raising the temperature of the water, rises to the surface as a yellow, transparent, gelatinous mass, which solidifies on cooling. It crystallises from alcohol in small, shining crystals, melts at 82 — 83° , and is easily soluble in alcohol, ether, and other organic solvents. The *copper* salt is obtained as a green precipitate on adding a hot alcoholic solution of copper acetate to an alcoholic solution of the free acid. The *lead* salt is obtained in a similar way as a white, powdery precipitate. The *barium* salt is obtained in crystalline flocks on adding barium chloride to an alcoholic solution of the ammonium salt. The *acetate*, $C_{15}H_{31}O_4Ac$, is obtained by boiling the acid with excess of acetic chloride, washing with water, and dissolving the oily product in ether. On distilling off the ether, it is obtained as a resinous mass. It crystallises from alcohol in white scales, melts at 62.5° , and is easily soluble in ether, less soluble in alcohol and other organic solvents.

α -Amidopalmitic acid is obtained by heating *α -bromopalmitic acid* with excess of alcoholic ammonia in a sealed tube for some hours on the water-bath. The product is mixed with water and acidified with sulphuric acid. A better yield is obtained by heating the mixture at 130 — 140° , and evaporating off the excess of ammonia and alcohol. It is a white, crystalline powder, insoluble in alcohol, ether, and

benzene, sparingly soluble in cold acetic acid, and easily soluble in hot acetic acid, and dissolves easily in alcoholic alkaline hydroxides, from which solution the alkali salt crystallises in beautiful plates of fatty lustre. The *acetyl* derivative is obtained by boiling with excess of acetic chloride as a thick oil, dissolves easily in ether and alcohol, and has not been obtained crystalline.

α-Anilidopalmitic acid is obtained by boiling bromopalmitic acid with excess of aniline. From boiling alcohol, it separates as a powdery precipitate, melts at 141–142°, and is easily soluble in benzene and ether. It has not been obtained crystalline.

Palmitanilide is obtained by boiling palmitic acid with excess of aniline for about five hours, and washing the product with dilute acid and water. It distils at 282–284° under 17 mm. pressure without decomposition, and is so obtained as a colourless liquid, which solidifies on cooling to a crystalline mass. It crystallises from alcohol in long, soft, shining needles, melts at 90.5°, and is easily soluble in alcohol, more soluble in ether, benzene, and carbon bisulphide.

E. C. R.

Cyanopalmitic Acid, Tetradecylmalonamic Acid, and Tetradecylmalonic Acid. By C. HELL and C. JORDANOFF (*Ber.*, 24, 987–993).—*Cyanopalmitic acid*, $C_{17}H_{31}NO_3$, is obtained when ethyl bromopalmitate is boiled for 4 to 5 days with potassium cyanide in alcoholic solution. The filtered solution is evaporated, the residue extracted with ether, the acid precipitated from the residual alkaline solution with hydrochloric acid, extracted by shaking with ether, and separated from regenerated palmitic acid by fractional crystallisation from light petroleum. It crystallises from hot glacial acetic acid in almost colourless plates, melts at 75–76°, and is moderately easily soluble in light petroleum; when heated at 220°, it is completely converted into palmitonitrile with evolution of carbonic anhydride, and when boiled with alcoholic potash, it yields palmitic acid.

Tetradecylmalonamic acid, $C_{14}H_{27}O_4N_2$, is formed when cyanopalmitic acid is boiled with concentrated alcoholic soda for about two days. It crystallises from hot alcohol in nacreous plates, is insoluble in water and ether, and decomposes at 130–140° with evolution of carbonic anhydride, but without melting, being converted into palmitamide (m. p. 104–105°).

Tetradecylmalonic acid, $C_{17}H_{33}O_4$, can be prepared by boiling the preceding compound for a long time with alcoholic potash; it is a semi-crystalline powder, melts at 117–118°, and is readily soluble in hot alcohol and boiling acetic acid, but only very sparingly in ether, and insoluble in water. When heated at 150–170°, it is converted into palmitic acid. The *silver* salt, $C_{17}H_{33}O_4Ag_2$, is colourless; the *calcium* salt, $C_{17}H_{33}O_4Ca$, *zinc* salt, $C_{17}H_{33}O_4Zn$, and *cadmium* salt, $C_{17}H_{33}O_4Cd$, are crystalline; the *copper* salt, $C_{17}H_{33}O_4Cu$, decomposes at 180°.

F. S. K.

Propylideneacetic Acid from Malonic Acid and from Orthamidophenol. By T. ZINCKE and F. KÜSTER (*Ber.*, 24, 908–911).—The authors undertook this work with the object of determining whether the acid $C_6H_5O_2$, obtained by them from catechol, was propyl-

idenaeacetic acid, $\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}\cdot\text{CH}\cdot\text{COOH}$, or was identical with the ethylidenepropionic acid, $\text{CH}_3\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}_2\cdot\text{COOH}$, obtained from acetaldehyde and succinic acid. The solution of this question was of interest, because the authors had based the constitution of the hexachlorodiketone and other chloro-compounds obtained from catechol on the production of propylidenaeacetic acid. Ethylidenepropionic and propylidenaeacetic acids are easily distinguished by treating the acid with hydrogen bromide and boiling the resulting compound with water. If valerolactone is formed, then the compound is ethylidenepropionic acid. The authors find that the acid obtained from malonic acid and that from catechol behave alike. From both, a minute quantity of valerolactone was obtained, but the main product is an acid not containing bromine, which is probably an hydroxy-acid. The formation of a small quantity of valerolactone is probably due to a small quantity of the propylidenaeacetic acid having undergone molecular change.

Propylidenaeacetic acid was prepared from malonic acid according to the directions of Fittig and Frankel. It boiled at $193-196^\circ$. The acid (4—5 grams), cooled with ice, was treated with somewhat more than an equal volume of hydrobromic acid saturated at 0° , and the mixture allowed to remain for a few days at the ordinary temperature, ice-cold water added, and the bromovaleric acid washed with ice-cold water and dried over potash and sulphuric acid. The bromovaleric acid was then boiled with water for some hours, the solution saturated with soda, and extracted with ether. On distillation of the product, 2—3 drops of valerolactone (b. p. $201.5-202^\circ$) were obtained. The main product of the action was not examined.

Propylidenaeacetic acid from orthamidophenol boiled at $192-195^\circ$. It was treated in the same way as the above acid, and yielded only a few drops of valerolactone. E. C. R.

Velocity of Lactone-formation in the Case of various Hydroxy-acids. By E. HJELT (*Ber.*, 24, 1236—1239).—The author has made a number of experiments on the relative velocity of the lactone formation in the case of the five hydroxy-acids named below. A solution of the pure lactone (0.0055 molecule in grams) is warmed with a slight excess of one-fifth normal potash, then cooled, exactly neutralised with hydrochloric acid, mixed with decinormal hydrochloric acid (50 c.c.), and diluted to 100 c.c. with water. The one-twentieth normal solution prepared in this way contains, besides the hydroxy-acid, potassium chloride and a small quantity of salt of the hydroxy-acid; the presence of the latter retards lactone-formation, but as the quantity is the same in all cases the values obtained are comparable one with another; the potassium chloride has no appreciable influence on the reaction. The prepared solutions are then heated at 100° in portions of 10 c.c., and after five minutes warming the initial condition is determined; portions of the solutions are taken after certain periods of time, poured into ice-cold water, and the acid present titrated with a centinormal solution of barium hydroxide.

The details of the results and the reaction coefficients calculated therefrom are given in a table. The times required for the conversion of 50 per cent. of the various acids into the corresponding lactones

were found to be as follows:—Hydroxybutyric acid, 906 minutes; hydroxyvaleric acid, 126 minutes; hydroxycaproic acid, 70 minutes; hydroxyisocaproic acid, 56 minutes; hydroxymethylbenzoic acid, 15 minutes. F. S. K.

Isomerism of Oximes. By A. HANTZSCH (*Ber.*, 24, 1192—1198).—Minunni's explanation of the isomerism of oximes (*Gazzetta*, 21, 113) is a very improbable, if not an impossible, one, for various reasons. In the first place the iso- or β -oximes do not show the characteristic properties of partially reduced benzene derivatives, as they should if Minunni's formulæ were correct. Secondly, the formation of nitriles from β -aldoximes is quite inexplicable assuming Minunni's views to be correct. Thirdly, the intramolecular change observed by Beckmann in the case of the isomeric ketoximes cannot be explained in accordance with Minunni's formulæ. Fourthly, the number of isomerides actually capable of existence as proved by experiment, is not the same as the number required by Minunni's theory. The existence of isomeric oximes belonging to the fatty series is also a conclusive proof that Minunni's explanation of isomerism in the aromatic series is not the correct one.

The author then goes on to discuss the question of the isomerism of oximes of the fatty series, especially with regard to the results obtained by Cramer (compare following abstract). F. S. K.

Monoximes of Succinic Acid. By C. CRAMER (*Ber.*, 24, 1198—1214).—The author's experiments have shown that the ethyl hydrogen oximidosuccinate obtained by Ebert from ethyl succinosuccinate and nitrous acid (*Abstr.*, 1885, 1122) is stereochemically isomeric with the compound prepared by Prutti from ethyl oxalacetate and hydroxylamine (compare *Abstr.*, 1889, 383 and 1890, 1239). The former is most probably the labile α -oxime of the configuration $\text{COOEt} \cdot \overset{\text{OH} \cdot \text{N}}{\underset{\text{||}}{\text{C}}} \cdot \text{CH}_2 \cdot \text{COOH}$, the latter the stable β -oxime of the configuration $\text{COOEt} \cdot \overset{\text{N} \cdot \text{OH}}{\underset{\text{||}}{\text{C}}} \cdot \text{CH}_2 \cdot \text{COOH}$. That this view is the correct

one is rendered highly probable by the fact that the β -derivative exhibits analogy with the oxime of acetoacetic acid, which has doubtless the configuration $\text{CH}_3 \cdot \overset{\text{N} \cdot \text{OH}}{\underset{\text{||}}{\text{C}}} \cdot \text{CH}_2 \cdot \text{COOH}$. The behaviour of the two compounds is also in harmony with this view; the β -dicarboxylic acid described below, which is obtained from the β -oximido-derivative, is readily converted into cyanoacetic acid, and the corresponding ethyl salt readily changes into ethyl nitrilosuccinate,

whereas the ethyl hydrogen salt of the α -derivative is readily decomposed into ethyl oximidopropionate and carbonic anhydride; these reactions are most easily explained by assuming the compounds to have the configurations assigned to them above.

Ethyl hydrogen α -oximidosuccinate, prepared as described by Ebert (*loc. cit.*), melts at 107° , and gives with ferric chloride a brown or a yellow coloration, according as the solution is concentrated or dilute; when heated at its melting point, or when warmed with water at about 80° , it is decomposed into ethyl β -oximidopropionate and carbonic anhydride.

Ethyl hydrogen β -oximidosuccinate (compare Piutti, *loc. cit.*) is most conveniently prepared by adding concentrated soda (1 mol.) to ethyl oxalacetate in the cold, and warming the sodium compound obtained in this way with a solution of a slight excess of the theoretical quantity of hydroxylamine hydrochloride, when the oxime is deposited as a colourless oil; soda (1 mol.) is then added, and, after keeping for several hours, the solution is strongly acidified, and the product extracted with ether. It melts at 54° , is more sparingly soluble than the α -compound, and gives an intense violet coloration with ferric chloride; under certain conditions, it undergoes decomposition into ethyl α -oximidopropionate and carbonic anhydride, but the change takes place far less readily than in the case of the α -compound.

α -Oximidosuccinic acid, $\text{COOH} \cdot \underset{\text{OH} \cdot \text{N}}{\underset{|}{\text{C}}} \cdot \text{CH}_2 \cdot \text{COOH}$, prepared by hydro-

lysing the ethyl hydrogen salt with alcoholic soda (compare Ebert, *loc. cit.*), melts at 125° , being decomposed into water, carbonic anhydride, and cyanoacetic acid; the same decomposition takes place on heating an aqueous solution of the acid at 105 – 130° . In concentrated solutions, ferric chloride produces a brown, in dilute solutions a yellow, coloration.

β -Oximidosuccinic acid, $\text{COOH} \cdot \underset{\text{N} \cdot \text{OH}}{\underset{|}{\text{C}}} \cdot \text{CH}_2 \cdot \text{COOH}$, or

is obtained when the β -compound described above is hydrolysed with soda in the cold, the solution acidified and extracted with ether. It melts at 88° with decomposition, and is more sparingly soluble in water, alcohol, and ether than the α -acid; it is insoluble in benzene, chloroform, and light petroleum. It turns red on exposure to the air, either in the dry state or in aqueous solution, and it gives a characteristic blue coloration with ferric chloride; in neutral ammoniacal solutions, most metallic salts produce colourless precipitates, the silver salt being very explosive. When the acid is heated at about 40° in concentrated aqueous solution, carbonic anhydride is evolved, and, on evaporating, cyanoacetic acid remains as a colourless, deliquescent, crystalline mass; the same decomposition takes place to a considerable extent when the β -oximido-acid is kept for some time over potash at the ordinary temperature; its acid solutions are also unstable even at the ordinary temperature, but its alkaline solutions can be boiled without undergoing any change.

When the ethyl hydrogen salt of the α -acid is treated with concentrated sulphuric acid, acetic chloride, or acetic anhydride, it is

converted into the corresponding β -compound; the α -dicarboxylic acid is also converted into the β -derivative on treatment with concentrated sulphuric acid.

β -Oximidosuccinic anhydride, $\text{OH}\cdot\text{N}\cdot\text{C} < \begin{smallmatrix} \text{CO}\cdot\text{O} \\ \text{CH}_2\cdot\text{CO} \end{smallmatrix}$, is formed when the β -acid is treated with acetic chloride; it forms colourless crystals, softens at 95° , and melts completely at 105° with decomposition. It is only moderately easily soluble in water, being thereby converted into the acid, but when heated alone it is readily decomposed into carbonic anhydride and cyanoacetic acid. The *acetyl* derivative $\text{OAc}\cdot\text{N}\cdot\text{C} < \begin{smallmatrix} \text{CO}\cdot\text{C} \\ \text{CH}_2\cdot\text{CO} \end{smallmatrix}$, prepared by treating the anhydride, or the acid, with acetic anhydride, forms large, colourless crystals, melts at 105° with decomposition, and is readily decomposed by water.

When the α -acid is treated with acetic chloride or with acetic anhydride, it yields products identical with those obtained from the β -acid in like manner, and which, on decomposition with water, yield the β -acid.

F. S. K.

Dioximidosuccinic Acids. By H. G. SÖDERBAUM (*Ber.*, 24, 1215—1235).—According to the theory of Hantzsch and Werner, there are three dioximidosuccinic acids capable of existence. The author has succeeded in preparing two of these compounds; the one is doubtless the $\alpha\alpha$ -dioxime of the configuration $\begin{smallmatrix} \text{COOH}\cdot\text{C}\cdot\text{C}\cdot\text{COOH} \\ \text{OH}\cdot\text{N}\cdot\text{N}\cdot\text{OH} \end{smallmatrix}$; the other is probably the $\beta\beta$ -dioxime of the configuration

whilst the third isomeride, namely, the $\alpha\beta$ -dioxime of the configuration $\begin{smallmatrix} \text{COOH}\cdot\text{C} & \text{---} & \text{C}\cdot\text{COOH} \\ \text{HO}\cdot\text{N} & & \text{OH}\cdot\text{N} \end{smallmatrix}$, could not be obtained. The various

reactions which throw light on the constitution of the two dioximes are described below (compare Hantzsch, this vol., p. 439).

$\beta\beta$ -Dioximidosuccinic acid (dihydroxytartaric acid *$\beta\beta$ -dioxime*) has been previously prepared by Müller (*Abstr.*, 1884, 584), who named it diisnitrososuccinic acid; although the method of preparation employed by Müller gives a very pure product, it occupies rather a long time, and the yield is only about 20 per cent. of the theoretical. The following method was found to be more convenient:—A mixture of commercial sodium dihydroxytartrate (1 mol.) and a slight excess of the theoretical quantity (2 mols.) of hydroxylamine hydrochloride is dissolved in the least possible quantity of cold, dilute hydrochloric acid of sp. gr. 1.03—1.04, the solution kept for about 12 hours at the ordinary temperature, filtered if necessary, and extracted 10 to 12 times with ether; the ethereal solution is dried over anhydrous sodium sulphate, about four-fifths of the ether evaporated on the water-bath, the residual solution cooled with ice and evaporated over sulphuric acid under reduced pressure. As soon as crystallisation commences, dry chloroform (about 3 parts) is added

with constant stirring, when the dioxime is almost completely deposited in crystals, whilst the furazancarboxylic acid, which is also produced, remains in solution. The colourless, crystalline product is quickly separated by filtration, pressed, and recrystallised from a mixture of ether and chloroform, from which it separates in large, colourless, transparent prisms containing 2 mols. H_2O , and melting at about 90° ; the yield is about 30 per cent. of the theoretical. It is deposited from aqueous solutions in crystals containing 4 mols. H_2O , which melt at $70\text{--}75^\circ$, and from ether it separates in crystals containing a quantity of water varying from 2 to 4 mols.; the crystals lose the whole of their water over sulphuric acid, the anhydrous compound melting at $145\text{--}150^\circ$ with decomposition. $\beta\beta$ -Dioximidosuccinic acid is very readily soluble in water, alcohol, and ether, but insoluble in benzene, chloroform, and light petroleum; it has acid properties, turns red litmus blue, and decomposes carbonates, but is also readily soluble in acids. The silver salt, $\text{C}_4\text{H}_2\text{N}_2\text{O}_6\text{Ag}_2$, crystallises in long, colourless needles melting at $140\text{--}150^\circ$ with decomposition. The calcium salt, $\text{C}_4\text{H}_2\text{N}_2\text{O}_6\text{Ca} + 4\text{H}_2\text{O}$, is deposited in microscopic, hexagonal plates on adding calcium acetate to a moderately concentrated solution of the acid; it loses 2 mols. H_2O at $95\text{--}100^\circ$, and is gradually decomposed at a higher temperature. In aqueous solutions of the acid, barium acetate produces no precipitate, but barium hydroxide gives a colourless, ferric chloride a dark red, and copper acetate a dirty green precipitate which soon turns brown; on adding a little soda and then ferrous sulphate to a solution of the acid, an intense violet coloration is produced. The acid crystallises unchanged from boiling water, but it is unstable towards acids, being thereby converted into the $\alpha\alpha$ -dioximido-compound. The diacetyl derivative, $\text{C}_4\text{H}_2\text{N}_2\text{O}_4(\text{OAc})_2$, is obtained in colourless needles or rhombic plates, when the pure anhydrous acid is kept in contact with acetic anhydride at 0° until dissolution is complete, and the excess of anhydride then evaporated over potash; it melts at about 150° with decomposition, gradually decomposes on exposure to the air with liberation of acetic acid, and is readily soluble in water, alcohol, and ether, but is insoluble in benzene. The silver salt is precipitated in well-defined rectangular plates on adding silver nitrate to a freshly prepared aqueous solution of the diacetyl derivative. When an aqueous solution of the diacetyl derivative is evaporated at the ordinary temperature, it is completely decomposed and the $\beta\beta$ -dioxime is deposited in crystals; the diacetyl derivative is also decomposed by soda or sodium carbonate into furazancarboxylic acid (see below) and carbonic anhydride.

When $\beta\beta$ -dioximidosuccinic acid is treated with excess of acetic chloride at the ordinary temperature, it gradually passes into solution, and on evaporating the excess of acetic chloride over potash, there remains an almost colourless oil, from which, in some experiments, a small quantity of a crystalline compound was gradually deposited; this oil is doubtless an acetyl derivative, but it was not analysed; it is quickly decomposed by water, being thereby converted into the $\alpha\alpha$ -dioxime, and when treated with sodium carbonate, or with dilute soda, it is transformed into furazancarboxylic acid.

αα-Dioximidosuccinic acid is most conveniently prepared by dissolving the $\beta\beta$ -compound in a little concentrated hydrochloric acid, and keeping the solution for some time at the ordinary temperature, when the $\alpha\alpha$ -dioxime is gradually deposited in crystals; it is also formed when the $\beta\beta$ -compound is treated with hydrogen chloride, or with phosphorus pentachloride, in ethereal solution. It usually separates from a mixture of chloroform and ether as an oil, which then solidifies to a mass of crystals, having the composition $C_4H_4N_2O_6 + 2H_2O$; these crystals lose their water at $40-45^\circ$, the anhydrous substance melting at $145-150^\circ$ with decomposition. It is very readily soluble in water, alcohol, and ether, but insoluble in chloroform, benzene, and light petroleum; as regards chemical behaviour and the solubility of its salts, it resembles closely the isomeride just described. The *silver* salt, $C_4H_2N_2O_6Ag_2 + H_2O$, prepared by adding silver nitrate to an aqueous solution of the acid, is a colourless, granular compound moderately stable in the light; it loses its water at 60° , melts at $145-150^\circ$, and explodes violently at about 153° . The *calcium* salt, $C_4H_2N_2O_6Ca + 3H_2O$, is precipitated in colourless, microscopic prisms on adding calcium acetate to a solution of the acid; it loses only part of its water at 100° . An aqueous solution of the $\alpha\alpha$ -acid gives the same reactions with ferrous sulphate and with ferric chloride as the $\beta\beta$ -compound, but with copper acetate there is produced a green, amorphous precipitate.

αα-Dioximidosuccinic acid is not decomposed by boiling dilute alkalis, but when treated with acetic anhydride at the ordinary temperature, it is gradually and completely decomposed into water, cyanogen, and carbonic anhydride. On treatment with acetic chloride, it yields a colourless oil which, in all probability, is identical with the compound obtained in like manner from the $\beta\beta$ -derivative; this oil is reconverted into the $\alpha\alpha$ -dioximido-acid by cold water, but alkalis decompose it into furazancarboxylic acid and carbonic anhydride.

Furazancarboxylic acid (azoxazolecarboxylic acid),

is obtained in the preparation of $\beta\beta$ -dioximidosuccinic acid as described above, and is isolated by evaporating the ethereal chloroform mother liquors from the dioxime; the yellow oil obtained in this way gradually solidifies and can then be recrystallised from cold chloroform; it is best prepared in a pure condition by treating either of the dioximido-acids with acetic chloride, and decomposing the product with soda or sodium carbonate. It crystallises in colourless needles, melts at $101-102^\circ$ with decomposition, and is very readily soluble in water, alcohol, and ether, and moderately easily in chloroform, but insoluble in benzene and light petroleum; it cannot be obtained in an anhydrous condition either by recrystallisation from dehydrating solvents or by careful heating. It dissolves in soda yielding a yellow solution, from which it is precipitated unchanged on acidifying, and it is not decomposed by cold concentrated sulphuric acid, but, on prolonged boiling with dilute hydrochloric acid, it is completely

destroyed, the principal product being oxalic acid; it is completely decomposed when heated at 100° , a strong odour of cyanogen being observed, and when treated with potassium permanganate at the ordinary temperature, it is completely destroyed, carbonic anhydride, cyanogen, and nitric acid being formed. The silver salt, $C_3H_3N_2O_3Ag$, is precipitated in colourless, granular crystals, on adding silver nitrate to an aqueous solution of the acid, but from neutral aqueous solutions a yellow, crystalline, explosive salt of the composition $C_3H_3N_2O_3Ag_2$ is precipitated; on adding copper acetate to a moderately concentrated solution of the acid, a dark-green solution is obtained, and after a short time a copper compound is deposited in well-defined plates, which explode violently when heated. The acid is not acted on by acetic anhydride at the ordinary temperature, but when heated therewith it is completely decomposed; attempts to prepare an acetyl derivative with the aid of acetic chloride were also unsuccessful.

F. S. K.

Trimethylsuccinic Acid. By C. A. BISCHOFF (*Ber.*, 24, 1041—1049).—No definite compound could be obtained by the action of sodium ethoxide on ethyl α -bromisobutyrate. On treatment with alcoholic potash, however, α -ethoxyisobutyric acid, methylacrylic acid, and α -hydroxyisobutyric acid are formed. *Methacrylic anilide*, $CH_2=CMe_2CO\cdot NPh$, crystallises from dilute alcohol in lustrous prisms, and melts at 120° .

Ethyl α -bromisobutyrate, on treatment with concentrated aqueous ammonia at low temperatures yields a crystalline *amide* of the formula $CMe_2Br\cdot CONH_2$, which melts at 147° . By the action of aniline at 0° , an anilide is formed in small quantity, which crystallises in needles and remains unmelted at 250° ; on heating the isobutyrate with aniline (2 mols.) at 150 — 160° , ethyl α -anilidisobutyrate, $NPh\cdot CMe_2\cdot COOEt$, is obtained. *α -Bromisobutyric anilide*, $CMe_2Br\cdot CO\cdot NPh$, is formed quantitatively by the action of aniline on α -bromisobutyric bromide in benzene solution at the ordinary temperature; it crystallises from dilute alcohol and melts at 83° ; a proof is thus afforded of the freedom of the ethyl α -bromisobutyrate from any β -bromo-derivative.

Trimethylsuccinic acid is prepared by treating ethyl sodiummethylmalonate with ethyl α -bromisobutyrate for 5 hours at 180 — 190° under pressure, the product is washed with water, distilled, and the portion boiling at 275 — 285° hydrolysed with alcoholic potash, the acid thus obtained is heated at 200° until carbonic anhydride ceases to be evolved, the residue is distilled, and the portion passing over up to 250° recrystallised, first from chloroform, then from benzene and light petroleum; the acid melts at 139.5° , its electrolytic conductivity is $M_{\infty} = 351$; $k = 0.031$, and it is in all respects identical with the trimethylsuccinic acid of Zelinsky and Besredka (this vol., p. 669). The higher fractions (b. p. 260 — 280°), separated during the distillation after hydrolysis, consist of symmetrical dimethylglutaric acid (m. p. 102 — 105°).

The acid (m. p. 106°) previously prepared by the author and Hall from amylene bromide, and termed trimethylsuccinic acid, is in

all probability asymmetrical ethylmethylsuccinic acid,

J. B. T.

Substituted Dimethylsuccinic Acids. By C. A. BISCHOFF (*Der.*, 24, 1050—1064).—It has previously been shown (this vol., p. 290) that ethyldimethylsuccinic acid, $\text{COOH}\cdot\text{CHEt}\cdot\text{CMe}_2\cdot\text{COOH}$, may be prepared by the action of ethyl α -bromisobutyrate on ethyl sodioethylmalonate; considerable quantities of ethylmethylglutaric acid, $\text{COOH}\cdot\text{CHEt}\cdot\text{CH}_2\cdot\text{CHMe}\cdot\text{COOH}$, are also formed during the reaction. The succinic acid gives a white precipitate with potassium aluminium sulphate, and with lead, mercury, and zinc salts; copper sulphate produces a green, flocculent precipitate, and ferric chloride a yellowish-brown one. The electrolytic conductivity has been re-determined, and found to be $M_\infty = 351$; $k = 0.056$. All attempts to convert the acid into an isomeric form were fruitless.

Ethylmethylcarboxylglutaric acid, $\text{COOH}\cdot\text{CHMe}\cdot\text{CH}_2\cdot\text{CEt}(\text{COOH})_2$, melts at 166.5° with evolution of carbonic anhydride, and is almost insoluble in light petroleum or carbon bisulphide; the *silver, mercury, and lead* salts are white and insoluble.

Parathyethylmethylglutaric acid crystallises from water in aggregates of small, slender needles, melts at 105° , and is insoluble in carbon bisulphide or xylene. The *lead, silver, aluminium, cupric, ferric, and zinc* salts are sparingly soluble; the last is crystalline, and is only precipitated on warming.

The meso-acid closely resembles the para-acid, from which it is separated by fractional crystallisation from water; it is deposited in concentric needles melting at 61° .

A mixture of these acids may be prepared by the following method, which also serves to show that they are actually glutaric acids. Ethyl sodiodicarboxylgluconate,

is treated with ethyl iodide, and the product reduced; the sodium derivative of the resulting ethyl ethyldicarboxylglutarate is treated with methyl iodide, and the ethyl methylethyldicarboxylglutarate, $\text{CEt}(\text{COOEt})_2\cdot\text{CH}_2\cdot\text{CMe}(\text{COOEt})_2$, thus obtained is hydrolysed; the acid melts at 150 — 170° with evolution of carbonic anhydride, and, after the complete elimination of this, crystals are deposited which melt at 70 — 76° , and behave in every way like a mixture of para- and meso-ethylmethylglutaric acid.

Propyldimethylsuccinic acid, $\text{COOH}\cdot\text{CMe}_2\cdot\text{CHPr}\cdot\text{COOH}$, is prepared from ethyl sodiopropylmalonate and ethyl α -bromisobutyrate, and crystallises from water in slender, rhombic needles; it is insoluble in light petroleum or carbon bisulphide, and melts at 140° . The electrolytic conductivity is $M_\infty = 350$; $k = 0.055$. It was not found possible to convert the acid into an isomeric modification. The *calcium, cadmium, zinc, aluminium, ferric, cupric, mercuric, lead, and silver* salts are all more or less insoluble.

Benzyl dimethylsuccinic acid, $\text{COOH}\cdot\text{CH}(\text{C}_6\text{H}_5)\cdot\text{CMe}_2\cdot\text{COOH}$, is obtained from ethyl sodiobenzylmalonate and ethyl α -bromisobutyrate by heating for 10 hours at 190 — 205° under a pressure of 5—6 atmos.;

the acid crystallises from water in short, prismatic needles and melts at 140° ; on heating at 152° , water is eliminated. The electrolytic conductivity is $M_{\infty} = 350$; $k = 0.046$. Like the preceding acids, this could not be converted into an isomeride. The calcium salt is deposited in needles; the zinc, mercuric, lead, and silver salts are crystalline; the aluminium and ferric salts flocculent.

On heating benzyl chloride with ethyl sodioisobutylenetricarboxylate in xylene solution for 12 hours under a pressure of 5–6 atmos., dibenzylmalonic acid is formed in considerable quantity; the highest boiling portion of the product consists of ethyl benzylisobutenyltricarboxylate, whilst the lowest fraction probably contains methylacrylic acid; no benzyldimethylsuccinic acid or benzylnethylglutaric acid could be detected.

J. B. T.

Transformation of Ethyl Disodiotartrate by Ethyl Chloride.

By E. MULDER (*Rec. Trav. Chim.* [9], 5, 238–275).—After some time, a solution of ethyl disodiotartrate in ethyl chloride yields a precipitate. The decanted mother liquor, freed from excess of ethyl chloride, and evaporated to dryness in an atmosphere of hydrogen under reduced pressure, gives a yellow, amorphous residue. This substance, dissolved in absolute ether, is recovered unaltered on evaporation of the solvent. It contains ethyl chloride, which is given off in a vacuum, leaving a product which gelatinises in damp air, and, in aqueous or alcoholic solutions, is coloured cherry-red by ferric chloride. On heating in an atmosphere of hydrogen under reduced pressure at about 90° , no ethyl chloride comes off, but about 10 per cent. of a gas, probably ethylene, is evolved.

The main constituent of the yellow, amorphous mass appears to have the composition

+ $1\frac{1}{2}$ molecular proportions of ethyl chloride, which are not lost when the compound is kept under diminished pressure. The yellow colour is probably due to the presence of a coloured impurity. The ethereal solution of this substance, when treated with hydrogen chloride, yields ethyl pyruvate.

The author concludes, from the results of his experiments, that a system of equilibrium exists between ethyl disodiotartrate, ethyl chloride, alcohol, and the substance formed in the reaction. Alcohol retards, ethyl chloride accelerates, the transformation.

It is claimed that by the use of ethyl chloride as a solvent for such substances as ethyl disodiotartrate, the study of many reactions is rendered possible.

W. T.

Acetyliodobenzene and Iodomandelic Acid. By R. SCHWEITZER (*Ber.*, 24, 997; compare this vol., p. 729).—The acetyliodobenzene recently described (this vol., p. 684) is probably identical with pariodacetophenone (m. p. 79°); when treated with bromine in carbon bisulphide solution, it is converted into the dibromo-derivative, $\text{C}_6\text{H}_4\text{I}\cdot\text{CO}\cdot\text{CHBr}_2$, which melts at 86° .

Iodomandelic acid, $C_6H_4I \cdot CH(OH) \cdot COOH$, is obtained when this bromo-derivative is treated with potash (1 : 10) at the ordinary temperature. It melts at 135° , and is readily soluble in water, alcohol, and ether, but only sparingly in light petroleum; the barium salt is readily soluble.

F. S. K.

Action of Aldehydes on Thioamides. By J. EPHRAIM (*Ber.*, 24, 1026—1031).—*Dibenzylidenedithioamide*,

is formed when dithioamide (1 gram) is heated to boiling with benzaldehyde (9 grams) in a reflux apparatus. The crystalline mass so obtained is dried on a porous plate, and crystallised from benzene or acetic acid. It crystallises in yellowish-white needles, melts at 209° , is a very indifferent substance, and does not dissolve in aqueous soda or hydrochloric acid. The sulphur is not displaced when the compound is treated with mercury oxide. It is not resolved into its components when heated with hydrochloric acid in a sealed tube; methyl iodide has no action on it. When oxidised with permanganate or chromic acid, benzoic acid, ammonia, and sulphuric acid are formed.

Dibenzylidenedithioamide, $C_{18}H_{12}S_2N_2O_2$, is obtained from salicylaldehyde and dithioamide in a similar way to the above. It dissolves in caustic soda to an orange-yellow solution, is reprecipitated by acids, and crystallises from chloroform. The *benzoyl compound*, $C_{18}H_{10}S_2N_2O_2Bz_2$, is pale-yellow, and melts at 156° .

Dinitrodibenzylidenedithioamide, $C_{18}H_{10}S_2N_4O_4$, is obtained by warming dibenzylidenedithioamide with nitric acid (sp. gr. = 1.50). It is a lemon-yellow compound, crystallises from boiling aniline, and melts at 269° . On oxidation with chromic acid, it yields para-nitrobenzoic acid, ammonia, and sulphuric acid. It is not reduced by tin and hydrochloric acid, nor by zinc and acetic acid. When heated with hydriodic acid (1.7) and phosphorus for some hours at 190° in a sealed tube, it yields hydrogen sulphide and amidobenzylamine.

Dibenzylidenedithioamide, when reduced with hydriodic acid, did not yield benzylamine, but benzoic acid. The author supposes that benzonitrile is first formed, and that this is then hydrolysed by the hydriodic acid to benzoic acid. He is at present engaged in further examination of this reaction.

The stability of these compounds towards acids shows that they are not analogous to the compounds formed from acid amides and aldehydes, which latter are easily decomposed into their components. The behaviour of the nitro-compound on reduction with hydriodic acid and phosphorus shows that the nitrogen of the dithioamide is combined with the benzaldehyde residue. Hence, the author concludes that the above formula of dibenzylidenedithioamide is correct. And he points out that dithioamide behaves in this reaction as if its constitution were $NH \cdot C(SH) \cdot C(SH) \cdot NH$.

Thiobenzamide reacts with benzaldehyde and salicylaldehyde to form compounds which do not contain sulphur. Thioacetanilide does not react with benzaldehyde.

E. C. R.

Theory of Dyeing. By L. VIGNON (*Compt. rend.*, **112**, 623—624).—The author has previously shown (*Abstr.*, 1890, 553, 939) that animal fibres, which dye easily, have well marked acidic or basic functions, whilst in vegetable fibres, which dye with difficulty, such functions are very feeble; that cotton, when heated with ammonia takes up nitrogen, acquires a basic function, and dyes readily with acid colouring matters (this vol., p. 662); that the power of stannic acid to combine with basic colouring matters is proportional to the energy of the acidic function of the acid (this vol., p. 807). Moreover, all the mordants employed in dyeing are either basic or acidic oxides. All soluble colouring matters natural and artificial, contain a salifiable group, OH, or a basic group, NH₂, or acidic group, NO₂. No true colouring matter is known which consists of a hydrocarbon only or which has not a basic or an acidic function, or both, with or without the functions of an alcohol, ketone, or aldehyde.

The author concludes that dyeing with soluble colouring matters and textile fibres or metallic oxides is a process of a purely chemical order, and depends essentially on the presence of basic and acidic functions in the colouring matter and its absorbent.

The only exception to this law is the group of tetrazoic colours which dye cotton in an alkaline bath without a mordant, but this group requires special investigation. C. H. B.

Allocinnamic Acid. By C. LIEBERMANN (*Ber.*, **24**, 1101—1110).—The author has not, as yet, carried out his purpose of fully examining the relationships of isocinnamic acid and allocinnamic acids, owing to his inability to obtain a fresh supply of the former compound. This may be due to the fact that the raw material employed did not contain any isocinnamic acid, or to the fact that it is converted into allocinnamic acid in the modified process employed for its purification. In place of the method previously described (*Abstr.*, 1890, 1417), about 1 kilo. of the raw material was dissolved in 10 litres of water, boiled with a slight excess of milk of lime for 2½ hours, allowed to cool, and filtered; the filtrate, after concentration to 2½ litres, was again separated from the precipitated calcium salts, acidified with hydrochloric acid, and extracted with ether. After evaporating off the latter, the residue was treated with light petroleum, and the product remaining on its evaporation, dissolved in benzene and treated with aniline. Aniline allocinnamate separates out as a magma of voluminous needles, which are filtered off, washed with light petroleum, and acidified with hydrochloric acid; the allocinnamic acid is extracted with ether, and after evaporating off the latter, recrystallised from light petroleum.

The crystals of allocinnamic acid obtained had the melting point previously found, namely 68°, and on crystallographic examination were found to have the same measurements as the original specimen, although the development differed considerably. Aniline allocinnamate (C₉H₉O₂)₂.C₆H₇N, has the same melting point and composition as the compound obtained from aniline and isocinnamic acid, and it appears extremely probable that isocinnamic acid is converted

by the action of aniline and subsequent treatment with acid into allocinnamic acid. If this is the case, the fact that no isocinnamic acid was obtained with the new method of purification is readily understood, and, according to a private communication to the author, Erlenmeyer has also found that the isocinnamic acid obtained from β -bromocinnamic acid is, in fact, converted into allocinnamic acid by this treatment. It would, therefore, appear probable that isocinnamic acid is a dimorphous, very labile form of allocinnamic acid; in confirmation of this, is the fact that the crystals of isocinnamic acid previously measured had undergone a change, and, on washing with light petroleum and then recrystallising from this liquid, had the melting point of allocinnamic acid.

Paratoluidine allocinnamate, $(C_6H_5O_2)_2.C_7H_7N$, is obtained by the direct union of the acid and base in benzene solution; it crystallises from water in silky, colourless needles and melts at $79-80^\circ$. *Phenylhydrazine allocinnamate*, $C_6H_5O_2.C_6H_5N_2$, forms colourless needles or plates and melts at 74° , whilst *tropine allocinnamate*, $C_6H_5O_2.C_8H_{15}NO$, separates first as an oil, and then solidifies to beautiful crystals, having a neutral reaction and melting at 138° .

The following compounds were also prepared for the sake of comparison:—*Phenylhydrazine cinnamate*, $C_6H_5O_2.C_6H_5N_2$, melting at 110° , and much less soluble in water and benzene than the allocinnamate; *phenylhydrazine hydrocinnamate*, crystallising in silky needles and melting at 57° ; and *tropine cinnamate*, which is an oil.

Methyl allocinnamate, $C_6H_5O_2Me$, is obtained by acting on the silver salt with methyl iodide, and forms a colourless, strongly refractive oil, the odour of which is similar to that of methyl isocinnamate and melted methyl cinnamate. By very careful addition of bromine in carbon bisulphide solution, it yields a mixture of the dibromide of methyl cinnamate with a little of the dibromide of methyl isocinnamate. The former crystallises out first, and the mother-liquor is then evaporated and treated with light petroleum, which dissolves out the allo-compound; this crystallises in cauliflower-shaped nodules melting at $52-53^\circ$. Both dibromides lose the added bromine on treatment with zinc turnings and alcohol, the first yielding methyl cinnamate, and the second a mixture of methyl cinnamate and methyl allocinnamate in the proportion of ten of the former to one of the latter. By more careful working, the quantity of the latter might probably be increased. H. G. C.

Amidotolyloxamic Acid. By H. SCHIFF and A. VANNI (*Ber.*, 24, 870–873).—The authors have already shown that in metatoluylenediamine the amido-group in the para-position to the methyl group is first attacked by acid residues (this vol., p. 702).

Amidotolyloxamic acid, $NH_2.C_6H_4Me.NH.C_6O_2.OH$ [1:2:4], is obtained, together with ethyl amidotolyloxamate, by boiling a solution of tolylenediamine and ethyl oxalate in 90–94 per cent. alcohol for some days in a reflux apparatus. The two compounds are separated by means of alcohol, in which the acid is only slightly soluble. It can also be obtained by boiling an alcoholic solution of the diamine with dehydrated oxalic acid. The acid is colourless, is insoluble in

water, sparingly soluble in boiling alcohol, easily soluble in dilute acids and alkalis, and melts at 223° with decomposition. The *potassium* salt forms easily soluble, colourless scales.

Amidotolyloxamide, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{NH}\cdot\text{C}_2\text{O}_2\cdot\text{NH}_2$ [1 : 2 : 4], is obtained by adding alcoholic ammonia to an alcoholic solution of ethyl amidotolyloxamate. It crystallises from alcohol in shining scales, melts at 223° , dissolves easily in hydrochloric acid, and yields a crystalline platinumchloride. Amidotolyloxamide is also formed when toluylenediamine and ethyl oxamate are heated together at 110 – 115° , and by boiling a dilute alcoholic solution of tolylenediamine with ethyl oxamate. In concentrated solution, however, a large quantity of ethyl amidotolyloxamate is formed.

Amidotolyloxamic acid, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{NH}\cdot\text{C}_2\text{O}_2\cdot\text{NHPh}$ [1 : 2 : 4], is obtained by boiling ethyl amidotolyloxamate or amidotolyloxamide with aniline, or by melting tolylenediamine with ethyl phenyloxamate. It crystallises from alcohol and dilute acetic acid, and melts at 185 – 186° . It is only a feeble base and the hydrochloride easily loses half its acid.

The amido-group of amidotolyloxamic acid is not attacked by ethyl oxalate unless the alcoholic solution of the two substances is heated in a sealed tube at 120° . The ethereal salts of the acid are, however, easily acted on by ethyl oxalate, and the dioxal compound, $\text{C}_7\text{H}_6(\text{NH}\cdot\text{C}_2\text{O}_2\cdot\text{OEt})_2$, is obtained.

Urethanotolyloxamic acid, $\text{COOEt}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{NH}\cdot\text{C}_2\text{O}_2\cdot\text{OH} + \frac{1}{2}\text{H}_2\text{O}$, is obtained by the action of ethyl chlorocarbonate on finely powdered potassium amidotolyloxamate under ether. The reaction must be completed by heating in a reflux apparatus. The acid forms small, colourless plates, melts at 168 – 170° , and dissolves easily in alcohol, not so easily in water. The aqueous solution tastes slightly sweet. By the action of ammonia, the urethane group is not converted into the uramido-group.

Uramidotolyloxamic acid, $\text{NH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{NH}\cdot\text{C}_2\text{O}_2\cdot\text{OH}$, is obtained by the action of potassium cyanate on finely powdered amidotolyloxamic acid suspended in water and precipitation with hydrochloric acid. It is a white, crystalline powder, slightly soluble in water, and melts at 203° . The *ethyl* salt is obtained in a similar way from ethyl amidotolyloxamate.

M. U. R.

Synthesis of Carbazole Derivatives. By F. TÄUBER and R. LOEWENHERZ (*Ber.*, 24, 1033–1036).—One of the authors has described the synthesis of diamidocarbazole and carbazole from benzidine (this vol., pp. 227 and 570). The present paper deals with the synthesis of homologues of carbazole from orthotolidine.

Diamidodimethylcarbazole.—Orthotolidine is easily converted into metadinitro-orthotolidine as described by Gerber; and the latter compound, on reduction with tin and hydrochloric acid, yields metadiamidorthotolidine. The hydrochloride of this base is precipitated from concentrated aqueous solution by strong hydrochloric acid as a white, crystalline powder. To obtain diamidodimethylcarbazole, the hydrochloride is heated with 20 per cent. hydrochloric acid (3–4 parts) in a sealed tube at 190 – 200° for 15 hours. The product is

purified by treating the aqueous solution with tin chloride and hydrogen sulphide, concentrating the filtrate by rapid boiling in a flask, and precipitating with hydrochloric acid; on cooling, the diamidodimethylcarbazole hydrochloride crystallises in pure white needles. The yield is 75 per cent. of that required by theory. The *sulphate* is obtained by adding sulphuric acid to a somewhat concentrated solution of the hydrochloride, and also in colourless needles (0.5 cm. long) on adding sodium sulphate to a dilute neutral solution. The base is obtained in white, microscopic needles by precipitating a hot, very dilute, solution of the hydrochloride. It is insoluble in water, sparingly soluble in cold alcohol, benzene, toluene, and ether, and more soluble in the hot solvents, crystallises from alcohol in small, colourless needles, blackens at 260°, and melts at 271°. Both the base and its salts, when moist, become coloured on exposure to air. The *diacetyl* compound, obtained by boiling the base with acetic acid (5 parts) for 6 hours, crystallises from acetic acid in slender, colourless needles, and melts above 300°. In accordance with the above synthesis, the constitution of the diamidodimethylcarbazole is represented by the formula

Dimethylcarbazole is obtained by heating orthodiamidoditolyl with 20 per cent. hydrochloric acid at 200°; and also from the above diamidodimethylcarbazole by eliminating the amido-groups. It closely resembles carbazole in appearance, solubility, crystalline form, and capacity for volatilisation. The picrate crystallises in reddish-brown needles and melts at 192°. The dimethylcarbazole regenerated from the latter, after crystallisation from benzene and sublimation, melts at 219°. Whilst a solution of carbazole in sulphuric acid is coloured greenish-blue by nitrous acid in the cold, a sulphuric acid solution of dimethylcarbazole is coloured pale brownish-yellow, and after a time or on warming, a pure blue. Chromic acid colours the sulphuric acid solution of carbazole deep blue; but a solution of dimethylcarbazole is coloured brown. On heating dimethylcarbazole with oxalic acid, no characteristic dye is obtained; carbazole on similar treatment yields a blue dye. The authors point out that those results tend to confirm the conclusion of Bamberger and Müller that carbazole-blue is a derivative of triphenylmethane, since in dimethylcarbazole the *para*-positions to the imido-group are occupied.

E. C. R.

Transformation of α -Diketones in Alkaline Solution. By S. HOOGWERFF and W. A. VAN DOEP (*Rec. Trav. Chim.*, 9, 225—237). —The reaction indicated by the equations $\text{COPh}\cdot\text{COPh} + \text{KOH} = \text{OH}\cdot\text{CPh}_2\cdot\text{COOK}$ is explained by the authors as brought about by an intramolecular transposition; thus the first stage consists of the production of $\text{OH}\cdot\text{CPh}(\text{OK})\cdot\text{COPh}$; the groups Ph and OK attached to contiguous carbon atoms are then interchanged with the production of $\text{OH}\cdot\text{CPh}_2\cdot\text{COOK}$. Numerous other examples of this transformation of α -diketones under the influence of hot potash are quoted.

Similar reactions have been explained in this way previously. Kekulé (*Annalen*, 221, 238) accounts for the formation of sodium tartronate on heating the sodium salt of dihydroxytartaric acid by the intermediate formation of dihydroxypyruvic acid, and the transformation of the latter into tartronic acid by the exchange of H and (OH) between contiguous carbon atoms.

This transformation occurs also in the change of glyoxal into glycollic acid (Debus, *Annalen*, 102, 26), and of benzoylformic acid into phenylglycollic acid (Engler and Wöhrle, *Abstr.*, 1887, 948). The formation of lactic acid by the action of water on dichloroacetone (Linnemann and v. Zotta, *Annalen*, 159, 247) seems also to belong to the same class of reactions. This reaction is not general for diketones, failing in the case of diacetyl, although even in this case a similar reaction takes place when the symmetrical tetrachlorodiacetyl is heated with ammonia.

Zincke has found similar processes to take place with naphthalene derivatives containing the group (CO·CO) in the $\alpha\beta$ -position; thus dichloro- β -naphthaquinone gives in alkaline solution dichlorindenehydroxycarboxylic acid. The stages of this reaction may be written—

Zincke has given a different explanation of the course of the reaction: by the assumption of 1 mol. of water and 1 mol. of potassium hydroxide the parent substance becomes

and this loses a molecule of water, yielding the final product as above. This method of viewing the mechanism of the change would require that in the formation of benzoic acid from benzile the diketone should split into C_6H_5 and $\text{C}_6\text{H}_5 \cdot \text{C(OH)}_2 \cdot \text{COOH}$, which afterwards unite to form the acid. The formation of croconic acid from rhodizonic acid, as also of tribromhydroxydiketopentamethylene from tetrabromotetraketohexamethylene, and some of Zincke and Küster's and of Hantzsch's results, admit of representation by the author's method.

The transformation of the α -glycols under the action of dehydrating agents, for instance of pinacons into $\text{CMe}_2 \cdot \text{CMe(OH)}_2$, and the formation of pinacolone by the elimination of H_2O from this substance, comes under the same category. Volhard has given a similar explanation of the formation of benzyl alcohol and benzoic acid from benzaldehyde (*Annalen*, 253, 238); but here we are dealing with an intermolecular reaction. The conclusion is drawn that forces of attraction exist between atoms in the molecule which are not represented in our formulæ as united; the resultant of these forces may bring about molecular transformations in many reactions which have not been otherwise explained.

W. T.

Diethylindigo and Orthotolylindigo. By K. HEUMANN (*Ber.*, 24, 977—979; compare this vol., pp. 206, 311, and 456).—Many of the derivatives of amidoacetic acid containing aromatic radicles are converted into leuco-compounds when heated with alkalis or alkaline earths; these leuco-compounds yield homologues or analogues of indigo on oxidation.

Ethylphenylamidoacetic acid, $\text{NEtPh}\cdot\text{CH}_2\cdot\text{COOH}$, prepared by treating ethylaniline with chloroacetic acid, is a thick, yellow oil, sparingly soluble in water.

Diethylindigo, $\text{C}_6\text{H}_4\langle\text{CO}\rangle^{\text{NEt}}\text{C}:\text{C}\langle\text{CO}\rangle^{\text{NEt}}\text{C}_6\text{H}_4$, is obtained when the preceding compound is heated with potash to about 360° , the mixture kept at this temperature for a few minutes, the brownish-red melt dissolved in water, and a stream of air passed through the solution. It is a dark-blue powder, and is probably identical with the compound obtained by Baeyer by reducing the diethyl derivative of pseudoisatin- α -oxime; it is sparingly soluble in hot alcohol, and dissolves in aniline yielding a bluish-green solution. The colours obtained on dyeing with diethylindigo and with its sulphonic acid are of a greener hue than those produced by indigo and indigo-carmin respectively. When the mixture of ethylphenylamidoacetic acid and potash is heated at 280 — 330° for 15 to 20 minutes, there is obtained a compound which, on oxidation, is converted into a substance having all the properties of indigo.

Orthotolylindigo, $\text{C}_6\text{H}_4\text{Me}\langle\text{CO}\rangle^{\text{NH}}\text{C}:\text{C}\langle\text{CO}\rangle^{\text{NH}}\text{C}_6\text{H}_4\text{Me}$, is formed when orthotolylamidoacetic acid is heated with potash (2 parts) at 300 — 350° , the melt dissolved in water, and a stream of air passed through the solution. It is only very sparingly soluble in boiling alcohol, yielding a deep-blue solution; it crystallises from hot aniline in slender, copper-red prisms. Cotton dyed with orthotolylindigo is of a slightly greener shade than that obtained with indigo. The sulphonic acid of orthotolylindigo is soluble in water, but is precipitated from the solution on adding sodium chloride; it dyes wool in an acid-bath, the shade obtained being of a redder hue than is the case with indigo-carmin.

F. S. K.

Phenanthridine. By A. PICTET and H. J. ANKERSMIT (*Chem. Centr.*, 1891, i, 361—362; from *Arch. sci. phys. nat. Genève*, 24, 598—606).—In addition to the synthesis of phenanthridine from benzylideneaniline (Abstr., 1890, 390), the authors have prepared it from orthophenylbenzoic acid. By nitrating this and reducing the resulting mixture of nitrophenylbenzoic acids with zinc powder and ammonia, the corresponding amido-acids are produced, from one only of which, namely, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ [2:2'], can the new base be derived. The reduced mixture is extracted with boiling alcohol, which solution deposits hydroxyphenanthridine in needles, from which phenanthridine is obtained by distilling with zinc powder.

Phenanthridine methylhydroxide, $\text{C}_{12}\text{H}_9\text{N}\cdot\text{MeOH}$, is prepared from the methiodide, by adding a few drops of sodium hydroxide solution, and pouring the mixture into water, when the hydroxide separates in

long needles melting at 109° ; it dissolves in alcohol and ether with beautiful fluorescence.

Phenanthridine on reduction is converted into *dihydrophenanthridine*, $C_{13}H_{11}N$, which forms white needles melting at 90° , nearly insoluble in water, soluble in alcohol and ether with blue fluorescence. It reacts as a secondary base. The *nitroso*-derivative, $C_{13}H_{10}N\cdot NO$, is a pale-yellow oil, which gives Liebermann's reaction for nitrosamines. The *methyl* derivative, $C_{13}H_{10}NMe$, forms white needles, melts at 108° , and is soluble in alcohol and ether with violet fluorescence. The *acetyl* derivative, $C_{13}H_{10}NAc$, forms prisms, and melts at 108° .

J. W. L.

Pyridine Compounds. By R. VARET (*Compt. rend.*, 112, 622—623).—When pyridine heated at 40° is saturated with zinc bromide, energetic action takes place, with considerable development of heat, and when the liquid cools, it deposits slender, prismatic needles of the compound $ZnBr_2 \cdot 2C_5NH_5$. It is stable at 110° , and is very soluble in water and in pyridine.

Finely powdered anhydrous nickel bromide, when boiled with pyridine for an hour, is converted into a green powder of the composition $NiBr_2 \cdot 4C_5NH_5$. This compound alters when exposed to air, loses pyridine when heated, and is very soluble in pyridine.

Cupric bromide acts energetically under similar conditions, and is converted into small, hard, deep-green crystals of the compound $CuBr_2 \cdot 4C_5NH_5$. It alters very readily, and evolves a strong odour of pyridine. When heated, or when exposed to air, it loses pyridine, and becomes bright-green. It dissolves in water and in pyridine.

Silver iodide is dissolved by boiling pyridine, and the solution, when cooled, deposits lamellæ or prismatic needles of the compound $AgI \cdot C_5NH_5$. It is somewhat soluble in pyridine, especially on heating, but is immediately decomposed by warm water, and more slowly by cold water; it alters when exposed to air, and loses all its pyridine when heated at 110° .

Silver bromide forms a similar compound, which crystallises in large, white, prismatic needles with a nacreous lustre. It is very unstable, and loses all its pyridine at 110° ; it is soluble in cold pyridine, but is insoluble in water, and is decomposed by it.

Silver chloride is dissolved by cold pyridine, but on the addition of ether the unaltered chloride is precipitated, and there is no compound of silver chloride and pyridine stable at the ordinary temperature. The attraction of the silver halides for pyridine decreases as the molecular weight of the halogen increases.

C. H. B.

Dicyanodiamide. By E. BAMBERGER and L. SEEBERGER (*Ber.*, 24, 899—907).—Three formulæ have been proposed for dicyanodiamide, all of which equally well explain its behaviour. They are:—

The author decides in favour of formula I, from a consideration of

the behaviour of dicyanodiamide towards ammonia bases of the types *Nabc* and *b.N'a*, when derivatives of biguanidine are formed.

Copper piperylbiguanidine, $\text{Cu}[\text{NH}\cdot\text{C}(\text{NH})\cdot\text{NH}\cdot\text{C}(\text{NH})\cdot\text{C}_6\text{NH}_{10}]_2$, is obtained by heating dicyanodiamide (1.7 grams) and copper sulphate (2.5 grams) with piperidine (2 grams) and water (10 c.c.) for some hours at 100–120°. The reaction also takes place at the ordinary temperature, and is then complete in a few days. It is sparingly soluble in cold water, more so in hot water, and comes down as a fine, rose-red, crystalline powder, is insoluble in benzene, light petroleum, and ether, and easily soluble in ethyl alcohol, acetone, and amyl alcohol. The yield amounts to 65 per cent. of that required by theory.

Copper piperylbiguanidine sulphate, $(\text{C}_7\text{H}_{14}\text{N}_6)_2\text{Cu}\cdot\text{H}_2\text{SO}_4$, is obtained by mixing the base with sulphuric acid in molecular proportion and warming the mixture on the water-bath. It crystallises from water in bright-red, shining needles, and blackens at 160° without melting. It is decomposed, by boiling with water, into copper oxide and piperylbiguanidine sulphate, $(\text{C}_7\text{H}_{14}\text{N}_6)_2\cdot\text{H}_2\text{SO}_4$.

Piperylbiguanidine, $\text{NH}_2\cdot\text{C}(\text{NH})\cdot\text{NH}\cdot\text{C}(\text{NH})\cdot\text{C}_6\text{NH}_{10}$, is obtained by treating the above copper base, dissolved in dilute sulphuric acid, with hydrogen sulphide. On adding excess of aqueous soda to the filtrate, the piperylbiguanidine crystallises in silky needles, and melts at 163°. It is, however, rapidly converted into carbonate, and the melting point rises. It reacts strongly alkaline, absorbs carbonic anhydride from the air with avidity, is easily soluble in water and chloroform, sparingly in aqueous soda, ether, and benzene, and crystallises from hot alcohol in lustrous prisms. The *hydrochloride*, $\text{C}_7\text{H}_{15}\text{N}_6\cdot 2\text{HCl}$, crystallises from alcoholic solution in thick crusts, dissolves easily in water and alcohol, and, on the addition of ether to the latter solution, crystallises in slender needles, melts at 217°, and has an acid reaction. The *acid sulphate*, $\text{C}_7\text{H}_{15}\text{N}_6\cdot\text{H}_2\text{SO}_4$, is obtained as a voluminous precipitate on adding sulphuric acid to an alcoholic solution of the base. It is obtained as a white, crystalline powder by precipitating a concentrated aqueous solution with alcohol, melts at 173°, and has an acid reaction, dissolves easily in water, sparingly in alcohol, and becomes electrical when rubbed. The *normal sulphate*, $(\text{C}_7\text{H}_{16}\text{N}_6)_2\cdot\text{H}_2\text{SO}_4$, obtained from the mother liquors of the above salt, crystallises in beautiful, thick, colourless prisms, has a neutral reaction, melts at 219°, and is easily soluble in water and alcohol. The *platinchloride*, $(\text{C}_7\text{H}_{15}\text{N}_6)_2\cdot\text{H}_2\text{PtCl}_6$, crystallises in lustrous, orange-red, rhombohedral prisms, is easily soluble in water, and melts at 252° with evolution of gas. The *aurochloride*, $\text{C}_7\text{H}_{15}\text{N}_6\cdot 2\text{HCl}\cdot\text{AuCl}_3$, is obtained as a golden-yellow, lustrous precipitate consisting of slender needles.

E. C. R.

Derivatives of Orthamidoazo-compounds. By H. GOLDSCHMIDT and A. POLTZER (*Ber.*, 24, 1000–1010).—The author has already described the compounds obtained by the combination of orthamidoazotoluene and benzeneazo- β -naphthylamine with benzaldehyde. These compounds differ essentially from the benzylidene derivatives of primary amines. They are not decomposed by hydro-

chloric acid at 150° , have distinctly basic properties, and are colourless. From their behaviour, the author concludes that they are compounds of the triazine series. Bischler (*Ber.*, 22, 2806) has

described the compound $C_6H_4 < \begin{smallmatrix} N-CH \\ | \quad | \\ N-N \end{smallmatrix}$, and named it phenotriazine.

The compounds described by the authors are derivatives of dihydrophenotriazine, $C_6H_4 < \begin{smallmatrix} N-CH_2 \\ | \quad | \\ N-NH \end{smallmatrix}$. Orthamidoazotoluene and benzaldehyde yield phenylparatolyl dihydroparatoltriazine,

and benzeneazo- β -naphthylamine and benzaldehyde yield diphenyldihydro- β -naphthatriazine, $C_{10}H_6 < \begin{smallmatrix} N-CHPh \\ | \quad | \\ N-NPh \end{smallmatrix}$.

In the present paper the authors describe a series of compounds formed from benzeneazo- β -naphthylamine and orthamidoazotoluene by the action of various aldehydes, namely, formaldehyde, acetaldehyde, propaldehyde, cinnamaldehyde, and furfuraldehyde. The compounds so obtained are mostly colourless, well crystallised substances, have distinctly basic properties, give, with concentrated hydrochloric acid, well crystallised hydrochlorides which dissolve in alcohol without decomposition, but are decomposed into hydrochloric acid, and the dihydrotriazine by a large quantity of water. The hydrochlorides easily yield platinochlorides. They are not decomposed when heated with concentrated hydrochloric acid at 150° under pressure, and are not altered when boiled with stannous chloride and hydrochloric acid. The authors point out that the formation of dihydrotriazine derivatives is evidence in support of the view that the orthamidoazo-compounds are to be considered as hydrazones of orthoquinonimides.

Phenyldihydro- β -naphthatriazine, $C_{10}H_6 < \begin{smallmatrix} N-CH_2 \\ | \quad | \\ N-NPh \end{smallmatrix}$, is obtained by heating benzeneazo- β -naphthylamine with alcohol and a 40 per cent. aqueous solution of formaldehyde for some hours at 140° in a sealed tube. It is better, however, to employ a slight excess of paraformaldehyde. The product is purified by crystallisation from alcohol and decolorisation with animal charcoal. It forms transparent tablets, melts at 164° , and contains $\frac{2}{3}$ mol. of water of crystallisation. After drying at 100° , it melts at 184° , is easily soluble in alcohol, sparingly in cold benzene and ether, and insoluble in light petroleum. The *hydrochloride*, $C_{11}H_7N_3HCl$, is obtained by adding concentrated hydrochloric acid to an alcoholic solution of the base. It crystallises in slender, white needles, melts at 254° , is soluble in alcohol and dilute hydrochloric acid, and is decomposed by pure water. The *platinochloride*, $(C_{11}H_7N_3)_2 \cdot H_2PtCl_6$, is obtained as a yellow precipitate on adding platinic chloride to an alcoholic solution of the base containing hydrochloric acid; it carbonises about 240° .

Methylphenyldihydro- β -naphthatriazine, $C_{10}H_6 < \begin{smallmatrix} N-CHMe \\ | \quad | \\ N-NPh \end{smallmatrix}$, is obtained by adding excess of acetaldehyde to benzeneazo- β -naphthyl-

amine suspended in alcohol. Heat is developed, and a deep-red solution is obtained in a short time. The product is purified either by crystallisation from alcohol and decolorisation with animal charcoal, or by dissolving in benzene and precipitation with petroleum. It crystallises in beautiful, colourless, rhombic tablets, is easily soluble in hot alcohol, more sparingly in benzene, and most sparingly in ether, and is insoluble in light petroleum. When heated with concentrated hydrochloric acid for some hours at 150° in a sealed tube, only the hydrochloride is formed, and the free base is regenerated on treatment with ammonia. It is unaltered when boiled with stannous chloride and hydrochloric acid, in alcoholic solution. The *hydrochloride*, $C_{18}H_{18}N_3 \cdot HCl$, forms beautiful, transparent tablets, and melts at 252° . The *platinochloride*, $(C_{18}H_{18}N_3)_2 \cdot H_2PtCl_6$, forms yellow needles which decompose at 260° with carbonisation.

Methylphenyldihydro- β -naphthatriazine methiodide, $C_{18}H_{19}N_3 \cdot MeI$, is obtained by heating the above base with methyl iodide and methyl alcohol at 100° under pressure, and purifying the product by crystallisation from alcohol. It forms transparent tablets, and melts at 244° . The iodide, when treated in alcoholic solution with freshly precipitated silver chloride is converted into chloride, and the latter yields a *platinochloride*, $(C_{18}H_{19}N_3 \cdot MeCl)_2 \cdot PtCl_4$, which forms slender, yellow needles, and melts at 260° .

Ethylphenyldihydro- β -naphthatriazine, $C_{10}H_6 \begin{smallmatrix} N-CH_2Et \\ | \\ N-NPh \end{smallmatrix}$, is obtained in a manner similar to the preceding methyl compound by employing propaldehyde in place of acetaldehyde. It crystallises in slender, white needles, melts at 219° , and is easily soluble in alcohol and hot benzene, sparingly in ether, and insoluble in light petroleum. The *hydrochloride* crystallises in beautiful, white needles, and melts at 258° . The *platinochloride* forms small, yellow crystals, and carbonises about 265° .

Heptylphenyldihydro- β -naphthatriazine, $C_{10}H_6 \begin{smallmatrix} N-CH \cdot C_6H_{13} \\ | \\ N-NPh \end{smallmatrix}$, is obtained by heating a mixture of the amidoazo-compound and cenanthaldehyde (normal heptylaldehyde) in molecular proportion for a few hours on the water-bath. It forms slender, white needles, melts at 176.5° , and is easily soluble in alcohol and benzene. The *hydrochloride* crystallises in long, white needles, and melts at 226° . The *platinochloride* is obtained as a yellow, crystalline precipitate, and melts at 225° .

Furfurphenyldihydro- β -naphthatriazine, $C_{10}H_6 \begin{smallmatrix} N-CH \cdot C_4H_3O \\ | \\ N-NPh \end{smallmatrix}$, is obtained in a similar way to the preceding compound. It forms slender, white needles, and melts at 241° . The *hydrochloride* crystallises in transparent tablets, and carbonises about 230° . The *platinochloride* is obtained as a bright-yellow, crystalline precipitate, and carbonises about 240° .

Paratolyldihydrotolutriazine, $C_7H_6 \begin{smallmatrix} N-CH_3 \\ | \\ N-N \cdot C_6H_4Me \end{smallmatrix}$, is obtained by

heating orthamidoazotoluene with excess of paraformaldehyde for some hours, at 140° , in a sealed tube. It crystallises in white, lustrous prisms, melts at 178° , and is easily soluble in hot alcohol, sparingly soluble in ether. The *hydrochloride* crystallises in white tablets, and melts at 220° . The *platinochloride* is obtained as a yellow, microcrystalline precipitate, and melts at 216° .

Ethylparatolylidihydrotolutriazine is obtained by heating a mixture of propaldehyde and orthamidoazotoluene at 140° . It crystallises from hot benzene in white needles, and melts at 168° . The *hydrochloride* forms long, white needles, and melts at 96° . The *platinochloride* forms small, yellow needles, and melts at 221° .

Hexylparatolylidihydrotolutriazine is obtained by heating orthamidoazotoluene with cenanthaldehyde for several hours, at 175° , in a sealed tube. It forms slender, white needles, and melts at 165° . The *hydrochloride* forms transparent tablets, and melts at 96° . The *platinochloride* is obtained as a yellow, crystalline precipitate, and melts at 171° .
E. C. R.

Sparteine. By F. B. AHRKS (Ber., 24, 1095—1097).—*Oxy-sparteine*, $C_{18}H_{24}N_2O$, prepared by the oxidation of sparteine, is purified by means of the platinochloride; it crystallises from ether in colourless, hygroscopic needles, melts at 83 — 84° , and is readily soluble in alcohol, chloroform, or water. The *hydrochloride*,

is obtained from water in large, broad needles, and melts at 48 — 50° . The *hydrobromide* is also crystalline; the *sulphate* is readily soluble, and crystallises in slender, lustrous needles. On the addition of platinic chloride to a dilute solution of the hydrochloride, lustrous, ruby-coloured crystals are deposited which have the formula $(C_{18}H_{24}N_2O)_2 \cdot PtCl_4 + 4H_2O$, and melt at 209° with decomposition. From the mother liquors, on evaporation, needle-shaped crystals of the *normal salt*, $C_{18}H_{24}N_2O \cdot H_2PtCl_6 + 2H_2O$, are formed; this melts at 221 — 223° with decomposition. The *anrochloride*, $C_{18}H_{24}N_2O \cdot HAuCl_4$, crystallises from water in lustrous needles or plates, softens at about 163° , and decomposes at about 186° . The corresponding *mercury* compound is crystalline; it softens at 52° , and melts at 57 — 58° . The *picrate* crystallises in long, lustrous needles, and melts at 176 — 178° .
J. B. T.

Alkaloids from the Seeds of Delphinium staphisagria, L. By CHARALAMPI (J. Pharm. [5], 23, 302—306; from Pharm. Zeit. Russ., 29, 641).—To extract these alkaloids, 2 kilos. of the seeds is digested in 8 kilos. of 80 per cent. alcohol during four days at 15° . The liquid is removed, and the residue is again treated until the extraction is complete. The alcohol is evaporated below 60° under diminished pressure and the residue from the distillation is diluted with an equal volume of water. After 24 hours, three layers are formed: an upper one of a greenish, fatty oil; a middle one of brown, aqueous, alcoholic liquid; and a lower one composed of a resinous mass. The lower layer is run off. The middle one is freed from alcohol at a tempera-

ture not exceeding 50°. The oily layer, which retains a considerable amount of alkaloids, is agitated with water containing a little sulphuric acid, allowed to remain five or six days, the layers formed separated, and the oily part again repeatedly treated (10 times). The acid liquids are united, filtered, treated with ether to remove the last traces of fat, and united with the liquid obtained from the aqueous alcoholic layer. Hydrogen sodium carbonate is added, and then ether to take up the alkaloids. The ethereal solution is removed and evaporated, spontaneously towards the end, when delphinine is not long in making its appearance on the sides of the vessel. This base is purified by combining it with tartaric acid, and repeating the treatment with hydrogen sodium carbonate and ether.

Delphinine has the formula $C_{22}H_{26}NO_{14}$, as deduced from direct analysis, and also from the composition of its aurochloride and platinochloride; this differs sensibly from the composition given by Dragendorff and Marquis, in 1877. It gives anhydrous, rhombic crystals. It withstands a temperature of 120°, but a little higher it begins to colour, and melts at 191·8°. It has a pungent, burning taste. 1 gram dissolves at 15° in 20·49 grams of benzene, in 642·4 grams of light petroleum (sp. gr. 0·633) in 53·4 grams of ether of 0·728 sp. gr., in 47·6 grams of absolute ether, in 44·4 grams of absolute alcohol, in 238 grams of 90 per cent. alcohol, and in 1594 grams of water. The recently prepared aqueous solution has an alkaline reaction. This base gives crystallisable salts with nitric and sulphuric acids sparingly soluble in water, alcohol, and ether; they easily dissolve in acidified water. Hydrochloric, acetic, oxalic, and tartaric acids yielded amorphous compounds.

The mother liquor, left after removal of the delphinine, when evaporated very slowly, yields a certain quantity of *delphisine*, $C_{22}H_{26}NO_{14}$, in the form of acicular crystals melting at 189·2°. This alkaloid dissolves at 15° in 75·2 parts of benzene, in 665 of light petroleum, in 43 of ether of sp. gr. 0·728, in 71 parts of absolute ether, in 104 of 90 per cent. alcohol, and in 370 parts of absolute alcohol. It is very slightly soluble in water, but dissolves readily in chloroform, as does delphinine.

Delphinonine, $C_{20}H_{22}NO_8$, obtained in an amorphous state after the foregoing, is scarcely soluble in water; at 15°, 1 part dissolves in 9·43 parts of light petroleum, in 30·5 of benzene, in 17·8 of 90 per cent. alcohol, in 4·03 of ether (sp. gr. 0·728), and in 37·03 of absolute ether. The author has also examined the product previously described as *staphisagrine*, which forms the residue of the operations yielding the alkaloids already described. This base appears to him to be really a mixture of four amorphous alkaloids. Delphinine, delphisine, and delphinoïdine, especially the two former, are highly poisonous, resembling aconitine in their action.

J. T.

Alkaloids of the Roots of *Sanguinaria canadensis* and *Chelidonium majus*. By G. KÖNIG (*Chem. Centr.*, 1891, i, 321—322; from *Zeit. Naturwiss. Halle*, 63, 369—426).—The roots of *Sanguinaria canadensis*, a native of North America, and the sanguinarine of commerce contain several alkaloids, including *chel-*

erythrine, which is present in greatest quantity, *sanguinarine*, γ -*homochelidonine*, and *protopine*.

Chelerythrine crystallises with a molecule of alcohol, which is not separated at a temperature of 150° ; the formula is $C_{27}H_{17}NO_4 + C_2H_5O$; melting point 203° . It is identical with the alkaloid which the author separated from the *ceiandine*, *Chelidonium majus*. The *aurochloride*, $C_{21}H_{17}NO_4 \cdot HANCl_4$, melts at 233° ; the *platinochloride* is $(C_{21}H_{17}NO_4)_2 \cdot H_2PtCl_6$; the *hydrochloride* crystallises out of aqueous solution with 5 mols. H_2O , and from alcohol with 4 mols. H_2O . The salts are lemon-yellow.

Sanguinarine, $C_{20}H_{15}NO_4$, is very similar to *chelerythrine* in its properties; it crystallises with $\frac{1}{2}$ mol. H_2O , and melts at 211° ; its salts are red. The *hydrochloride*, $C_{20}H_{15}NO_4 \cdot HCl + 5H_2O$, the *nitrate*, $C_{20}H_{15}NO_4 \cdot HNO_3 + H_2O$, the *aurochloride*, $C_{20}H_{15}NO_4 \cdot HANCl_4$, and the *platinochloride*, $(C_{20}H_{15}NO_4)_2 \cdot H_2PtCl_6$, were prepared.

The base which the author has named γ -*homochelidonine* is probably identical with that separated by Selle from *Chelidonium majus*, and its formula is probably $C_{22}H_{21}NO_4$. Its behaviour with alkaloid reagents resembles that of Selle's γ -*homochelidonine*. The fourth alkaloid, *protopine*, was prepared from *Chelidonium majus*, *Sanguinaria canadensis*, and from opium, all the three specimens being identical. Its formula is $C_{20}H_{17}NO_5$, and it melts at 204° ; the *platinochloride*, $(C_{20}H_{17}NO_5)_2 \cdot H_2PtCl_6 + 3H_2O$; and the *aurochloride*,

melting at 182° , were prepared; the *hydrochloride*, $C_{20}H_{17}NO_5 \cdot HCl$, crystallises in two different forms, and appears to be free from combined water.

J. W. L.

Alkaloids of Sabadilla Seeds. By E. MERCK (*Chem. Centr.*, 1891, i, 363).—The author has isolated two alkaloids from *sabadilla* seeds. *Asagrea officinalis*. *Sabadine* is best separated as the nitrate: It has the formula $C_{28}H_{31}NO_6$, melts at 238 – 240° with decomposition, and is readily soluble in alcohol and ether, sparingly soluble in light petroleum. With concentrated sulphuric acid, a yellowish coloration is at first produced, showing a green fluorescence, which gradually changes to blood-red and finally to violet. The alkaloid attacks the mucous membrane of the nose and causes sneezing. The *hydrochloride* crystallises with 2 mols. H_2O , which it loses at 101° ; it melts at 282 – 284° with decomposition. The *hydrobromide*, the *nitrate*, and the *aurochloride* were analysed.

Sabadinine, $C_{27}H_{25}NO_6$, the second alkaloid, does not melt at any definite temperature. It is separated from the sulphate by soda solution, and extracted with chloroform. With concentrated sulphuric acid, a permanent blood-red coloration is produced. It does not irritate the nasal mucous membrane. The sulphate crystallises with $2\frac{1}{2}$ mols. H_2O . Neither *sabadine* nor *sabadinine* is precipitated from the solution of its salts by the addition of caustic alkalis, alkaline carbonates, or ammonia in the cold, it being necessary to warm the solution, when the alkaloid is precipitated in flakes.

J. W. L.

Ptomaines. By O. DE CONINCK (*Compt. rend.*, 112, 584—585).—The ptomaine $C_{10}H_{15}N$ (Abstr., 1890, 1170) yields a *hydrobromide* crystallising in white needles, which become rose-coloured when exposed to air. It is deliquescent, very soluble in water, less soluble in strong alcohol, and almost insoluble in pure ether. The same precautions must be observed when preparing this compound as in the preparation of the hydrochloride (*loc. cit.*). The *modified platinum-chloride*, $(C_{10}H_{15}N)_2PtCl_4$, should be prepared with tepid water that has previously been boiled. It forms pale-brown plates, insoluble in cold water, soluble in hot water, but decomposed if ebullition is prolonged. It melts at about 206° , and is stable in moist air, differing in this respect from the normal platinumchloride. The *aurochloride*, $C_{10}H_{15}N \cdot HAuCl_4$, is a pale-yellow compound, insoluble in cold water, soluble in warm water, and decomposed by boiling water. It is somewhat stable in moist air. With alcoholic potash, the methiodide of the ptomaine gives, when heated, an immediate bright-red colour, which rapidly changes to brown, and after some time acquires a persistent greenish-blue fluorescence. C. H. B.

Vegetable Hæmatin. By T. L. PHIPSON (*Compt. rend.*, 112, 666—667).—The vegetable hæmatin obtained by Linossier from *Aspergillus niger* (this vol., p. 751) is in all probability identical with the *palmelline* obtained by the author in 1879 from *Palmella cruenta*.

Palmella cruenta, which was formerly called *Chaos sanguinea*, is sometimes found completely green in the neighbourhood of London, and becomes blood-red towards the end of vegetation. In this connection it is noteworthy that biliverdin has a green colour very similar to that of chlorophyll, and gives a definite absorption spectrum. C. H. B.

Physiological Chemistry.

Hæmoglobin. By M. SIEGFRIED (*Chem. Centr.*, 1891, i, 228—229).—Schützenberger's indigo-carmin method of estimating oxygen in blood is stated to give a higher result than that with the air-pump. In the present research, operations were performed in an atmosphere of hydrogen. The result was that with defibrinated dog's blood, the percentage of oxygen found by the air-pump was 16.1 per cent.; and by Schützenberger's method 7.6—7.9 per cent. This difference is put down to one of the two following factors: either the blood spectrum which shows the bands of reduced hæmoglobin is untrustworthy, and the blood still contains a good deal of oxygen; or else the titration with the hyposulphite solution was incorrect. The former alternative is decided on, and the term pseudohæmoglobin is applied to the supposed compound of oxygen with hæmoglobin which shows the band of reduced hæmoglobin. W. D. H.

Myelin. By J. GAD and J. F. HEYMANS (*Chem. Centr.*, 1891, i, 230).—The name myelin is applied to the white substance sheathing nerve-fibres, and stated to contain proteids, extractives, neurokeratin, lecithin, protagon, cerebrin, and cholesterol. This sheath, moreover, is stained black by osmic acid. The present research is directed to determining more exactly what myelin is. The characteristic properties of myelin are believed to be due to lecithin, either free or only loosely combined, because lecithin elsewhere, for instance, in nerve-cells, where it is probably more firmly combined, does not show the characters of myelin.

Nerve-fibres are divided into groups corresponding to the presence or absence of myelin in their sheaths. W. D. H.

Influence of Carbohydrates on Proteid Metabolism. By G. LUSK (*Zeit. Biol.*, 27, 459—481).—The influence on proteid metabolism of carbohydrates taken as diet, or circulating abnormally in the system in diabetes, is of some pathological importance. Cases of diabetes not, however, being forthcoming, certain experiments bearing on the subject were undertaken by the experimenter on his own person.

Two double series of observations were made, each lasting two or three days, and the general results may be stated in the following tabular form:—

Experi- ment.	Daily averages.			
	Food.		Nitrogen excreted.	Difference be- tween N ingested and N excreted.
	Nitrogen.	Carbohydrate.		
1a	20·549	357·37	19·837	+ 0·712
1b	20·549	10·8	25·980	- 5·381
2a	9·230	347·8	13·785	- 4·555
2b	9·230	2·8	15·807	- 6·577

In both cases, it is seen that the absence of carbohydrate food increases the proteid waste in the tissue, the carbohydrate protecting a certain amount of proteid from destruction. Further experiments showed that the amount of fat undergoing combustion was increased during deprivation of carbohydrate.

There can be no doubt, therefore, that in diabetes the upsetting of the metabolic balance is due to the non-destruction and the consequent separation in the urine of a large quantity of sugar, which under normal circumstances would have undergone combustion and saved much proteid and fat from destruction. The increase of oxygen consumed and carbonic anhydride given off would not, however, be markedly different from that observable in a healthy person under similar circumstances; the total amount would, however, prob-

ably be less, as the diabetic would, other things being equal, weigh less than the healthy person.

W. D. H.

Muscular Work and the Excretion of Urea. By I. MUNK (*Chem. Centr.*, 1891, i, 230—231).—The work of Argutinsky on this subject is criticised, and the older opinion that moderate work does not increase the excretion of urea upheld (compare this vol., p. 596).

W. D. H.

Inorganic Constituents of Bone and Organs of Normal and Rachitic Children. By H. BRUBAKER (*Zeit. Biol.*, 27, 517—549).—The bodies of three healthy children were investigated in reference to the inorganic constituents, and especially the calcium, in the bones and other organs. The three subjects of analysis were aged, 28 weeks' foetus, new-born child, and 4 years respectively, and very full tables of analyses are given. The following general results were obtained:—

(1.) The skeleton (as was formerly shown by E. Voit) becomes poorer in water as age progresses, and richer in ash and in the chief constituents of the ash.

(2.) The amount of water in soft parts similarly diminishes with age. The constituents insoluble in water, like chalk and iron, diminish, the phosphoric acid increasing. This is different from what Voit found in dogs.

(3.) Cartilage and spongy bone are in these particulars like the soft parts.

(4.) The increase of ash in the bones more than compensates for the diminution in other parts, so that the ash of the whole body increases with age up to a certain maximum.

The following selections from the tables illustrate the foregoing points:—

Bone (Three Healthy Children).

Constitu- ents.	In 100 parts.			In 100 parts dry fat-free bone.			In 100 parts ash.		
	1.	2.	3.	1.	2.	3.	1.	2.	3.
Water	72.2	—	45.0	—	—	—	—	—	—
Fat	0.6	—	2.5	—	—	—	—	—	—
Ash	11.3	—	27.9	41.5	48.8	53.2	—	—	—
CaO	5.4	—	15.0	19.9	23.9	28.6	48.0	48.9	53.8
MgO	0.16	—	0.4	0.6	0.6	0.8	1.4	1.3	1.6
P ₂ O ₅	4.5	—	11.9	16.7	19.8	22.6	40.2	40.7	42.6

The bodies of five rachitic children were then investigated in much the same way. These were also of different ages. It was found that the diminution of calcium salts occurred in the bones and not in the soft tissues, and the general conclusion is drawn that the administration of calcium salts would not in the greater number of cases of rickets be of any avail.

Muscles (Healthy Children).

Constituents.	In 100 parts.			In 100 parts of dry fat-free organ.			In 100 parts of ash.		
	1.	2.	3.	1.	2.	3.	1.	2.	3.
Water.....	83.9	—	77.2	—	—	—	—	—	—
Fat.....	2.2	—	1.8	—	—	—	—	—	—
Ash.....	1.0	—	1.0	7.5	6.4	5.3	—	—	—
CaO.....	0.03	—	0.01	0.2	0.2	0.04	2.8	3.1	0.82
MgO.....	3.02	—	0.02	0.1	0.1	0.1	1.9	2.1	2.2
P ₂ O ₅	0.3	—	—	1.9	1.5	2.0	28.7	23.6	37.9
Fe ₂ O ₃	0.01	—	0.01	0.1	0.1	0.04	1.14	1.4	0.7

The following analyses of two of these cases, the ages of which agree pretty well with those of the healthy subjects investigated, may be quoted:—

Bone (Rachitic Children).

Constituents.	In 100 parts.		In 100 parts of dry fat-free bone.		In 100 parts of ash.	
	A. 8 mths. fetus.	D., aged 3 yr. 8 m.	A.	D.	A.	D.
Water....	79.3	73.2	—	—	—	—
Fat.....	0.5	0.5	—	—	—	—
Ash.....	6.38	6.2	31.6	13.52	—	—
CaO.....	2.5	2.7	12.4	10.4	39.2	44.2
MgO.....	0.04	0.04	0.2	0.1	0.7	0.5
P ₂ O ₅	2.16	1.97	10.7	7.5	38.8	31.8

W. D. H.

The Influence of Acid Mineral Salts on the Composition of Bones. By H. WEISKE (*Landw. Versuchs-Statt.*, 39, 17—30).—Experiments were made on rabbits by adding sodium hydrogen phosphate to their food, to ascertain if mineral matter was removed from the skeleton; but the results were unsatisfactory; the differences between the composition of the normal bones and that of those animals which had not received phosphate were too slight to indicate any real change. The urine was always found to be alkaline, whilst in experiments previously made with free acid, the urine had been neutral, or slightly acid. Possibly larger doses of acid phosphate might have the desired effect.

E. W. P.

Iron in the Liver and Spleen. By F. KRÜGER, C. MEYER, and M. PERROT (*Zeit. Biol.*, 27, 439—458).—The importance of estimations of iron in the liver and spleen has been, during recent years,

increased, as it has been shown by Quincke and others that in pernicious anæmia the amount normally present is much increased. Comparatively few observations have, however, hitherto been made on the relative amount of the metal at different ages, and the present communication relates to this point. The animals, the organs of which were investigated, were calves, cows, and oxen, and also human fœtuses of various ages. The present paper contains references to former work on the subject, tables of analyses performed in the present research, and the following general conclusions:—

1. The amount of iron in the liver cells of the fœtus is very much higher, in the mean, 10 times higher, than that in adults. Care was taken in these experiments, as also in those with the cells of the spleen, to obtain the cellular elements, after crushing the organ completely, free from hæmoglobin and other impurities by carefully washing with salt solution (0.6 per cent.) and the use of the centrifugal machine. It was found that, although the saline solution dissolves out a small quantity of proteid matter from the cells, it does not remove from them any iron-containing constituents.

2. The iron of fœtal liver cells differs in amount at different stages of development. It begins to increase markedly about the end of the first half of pregnancy, reaches a maximum, then falls, and rising, reaches a second maximum three or four weeks before birth. From then until four weeks after birth, it sinks in amount until it is nearly normal.

3. In calves, it was found that for the first week after birth the iron is seven times more abundant in the liver than in the adult animal; it reaches the adult standard in about four or six weeks.

4. The amount of iron in the liver of adult animals shows very slight variations, and no noteworthy difference in the amount in the liver of cows and oxen was found.

5. The splenic cells of the fœtus are poor in iron as compared with those of the adult. The amount of iron in them begins to increase after birth, reaching the normal in about two months.

6. Although there is no difference in the amount of iron contained in the splenic cells of pregnant and non-pregnant cows, it is five times greater than that in the splenic cells of the ox.

7. The amount of iron in the spleen of adult animals, especially females, undergoes greater changes than that in calves or fœtuses.

W. D. H.

Composition of Butter Fats. By W. JOHNSTONE (*Chem. News*, 63, 56).—The author states that butter fat contains neither stearin nor normal oleic acid; but that it consists of a mixture of glyceryl "isoleate-palmitate-caprate" and "tri-nondecatoate" in varying proportions. In some butter fats, the radicle of cœnanthoic acid replaces one of the nondecatoic groups in the triglyceride, and forms glyceryl "dinondecatoate-cœnanthoate."

G. T. M.

Human Lymph and Chyle. By I. MUNK and A. ROSENSTEIN (*Virchow's Archiv*, 123, 484—518).—The present paper is a continuation of one already published (this vol., p. 755). Amyl oleate was administered to a patient suffering from a lymphatic fistula; during the 12 hours following its administration, 26 per cent. of the fat given

was recovered in the chyle, in the form of olein, the synthesis of oleic acid with glycerol having occurred in the process of absorption. No amyl alcohol was found in the chyle. Artificial digestion experiments showed that pancreatic juice has the power of splitting amyl oleate into amyl alcohol and oleic acid.

Charcoal, in a fine state of subdivision, was next given, with the view of ascertaining whether fine particles as small as or smaller than the oil globules of an emulsion are taken up in the same way. But the lymph was entirely free from them, showing, as has been previously stated, that absorption of fine solid particles does not occur.

Is oil absorbed from the rectum? was the next point investigated; after injection of olein into the rectum, it was found that from 3.7 to 5.5 per cent. of the fat given appeared in the chyle.

Similar experiments were then undertaken to determine whether proteid and sugar (given in large doses) appear in the chyle after being administered as food. It was found that the administration of proteid, as of any food, increases the flow of lymph, but that its percentage of proteid does not rise. On the other hand, the sugar in the chyle is increased, and after a large quantity of sugar as food, the percentage in the chyle may be doubled as compared with the amount during inanition (compare Ginsberg, *Abstr.*, 1890, 276).

The paper concludes with further analytical data respecting the solid constituents and inorganic salts of the chyle and lymph. The composition of the lymph ash was as follows:—In 100 parts of lymph, 0.8675 part of ash was obtained; in 100 parts of the ash, the following numbers give the percentages of its different constituents:—NaCl, 67.0; Na_2CO_3 , 24.9; K_2HPO_4 , 3.2; $\text{Ca}_3(\text{PO}_4)_2$, 3.2; $\text{Mg}_3(\text{PO}_4)_2$, 1.1; $\text{Fe}(\text{PO}_4)_2$, 0.3.

Further, it was found that lymph and chyle contain an amylolytic ferment; but that neither contains a sugar-destroying ferment as stated by Lépine.

W. D. H.

Indigo-red (Indirubin) in Urine. By H. ROSIN (*Virchow's Archiv*, 123, 519—566).—Many red pigments under different names have been described in normal, and more particularly in morbid, urines. One of these appears to be indirubin or indigo-red, although its absolute identification with the indigo-red obtained from plants has not, hitherto, been thoroughly worked out. The imperfect data given by various workers on urinary pigments render it also desirable that those which are, and those which are not, identical with indigo-red should be accurately determined.

Indigo-red was prepared artificially from commercial indigo; it was also prepared by a modification of Berzelius' method from the indican of plants, and also from the urine. The percentage composition, the crystalline form, and other properties, and the relation of the pigments to indigo-blue were in all cases absolutely identical.

The pigments which are identical with indigo-red are Heller's urrhodin, as Schunk first showed, Leube's pathological urinary pigment, and Plósz's urorubin. Those red pigments which are not the same as indigo-red are the scatole pigment, Nencki and Sieber's urorosein, which has characteristic solubilities and reactions, uroerythrin (the

pigment in deposits of urates), urohæmatin, Giacosa's pigment, and urorubrohæmatin.
W. D. H.

Analysis of Pathological Liquids. By G. PATEIN (*J. Pharm.* [5], 23, 390—394).—From a hydrocephalous subject was taken 380 c.c. of a colourless liquid, turbid after filtration, in which some flocculent filaments appeared after being some time in repose. The reaction was alkaline, and only faint traces of albumin appeared on boiling in presence of 2 drops of acetic acid. Sp. gr. 1·004; solid residue 9·4 grams per kilo.; anhydrous salts 7·6 grams, containing sulphates, hydrogen carbonates, but no phosphates. Agitation with ether did not extract either fatty matters or cholesterol. Fehling's solution was not reduced.

Ovarian Cysts.—1. Syrupy liquid, not stringy, reddish, with pulverulent deposit. Sp. gr. 1·013; solid residue 61·5 per kilo.; anhydrous salts 7·5; chlorides 6·5; proteid matters 54·0. No globulin was precipitated by magnesium sulphate. The liquid was coagulable by heat, but the coagulum disappeared on the least addition of acetic acid. 2. Fibrome, size of an orange, from a woman 47 years old.—The fibrome contained water 750·0 grams per kilo.; solid matters 242·0; anhydrous salts 6·2 grams, with traces of urea, cholesterol, myosin, and fats. The contents of the cyst were gelatinous, and included a notable amount of mucin; it did not coagulate either when boiled alone or with acetic acid. 3. Cyst from a woman of 38 years.—Amount of liquids 35 litres; reaction scarcely alkaline. Sp. gr. 1·004; solids 12·6 grams per kilo.; anhydrous salts 9·15; albumin 1·10. Neither globulin, fat, nor cholesterol were present. The proteid matters were completely precipitated by heat and acetic acid. 4. Cyst from a woman of 51 years.—Amount of liquid 40 litres, alkaline, chocolate coloured, somewhat thick consistency. Sp. gr. 1·019; total solids 57·3 grams per kilo.; anhydrous salts 9·20. The proteid substances were completely precipitated by heat and acetic acid. From these results it is evident that albumin is subject to modification, which must be considered in its detection and estimation.

The following table gives the results of analyses (in grams per kilo.) of healthy and altered tissues in cases of cancer. 1. Cancer of the breast running a very rapid course. 2. Breast cancer of recent development.

	Healthy tissue adjoining.		Tumour.		Liquid portion.
	1.	2.	1.	2.	1.
Water	175·5	476·0	830·5	849·0	928·6
Total solids	824·5	524·0	169·5	161·0	71·4
Anhydrous salts....	4·2	8·5	11·5	16·4	—
Fat	considerable amount	notable amount.	0·0	0·0	—
Proteid	—	—	—	—	60·5
Globulin & mucin..	—	—	—	—	traces

The liquid portion of 1 did not coagulate on boiling with 2 drops of acetic acid. A third tumour has given traces of cholesterol.

Polypes of the Nose.—These are generally of small weight, and contain a large proportion of water; their albumin may or may not coagulate when boiled with acetic acid. In a particular case, one weighed 373 milligrams with 13.37 per cent. of solids; it contained a notable amount of calcium phosphate. The presence of this compound in all nasal polypes is worthy of note.

A tumour taken from the kidney gave 1100 c.c. of liquid of a neutral reaction. Sp. gr. 1.023; total solids 118.8 grams per kilo.; anhydrous salts 7.6; chlorides 5.45. Mucin and albuminose were present, but neither uric acid, urea, hippuric acid, fat, nor cholesterol was found. After elimination of mucin and albuminose, the proteid matters are not coagulated on boiling with acetic acid. It is seen that the tumour contains no element of urine.

J. T.

Action of Opium and Morphine on the Intestine. By W. SPITZER (*Brit. Med. J. Epitome*, 1891, 134; from *Virchow's Archiv*, 123, 593—628).—The experiments were carried out on rabbits, frogs, and men, their object being to increase our knowledge of the action of opium on the intestine, and to determine whether opium is better than morphine as an anti-diarrhoeic and anodyne. In frogs, the bowel was exposed and kept moist with saline solution. Very small doses of aqueous extract of opium given subcutaneously sufficed to diminish the sensitiveness of the bowel to painful stimuli, whilst leaving intact the sensitiveness to stimuli which excite peristalsis. The sensitiveness of the skin was also not affected, nor was there any general narcosis. The conclusion is drawn that the action of opium cannot under these circumstances be on the brain, as the same result is obtained with headless frogs; nor on the spinal cord, as its other functions are intact, but on the bowel locally. The local action of opium was also shown by giving a frog strychnine; then tying the intestine midway between the stomach and anus, opium was injected into the lower half, and its power of calling forth convulsions on stimulation was then markedly diminished. The opinion is held that opium paralyzes not the sensory endings, but sensory ganglia on the course of the sensory nerves in the wall of the canal. The motor ganglia are not so readily affected, larger doses being necessary to lessen peristalsis.

The diminution of peristalsis may be due to paralysis of motor ganglia in the bowel, or to a stimulation of the inhibitory centres in the cord from which the splanchnic nerves arise. Paralysis of the sensory nerve terminations in the wall of the intestine does not occur, because after very large doses of morphine the peristaltic movements of the bowel become very marked, and experiments pointed to the conclusion that the diminution in peristalsis was very largely due to an action of the opium in paralyzing the motor ganglia in the walls of the intestinal canal. Large doses caused great increase of bowel peristalsis before general spinal tetanus was induced. This is probably due to paralysis of the spinal cord, and consequent paralysis of the inhibitory action exerted by the splanchnic nerves. In this condition,

however, the sensitiveness of the intestine to painful stimuli is much diminished. Morphine has the same action in every way, and quantitatively the activity of the opium is proportional to the amount of morphine it contains. The other alkaloids of opium have very little action on the bowel. On rabbits, observations were made after exposing the bowel while the animal lay in a warm bath of saline solution. The experiments of Nothnagel are confirmed, in which he found that irritation of the bowel with sodium chloride is not nearly so effectual in increasing peristalsis after the administration of opium or morphine. If a portion of bowel be completely isolated and the same experiment repeated, then peristalsis is not interfered with; this result is regarded as proving that in this case the opium acts on the spinal cord, and diminishes the inhibitory action of the splanchnic nerves. It is, however, pointed out that irritation of the bowel from without with sodium chloride scarcely corresponds with physiological peristalsis or increased peristalsis after purgatives or irritation from within of the mucous membrane, as the peristalsis takes place towards the pylorus, and is very inconstant in amount. The bowel was therefore irritated by injecting into it a 15 per cent. salt solution, coloured with indigo-carmin. The rate at which this solution progressed down the intestine was observed in normal animals, and was found to be two or three times slower after opium or morphine, the peristalsis being also much more gentle and regular in the latter case. Even after complete isolation of a portion of the intestinal canal from its mesenteric nerves, opium greatly diminishes the peristalsis. Opium given subcutaneously acts exactly to the same extent, and no better than, morphine subcutaneously, its activity being proportional to the amount of morphine it contains. In healthy men, opium by the mouth acts somewhat more powerfully on the bowel than when given subcutaneously. The reason, probably, is that the morphine is only slowly abstracted from the opium, and thus acts gently along the whole length of the bowel; it is not so quickly absorbed as pure morphine is, and in consequence does not produce so marked a general action. In diarrhoea, opium by the mouth is more powerful than opium extract or morphine subcutaneously, or morphine by the mouth. In slight intestinal pain, opium by the mouth is the best treatment, as we get the desired analgesia with small doses and without constitutional effect, the local action on the bowel being probably sufficient; in very severe pain, hypodermic injection of morphine is most effectual.

Poisoning by Aniline, Chlorates, and Mercuric Chloride. By W. FALKENBERG (*Virchow's Archiv*, 123, 567—602).—Silbermann (*Zeit. klin. Med.*, 11, Heft 5 and 6; *Deutsch. med. Wochens.*, 14, No. 25) has stated that pyrogallol, glycerol, and potassium or sodium chlorate produce not only hæmoglobinuria (or methæmoglobinuria), but that death ensues from intravascular coagulation, set up presumably by the liberation of fibrin ferment from the disintegrated corpuscles. The situation of the clots produced is described, and the term "capillary thrombosis" is in the present paper criticised, it being so difficult to say with certainty whether the blood in the

capillaries is coagulated or not during life. Further criticisms are passed on other points. Silbermann extended a few observations, followed by similar results, to other drugs, aniline, toluylenediamine, arsenic, phosphorus, and Kaufmann states the same is true for corrosive sublimate.

The present paper is largely polemical, but also describes numerous experiments with aniline, sodium chlorate, and corrosive sublimate. In respect to these poisons at least, the cause of death was not intravascular coagulation. The blood, on the contrary, had less tendency than normal to coagulate.

W. D. H.

Physiological Action of Lupetidine and Allied Substances in Relation to their Chemical Constitution. By A. GÜRBER (*Chem. Centr.*, 1891, 1, 232—235).—The series of substances, copellidine, parpevoline, propyllupetidine, isobutyllupetidine, and hexyllupetidine have for their nucleus piperidine, of which lupetidine is a dimethyl substitution product; and if the hydrogen atom adjacent to the nitrogen atom is replaced by methyl, ethyl, &c., further members of the group are obtained. Small doses of these substances were administered to animals. The intensity of their action (paralysis of the voluntary muscles) may be compared by the following numbers: lupetidine, 50; copellidine, 100; parpevoline, 200; hexyllupetidine, 200; isobutyllupetidine, 250; propyllupetidine, 400. The actual seat of paralysis, whether central or peripheral, was not definitely determined. The intensity of the action is proportional to the number of methyl groups present in the molecule.

W. D. H.

Use of Liquefied Carbonic Anhydride for the Rapid Filtration and Sterilisation of Organic Liquids. By A. D'ARSONVAL (*Compt. rend.*, 112, 667—669).—A long cylindrical copper or steel tube containing a biscuit porcelain Pasteur-Chamberland filter is connected with a cylinder containing liquid carbonic anhydride. The gas not only drives the liquid through the filter, but under the high pressure, especially if its action is prolonged and the liquid is heated to 40°, it exerts a very powerful bactericidal and sterilising effect. The richness of the filtrate in colloids increases with the pressure, and by varying the pressure it is possible to obtain from one and the same liquid (e.g., pancreatic juice) filtrates having very different properties.

Chemistry of Vegetable Physiology and Agriculture.

Alcoholic Fermentation and the Conversion of Alcohol into Aldehyde by the "Champignon du Muguet." By G. LIXOSSIER and G. ROUX (*Bull. Soc. Chim.* [3], 4, 697—706; see also *Abstr.*, 1890, 1179).—Contradictory statements have been made by previous authors as to the character of the fermentation induced by the "Champignon du muguet" (a fungus producing the disease "thrush"

in the mouth). Sterilised solutions inoculated with the pure fungus yield alcohol, the maximum amounts obtained being 2·7 per cent. in 43 days, using dextrose solution (*plus* necessary salts); and 5·5 per cent. in 124 days, using wort from dried raisins.

Three stages may be distinguished during the fermentation:—(1) rapid growth of the organism; (2) active fermentation; (3) lessened activity due to the toxic influence of the fermentation products, aldehyde having, it would seem, the greatest effect. “Muguet” can cause the fermentation of dextrose, levulose, and maltose; saccharose is neither inverted nor fermented, but serves as a food material; lactose cannot even be used as food. Substances other than sugars, although unfermentable, can support the growth of this fungus; such food materials, in order of nutritive value, are, dextrin, mannitol, alcohol, sodium lactate, lactic acid, gum, and glycerol; tartaric acid and tartrates barely serve to sustain life; starch, erythrol, acetic acid, acetates, oxalic acid, oxalates, aldehyde, acetone, and aromatic substances are not foods.

The sugar present is never wholly fermented by this organism, neither are the various sugars attacked at the same rate. In a mixture of equal proportions of dextrose and levulose, the ratio dextrose/levulose tends towards a minimum (0·3); hence, it is impossible to use the fungus as a means for obtaining pure levulose.

The growth of the organism is favoured by the alkalinity of the solution employed; more of the sugar is then used up, but the ratio of alcohol produced to sugar used is lowered. In addition to glycerol and succinic acid, considerable quantities of acetic acid and acetaldehyde are produced. The ordinary ferments give for the ratio glucose destroyed/acetic acid produced, a mean value 0·0025; this quantity is 0·09 to 0·14 for muguet. The aldehyde is mainly produced by the oxidation of the alcohol induced in presence of air by the ferment. A small proportion of the acetic acid present is a true excretory product of the organism, but the greater part is undoubtedly produced by the oxidation of the aldehyde without the intervention of the ferment, for muguet does not grow in an aldehyde solution. In the slowness with which fermentation takes place, in the maximum concentration of alcohol produced, and in the ratio of weight of sugar destroyed to weight of organism produced, the “Champignon du muguet” exhibits marked analogies with the *Mucorini*, and differs considerably from the *Saccharomycetes*. The conclusion that the organism does not belong to the latter is borne out by the results of a careful morphological study. W. T.

Assimilation of Nitrogen by Plants. By B. FRANK and R. OTTO (*Chem. Centr.*, 1891, i, 332—333; from *Ber. deut. bot. Ges.*, 8, 331—342).—The authors have endeavoured to prove experimentally whether the Leguminosæ directly absorb pure nitrogen by means of the leaves or not, and to this end experiments have been made with cut leaves. So far, however, the results obtained are not sufficiently definite.

Experiments on the growth of the rhizobium of the root nodules in the presence of the organism of the nodules in solutions contain-

ing (a) sugar, (b) sugar and asparagine, (c) asparagine, show that the growth was most rapid in the presence of both sugar and asparagine, and least rapid when sugar alone was supplied.

Finally, peas were grown in unsterilised earth, in sterilised earth, and in sterilised earth to which a small quantity of the fresh soil was added. All the plants grew perfectly, and assimilation of nitrogen took place in every case. J. W. L.

Simultaneous Evolution of Oxygen and Carbonic Anhydride by Cactæ. By E. AUBERT (*Compt. rend.*, 112, 674—676).—Cactæ, when exposed to light of moderate intensity at a temperature of 35°, evolve oxygen and carbonic anhydride, their respiration ratios being 0.98 (*Opuntia*) to 0.88 (*Mamillaria*), whilst their assimilation ratios are 2.38 to 2.28. This result is probably due to the fact that the thin superficial chlorophyllian layer is not able to decompose the whole of the carbonic anhydride evolved by respiration from the colourless parenchyma underneath. The intense light of the tropics decomposes the whole of the carbonic anhydride, and in the tropics loss of carbon takes place only during the night. C. H. B.

Influence of Salt on the Formation of Starch in Vegetable Organs containing Chlorophyll. By P. LESAGE (*Compt. rend.*, 112, 672—673).—The examination of the leaves of plants growing on the sea shore, and experiments made by watering plants with pure water and with salt solutions of various strengths, show that salt has a distinct influence on the formation of starch in the chlorophyllian organs of plants, and in extreme cases prevents it. The necessary result is a decrease in the assimilation of carbon. The author has previously shown that salt reduces the quantity of chlorophyll. C. H. B.

Presence and Function of Diastase in Plants. By J. WORTMANN (*Ann. Agron.*, 17, 84—89; from *Bot. Zeit.*, 1890, Nos. 37—41).—After a variety of experiments, the author concludes that diastase in plants has not the importance which has been ascribed to it, and that starch is transformed into soluble products by other means, probably by the agency of living protoplasm. Diastase is formed in small quantities, certainly, in leaves which contain no starch; the quantity of diastase present is in no case proportional to the amount of starch; from some starch-containing leaves, it is quite absent, and yet these leaves are the seat of very active starch-transformation. It is in special cases only, such as the germination of seeds, tubercles, and rhizomes containing starch that the solution of the starch is accomplished by diastase. The author points out that in testing for the disappearance of starch under the action of diastase the result is conclusive only when the liquid gives no blue colour with iodine after being boiled and cooled. J. M. H. M.

Formation of Nitrogenous Organic Bases by the Decomposition of Proteids in the Vegetable Organism. By E. SCHULZE (*Ber.*, 24, 1098—1101).—When the seeds of *Lupinus luteus*, *Soja hispida*, and *Ocucurbita pepo* are allowed to vegetate in the dark for 12—14 days and the shoots extracted with water, a solution is obtained

which, after removing proteids as completely as possible, yields a precipitate with phosphotungstic acid. This contains considerable quantities of nitrogen, and, on treatment with milk of lime, yields nitrogenous organic bases. From *Lupinus luteus* and *Cucurbita pepo*, the author has been able to isolate the arginine described by Schultz and Steiger (Abstr., 1886, 725), whilst *Soja hispida* yields a base which is either identical with or very closely allied to arginine. The quantity of arginine obtained from *Cucurbita pepo* is small, but *Lupinus luteus* yields it in such quantities that the author has been able to show by quantitative experiments that it must have been formed at the cost of the proteids present as reserve substance in the cotyledon.

Arginine only differs from the lysatine described by Dreschsel, inasmuch as it contains an additional atom of nitrogen and of hydrogen in the molecule. Experiments are in progress to determine, if possible, the relation existing between them. H. G. C.

Physiological Importance of Calcium Oxalate in Plants. By KOHL (*Ann. Agron.*, 17, 90—91).—The author adds some observations to his previous work on this subject (Abstr., 1890, 191). He shares with Palladin the theory that this salt is eliminated as an accessory during the synthesis of proteids from amides and carbohydrates. If this be true, oxalates should be found in all plants. The author shows that in many cases amongst algæ and fungi, even where little or no calcium oxalate is found, oxalic acid or soluble oxalates are still present, and diffuse rapidly out of the plant, so that a calcium salt gives a precipitate in the vicinity of many fungi, and the hyphæ of some of them are encrusted on the outside by crystals of calcium oxalate formed from the lime in the soil. Amongst fungi forming oxalic acid in large quantities the author notes *Saccharomyces Hansenii*, the *oxalic ferment* recently discovered by Kopf. But if the formation of oxalic acid by this and other fungi, and that of acetic acid by the schizophytæ, are regarded as fermentations, why should not the idea be enlarged to cover the formation of tartaric and malic acids, &c., in the higher plants? The author expands this idea, and suggests that the lower plants give by preference molecular fermentations resulting in the production of alcohol, lactic and butyric acids, &c., whilst fermentations of oxidation resulting in carbonic, oxalic, malic, and tartaric acids prevail amongst the higher plants. The migration of calcium oxalate in the tissues, maintained by Schimper, is now admitted by the author, who supports also Schimper's idea that the calcium oxalate is rendered soluble for this migration, whether by free oxalic acid (Währlich) or some other substance. He has recognised the presence of calcium oxalate in the expressed and filtered juice of many plants, as many as four crystalline forms of this salt being deposited on allowing these liquids to evaporate. J. M. H. M.

Calcium and Magnesium Oxalates in Plants. By MONTEVERDE (*Ann. Agron.*, 17, 92—94).—This abstract, from a long memoir in Russian, sums up the principal conclusions arrived at by the author. He shows the presence of these salts in a great number of Gramineæ not hitherto examined. He denies the statement of Schimper that

oxalates migrate in the plant tissues, and that of *Aé* that they disappear gradually in organs etiolated by darkness. The formation of oxalates is greatly promoted by light, both directly and as a consequence of increased assimilation. Blue light is better than darkness, but vastly inferior to orange. The quantity of lime in the soil or nutritive medium has an influence up to a certain point; apparently the normal quantity of oxalic acid formed by the plant combines wholly with lime, if enough is present, and in default with magnesia and other bases. After taking exception to Schimper's classification of the oxalate deposits into primary, secondary, and tertiary, the author remarks that the primary deposits of oxalate are accessory to the transformation of albuminoids, and not to respiration or to the formation of cellulose. The secondary oxalate appearing in the leaves as the nitrates absorbed by the plant are destroyed is accessory to the synthesis of albuminoids.
J. M. H. M.

Peculiar Odour of Soil. By BERTHELOT and G. ANDRÉ (*Compt. rend.*, 112, 598—599).—With a view to ascertain the cause of the peculiar smell observed when soil is moistened, a quantity of soil, free from all visible vegetable *débris*, &c., was extracted with water at 60°, and the liquid distilled. The distillate has the peculiar odour of the moistened soil, and its intensity increases if the first distillate is redistilled and only the first portion collected. The odour, however, is still perceptible in the residual liquid.

The substance is neither an acid nor an alkali, nor a normal aldehyde; its concentrated aqueous solutions are precipitated by potassium carbonate with production of a resinous ring. When heated with potassium hydroxide, an acrid odour like that of aldehyde resin is developed. It does not reduce ammoniacal silver nitrate, and with alcohol and iodine it gives the iodoform reaction.
C. H. B.

Analysis of Fodders, with special reference to the Proteïds. By A. STUTZER (*Landw. Versuchs-Stat.*, 38, 469—477).—Tables of the analysis of 58 feeding stuffs, showing percentage of non-proteïds, albumin, and indigestible proteïds.
E. W. P.

The Climatic Conditions for the Development of Nicotine in Tobacco Plants. By A. MAYER (*Landw. Versuchs-Stat.*, 38, 453—467).—In a previous communication, the author showed that by the use of a rich and easily assimilable nitrogenous manure, the percentage of nicotine in tobacco plants was increased; in the series of experiments now described, the influence of heat, water, light, and the moisture in the air have been inquired into. Plants grown under glass contained in some cases double the percentage of alkaloid found in those plants grown in the open and consequently at a lower temperature, and in those plants growing under shelter, a higher temperature corresponded with a higher percentage of nicotine. Full lighting also was accompanied by increase of alkaloid, even up to 100 per cent. of that contained in plants from which the light was in a measure cut off. A small supply of water seemed to be most beneficial to the full development, an excess being inimical. Increase of the moisture of the atmosphere surrounding the plant, whereby

transpiration was diminished, led to an increase in the amount of alkaloid. E. W. P.

Drainage Waters from Bare and Cultivated Soils. By P. P. DEHÉRAIN (*Ann. Agron.*, 17, 49—82).—The mode of experiment and the first results obtained have been described in a previous memoir (*Abstr.*, 1890, 1459). The results of a second season's observations are given in this memoir. Soils of different natures, obtained from different localities, showed a great difference in retentive power, the ratio of total rainfall (March 1 to November 7) to drainage water being in four cases 3·7, 2·9, 2·9, and 2·3 respectively; the most retentive were the strong clays. The nitrates found in the drainage waters from the same four soils, reckoned into kilos. nitric nitrogen per hectare, were respectively 152·4, 128·1, 62·5, and 45·2; so that the nitrate lost was far from being proportional to the quantity of water percolating; neither had it any connection with the richness in nitrogen of the soils. Ammonium sulphate was added to some pots of bare soil, in order to ascertain whether autumn or spring applications of this salt are preferable, having regard to the nitrogen lost as nitrate in drainage. The results are exhibited in the following table, the sulphate having been added to the soil in November:—

	Drainage water.		Nitric nitrogen.	
	Soil alone.	Soil with ammonium sulphate.	Soil alone.	Soil with ammonium sulphate.
	c.c.	c.c.	mgrm.	mgrm.
Jan. 6 to Jan. 24	2900	1910	52	112
Jan. 24 to Feb. 3	1840	3150	27	178
Feb. 3 to May 4	1960	1950	68	129
May 4 to May 31	3330	2680	124	153
June 3 to July 15	7850	6820	375	2039
Total	17880	16710	646	2611

In this particular season, no considerable nitrification of the ammonium salt occurred until the hot and wet month of July, and the quantity washed through during the winter was certainly less than the roots of the wheat crop could have assimilated.

A previous experiment of the author's having suggested that for some crops (sugar-beet, for example) the presence of humus is as essential to a proper development as a due supply of nitrogen, phosphates, and potash in mineral forms, or at any rate that the latter do not suffice to produce a full development of the crop in the absence of the former, further experiments were undertaken to elucidate this most important point. The mode of pot culture was adopted; several different plants were tried, and the quantity of drainage water in each case, and of nitrate contained therein, were ascertained. The humic matter added to the soil for the purpose of the experiments was obtained by

percolation of condensed steam through farmyard manure; such an extract contains, in addition to the nitrogenous organic matter, manurial ingredients in the form of a little phosphate and a considerable quantity of potash. The comparisons were between five pots in each series (1) good soil; (2) exhausted soil; (3) ditto with mineral manures (sodium nitrate, superphosphate, and potassium chloride); (4) the same soil as No. 2, with 1 litre of humic extract; (5) the same soil as No. 2, with 1 litre of humic extract and mineral manures. The plants tried were oats, hemp, peas, rye-grass, and clover; wheat and sugar-beet were included, but failed from accidental causes. The results are, perhaps, comparable amongst themselves, but in no case was as good a crop obtained as would be the case in field culture. The most important results may be thus summarised:—

Oats.—The mineral manures produced full effect; no special influence could be traced to the humus, and the nitrate found in the drainage water was inconsiderable in every case save that of the good soil unmanured, which produced a poor crop.

Hemp.—The worst crops were obtained in the exhausted soil, and in the same with addition of the three saline manures only, and from these two occurred by far the greatest loss of nitrate by drainage, as the following table shows:—

	Pot 1.	Pot 2.	Pot 3.	Pot 4.	Pot 5.
Weight of crop....	35·8	15·5	22·8	25·7	38·4 grms.
N as nitrate in drainage	61	632	1222	40	36 mgrms.

It is true that pot 5 received more total nitrogen, phosphate, and potash than pot 4, but it seems fairly inferable from the poor crop in pot 2, and the loss of nitrate therefrom, that these ingredients, when presented in the purely saline form, could not be fully utilised by this crop.

Rye-grass.—Two cuts were made, and the produce weighed as hay:—

	Pot 1.	Pot 2.	Pot 3.	Pot 4.	Pot 5.
Total produce	66	37	53	51	63 grms.
N as nitrate in drainage water ..	33	149	196	140	45 mgrms.

Here also there seems some reason to attribute specific favourable action to the humic matter.

Peas.—In this case the good soil of pot No. 1 (manured year after year) yielded a better crop than any of the rest:—

	Pot 1.	Pot 2.	Pot 3.	Pot 4.	Pot 5.
Total dry produce .	121	66	69	70	83 grms.
N as nitrate in drainage	220	118	132	247	285 mgrms.

Special conditions, and not the mere supply of manurial ingredients, whether as salts or in humus, are necessary to the successful growth of this and probably other leguminous crops; and their indifference.

now well established, to the artificial supply of nitrogen is well shown in the large amount of nitrate lost in the drainage water from all the pots.

Clover.—The results are similar to those given by the peas.

	Pot 1.	Pot 2.	Pot 3.	Pot 4.	Pot 5.
Total dry produce .	130	82	85	80	92 grms.
N as nitrate in drainage	269	159	164	196	216 mgrms.

The following interesting table is compiled from the results of these pot experiments :—

Milligrams per Litre of Nitric Nitrogen in the Drainage Water from different Soils under different Crops.

	No. crop.	Oats.	Rye-grass.	Peas.	Clover.	Hemp.
1. Rich soil	38	7·3	1·7	42	31	3·5
2. Exhausted soil	29	0·2	6·0	15	19	22·0
3. No. 2 with chemical manures	—	0·2	10·2	21	21	45·0
4. No. 2 with humic extract	—	2·3	5·0	40	29	2·0
5. No. 2 with chemical manures and humic extract	—	0·0	2·0	31	32	2·0

Experiments were also made on the best crops for growing during the autumn as green manures, to prevent the great loss of nitrates by drainage which occurs in a wet season after the removal of the summer crop. The autumn of 1890 was, however, very unfavourable for these trials, being very dry, and the long frost which set in about the middle of November, and lasted into January, effectually stopped loss of nitrate, and put an end to the growth of all the autumn green crops.

The following table, nevertheless, is of interest, showing the quantity of nitric nitrogen per hectare lost during the November rains under the different circumstances :—

Summer Crop.	Green manure.	Nitric nitrogen in November drainage.
Sugar beet.....	none	7·5 kilos.
Maize (forage)	none	14·5 "
Oats	rape	0·37 "
Hemp	none	10·5 "
Peas	turnips	0·51 "
Rye grass continued in	rye grass	0·38 "
Clover	clover	1·10 "

In dry autumns, it is probable the cost of cultivating and sowing a crop for green manure would exceed the advantage to be gained in

preservation of nitrates in the soil; in wet autumns, the green manuring should be very advantageous. The author suggests for this purpose a mixture of rape and vetches, the former to prevent washing out of nitrates, the latter to accumulate nitrogen from the atmosphere.

J. M. H. M.

Analytical Chemistry.

Kjeldahl's Process. By V. EDWARDS (*Chem. News*, 63, 14—15).—The digestion of the substance, 1 gram for ordinary manure, 0.5 gram for guanos and rich substances, is carried out in the manner already described (*Chem. News*, 59), except that rather less mercury oxide (about 0.2 gram) will suffice. The distillation of the ammonia is conducted from a 500 c.c. flask resting on a sand-bath and fitted with a rubber stopper, through which passes a tube, which is carried about 3 inches into a small, tubulated retort holding about 110 c.c., and serving to condense the quantity of distillate which will contain all the ammonia. The stopper of the retort is replaced by a cork, through which passes the bent end of a Will and Varrentrap's nitrogen tube containing the standard sulphuric acid. With the modified apparatus, certain precautions are necessary; thus, care must be taken that the heating of the distilling flask is gradually and cautiously performed, and that the gas does not pass too quickly through the Will and Varrentrap tube.

G. T. M.

Detection of the Sulphur not combined with Hydrogen in Illuminating Gas. By L. ILOSVAY (*Bull. Soc. Chim.* [3], 4, 714—715).—The gas is passed through a glass tube containing asbestos, which is maintained at a dull-red heat. After being washed by passing through a little water, the gas is filtered through wadding and then traverses a tube containing lead-paper, which is blackened by the hydrogen sulphide formed when the sulphur compounds contained in the gas are heated.

W. T.

Estimation of Free and Combined Carbonic Anhydride in Mineral Waters. By H. BRETER (*J. Pharm.* [5], 23, 339—341).—To 50 c.c. of the mineral water two or three drops of phenolphthaleïn is added, and standard potash solution is run in very slowly towards the end, until the last drop gives a persistent rose tint. The quantity of free carbonic anhydride is double the equivalent of the potash used. Standard potassium carbonate solution can also be employed, and with advantage, as it is more constant than the hydroxide solution; but with the carbonate, one equivalent is the measure of the free carbonic anhydride.

Two or three assays should be made, and the mean result, omitting the first one, should be taken. The amount of solution required by the first assay is added at once in the second assay, and is always too

little; more is now added, with gentle stirring, so as to avoid all possible loss of free gas. The total carbonic anhydride is now estimated by adding standard sulphuric acid to the solutions just obtained until a slight excess is present, the solution being boiled to expel the free anhydride, and the excess of acid titrated back with standard potash.

J. T.

Estimation of Metallic Zinc in Zinc-dust. By W. MINOR (*Chem. Zeit.*, 14, 1142—1143).—One gram of zinc is treated with 60 c.c. of potassium dichromate solution (containing 30 grams of the salt per litre, and standardised with pure zinc) diluted with water, and about 20 c.c. of dilute sulphuric acid is run in gradually with constant agitation, so that the operation lasts 20 minutes; more acid is then added, and the excess of dichromate titrated with a solution of ammonium ferrous sulphate containing 150 grams of ferrous sulphate and 75 grams of ammonium sulphate, dissolved in water, and 100 c.c. of strong sulphuric acid, all diluted to 1 litre, and titrated against the dichromate previous to use. The zinc numbers obtained include the cadmium and iron present, which is immaterial when the zinc is only required for purposes of reduction; a method, however, is furnished for calculating the actual proportion of zinc present.

D. A. L.

Estimation of Zinc Carbonate and Silicate in Calamine containing Lead. By W. MINOR (*Chem. Zeit.*, 14, 1003).—The method previously described (*Abstr.*, 1890, 418) requires modification when lead is present, but the following amended method is applicable to all samples of calamine.

The calamine is boiled for about a quarter of an hour with dilute sodium hydroxide, filtered, the treatment repeated with the residue, which is then filtered off and well washed with hot dilute sodium hydroxide. The lead is separated from the combined filtrates by supersaturating with sulphuric acid, &c.; the solution is then rendered alkaline with ammonia, and the zinc titrated with sodium sulphide; alumina does not interfere with the titration.

D. A. L.

Assay of Lead Ores by the Cyanide Process. By A. W. WARWICK (*Chem. News*, 63, 30—32).—The author has carefully determined the value of the cyanide process in the assay of lead ores, using in his investigations (1) a galena with siliceous gangue, the lead, however, containing but a small amount of other base metals; (2) a rather poorer galena containing a considerable quantity of copper pyrites; (3) a pure specimen of galena; and (4) a pure sample of cerussite. He finds that the cyanide assay, when carefully performed, is capable of giving with rich ores results as trustworthy as the best of the other methods, and is to be preferred when the ore is poor. The precautions to be observed are that the temperature is not allowed to rise too high, that the time of fusion does not exceed 20 minutes, and that the amount of cyanide used be not too small. The assay may be conducted in a Battersea crucible. A quantity of cyanide is rammed into it, and on this is placed 100 grains of the ore mixed with about six times its weight of Becker's stick cyanide of potassium, and the

whole covered with a layer of cyanide and finally a layer of salt, the total weight of cyanide used being 750 grains. The charge is best heated in a Fletcher's gas furnace at a low red heat for 15 minutes, and at a full red heat for an additional 5 minutes. On breaking the crucible, the button of lead is obtained in a very clean condition.

G. T. M.

Detection of Mercury in Toxicological Researches. By M. T. LECCO (*Ber.*, 24, 928—929).—It is generally assumed that mercury dissolves easily in hydrochloric acid on addition of potassium chlorate, and that when organic substances containing mercury are treated with hydrochloric acid and potassium chlorate, the whole of the mercury goes into solution. During the examination of a human stomach containing mercury, the author observed that the solution obtained by treatment with hydrochloric acid and potassium chlorate contained scarcely a trace of mercury. The insoluble residue was therefore examined, and found to contain the mercury undissolved. A fresh portion of the stomach was treated with hydrochloric acid and chlorate in a glass dish, and after a short time small globules of mercury were observed on the bottom of the dish which remained undissolved after the organic matter had been destroyed.

The author then treated pure mercury with concentrated and dilute hydrochloric acid and potassium chlorate, both at the ordinary temperature and on the water-bath, and in all cases found that the mercury is difficult to dissolve. Hence it is absolutely necessary to continue the action of hydrochloric acid and chlorate for many hours after the destruction of the organic material when mercury is to be detected.

E. C. R.

Analysis of Sodium Aluminate. By K. J. BAYER (*Chem. Zeit.*, 14, 736—737).—The author draws attention to the fact that the method of analysis of sodium aluminate proposed by Lunge (this vol., p. 365) has been used by himself for some time (*Abstr.*, 1886, 281, 651). He takes exception to Lunge's remarks as regards the interference of silica, for not only has silica no neutralising effect for the acids, but it is shown that sodium aluminate cannot retain more than traces of silica any more than sodium silicate can contain much alumina, inasmuch as the excess in both cases forms a gelatinous precipitate, which, when washed and air-dried, has the percentage composition SiO_2 , 35.24; Al_2O_3 , 19.74; Na_2O , 10.55; water at 100° , 25.95; water on ignition, 8.50; corresponding with the formula $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 + 9\text{H}_2\text{O}$. This substance forms a very fine, light, probably crystalline powder, readily soluble in acids, sparingly soluble in water, and having an alkaline reaction. When dissolved in a definite quantity of normal acid and titrated back with standard soda and methyl-orange, numbers for both the alumina and the soda present in the compound are obtained; with phenolphthalein as indicator, however, the numbers are below those required for the soda present, owing presumably to the regeneration of the original compound, or the formation of some similar one. The author then shows that the highest possible error attributable to silica is insignificant, and the only defect he recognises in this method of titrating alumina is the indistinctness of the end reaction, which may be overcome to

a certain extent by practice or by adding methyl-violet or some such blue colour changed by acids.

It is pointed out that almost all the silica of the raw material in the preparation of sodium aluminate remains behind on lixiviation in the form of $\text{Na}_2\text{O}, \text{Al}_2\text{O}_3, 3\text{SiO}_2 + 9\text{H}_2\text{O}$, and entails for each per cent. of silica a loss per cent. of 0.57 alumina and 0.34 sodium oxide (compare Abstr., 1889, 213). D. A. L.

Influence of Extractive Matter on the Real Alcoholic Strength of Spirits. By C. BLAREZ (*Compt. rend.*, 112, 585—588).—The presence of extractive matter (sugar, glycerol, &c.) in an alcoholic liquid reduces the apparent alcoholic strength by increasing the sp. gr. The results of a large number of analyses of brandy, rum, and tafia have shown that the real alcoholic strength can be calculated from the apparent alcoholic strength by adding to the latter the product of a coefficient into the number of grams of extractive matter per litre. The coefficient = $0.58 - 0.0108 d + 0.0000064 d^2$, where d is the real alcoholic strength. The apparent alcoholic strength and the quantity of extractive matter must be carefully determined. A first approximation is made by proceeding in the manner indicated, substituting the apparent alcoholic strength for the real in the expression for the coefficient. The result is then used in a second approximation, which is generally sufficiently accurate; with 0.4 to 0.5 per cent. of extractive matter only, the first approximation may be taken. C. H. B.

Estimation of Crude Fibre and Starch. By M. HÖNIG (*Chem. Zeit.*, 14, 868, 902—903).—When starch is heated steadily at 210° with glycerol, water vapour is at first evolved with frothing, but a clear, transparent, mobile liquid gradually forms, from which, when cool, a mixture of alcohol and ether precipitates the starch quantitatively. Under similar circumstances, cellulose remains unaltered, but glucose caramelises, is partially converted into humous matters, and yields a solution which is not precipitated by the ether and alcohol mixture; whilst albumin, when heated with glycerol, at first coagulates, but subsequently, with the aid of agitation, gradually forms a solution which is neither coagulated when boiled with water nor precipitated by the mixture of alcohol and ether; this solution, however, gives a precipitate with hydrochloric acid, dissolving in excess of the acid, and the usual precipitates with phosphotungstic and phosphomolybdic acids. It hence appears that albumin, like starch, can be made to assume simpler molecular aggregations without undergoing complete chemical change.

The above variations in the behaviour of the substances enumerated, when heated with glycerol, are applied to the estimation of starch and crude fibre in vegetable matter in the following manner:—The finely-pulverised material, along with glycerol, is placed in a test-tube supported in a flask of concentrated sulphuric acid, and gradually heated to 210° ; the decomposition is complete in about $\frac{1}{2}$ to $\frac{3}{4}$ of an hour, the tube is then cooled to 130° , the contents poured into 95 per cent. alcohol, the tube rinsed out with water, and ether added.

The precipitate is washed with a mixture of alcohol and ether (5 : 1), drained, and boiled with water; the starch dissolves, and when all the alcohol has been driven off, is inverted and estimated with Fehling's solution: the cellulose, which is always free from nitrogen, is then washed, dried, weighed, ignited, and the weight of the ash deducted. Filtration is facilitated, without any danger of seriously attacking the cellulose, by heating the mixture of starch and cellulose for half an hour with dilute hydrochloric acid.

D. A. L.

Analysis of Celluloïds. By H. ZAUNSCHIRM (*Chem Zeit*, 14, 905).—The finely-divided celluloïd is well stirred, by means of a platinum wire, with sulphuric acid in the funnel of a nitrometer, and, when dissolved, the nitrogen is estimated in the solution in the usual manner. To prevent interference from camphor, the following treatment is suggested:—Dissolve a weighed quantity of the celluloïd in a mixture of ether and alcohol or in methyl alcohol, mix with a weighed quantity of washed and ignited asbestos or pumice-stone, dry, disintegrate the mass, and extract the camphor with chloroform, dry, and weigh; then extract with absolute methyl alcohol, evaporate, weigh, and examine the nitrocellulose in the nitrometer.

D. A. L.

Gum Arabic and Gum Senegal. By L. LIEBERMANN (*Chem. Zeit.*, 14, 665—666).—The employment of gum senegal as an adulterant of, or even as a substitute for, gum arabic led the author to investigate the properties of these two gums.

Gum arabic forms rounded or angular, colourless, yellowish, or brownish, and strongly-refractive little lumps; whilst gum senegal is usually in long, straight or curled cylindrical pieces, but occasionally in mulberry-shaped nodules, and is either colourless or faintly-yellow or white, like etched glass, superficially, and lustrous and transparent internally. The two gums are therefore readily detected in the uncrushed condition, but under other circumstances they require further investigation for their identification.

Water dissolves both gums, leaving a residue of wood fibres, these being usually red if from gum arabic and black from gum senegal. Potassium hydroxide and copper sulphate produce a blue precipitate in both solutions; the gum arabic precipitate is more considerable than the senegal precipitate. Moreover, the former is coherent, and rises to the surface; whereas the latter is more flocculent, and remains disseminated in the liquid. The precipitates are only very slightly soluble on warming, and are not reduced even on boiling. Under similar treatment, dextrin also gives a bluish precipitate insoluble in the cold, but soluble to a clear, dark-blue solution on warming, which solution is completely reduced by prolonged boiling. By heating with dilute potassium hydroxide for some time, solutions of gum arabic or dextrin become amber-yellow; solutions of gum senegal, on the other hand, scarcely alter or are but very faintly yellow.

Mixtures of the gums arabic and senegal behave, with potassium hydroxide alone, like gum arabic; with potassium hydroxide and copper sulphate, like gum senegal. The blue precipitates from mixtures of dextrin with gum arabic or gum senegal are reduced on

boiling; provided the quantity of dextrin is not too small; but when the latter is the case, after thorough warming, the precipitate must first be filtered off, then, on boiling the filtrate, reduction takes place if dextrin is present. When both gums as well as dextrin are present, the precipitate is washed, dissolved in dilute hydrochloric acid, and the gums precipitated by means of a large excess of alcohol; when settled, they are washed and examined by the above methods.

The examination of a sample of gum arabic may be conducted in the following manner:—Dissolve the powdered substance in lukewarm water, examine residue—any gelatinous matter indicating foreign gums; treat the solution with excess of potassium hydroxide and copper sulphate, warm, filter, and examine for dextrin and senegal as described above.

Gum senegal has been stated to be more hygroscopic than gum arabic; but on drying at 105°, the former lost 13·39 per cent., the latter 14·56 per cent., and, on exposure to the moist atmosphere, the former reabsorbed 6·15, the latter 6·34 per cent. of water.

D. A. L.

Formation, Detection, and Significance of Furfuraldehyde. By E. NICKEL (*Chem. Zeit.*, 14, 836).—The formation of furfuraldehyde being characteristic of certain classes of compounds, such as the carbohydrates and their derivatives (glucosides) and the proteids, the author gives a simple means of detecting it:—The substance is either submitted to dry distillation in a perfectly clean test-tube, or it is carefully heated with a small excess of concentrated sulphuric acid; in either case, the presence of furfuraldehyde in the vapour is ascertained by its reddening paper charged with an aniline or xylydine salt; or the furfuraldehyde may be identified in solution by the use of well-known reagents, such as α -naphthol, phloroglucinol, &c.

D. A. L.

Sensitive Reaction for Tartaric Acid. By E. MOHLER (*Bull. Soc. Chim.* [3], 4, 728—729).—Crystals of tartaric acid, when thrown on sulphuric acid of 66° B. containing 1 per cent. of resorcinol and heated gradually, produce a fine, red-violet coloration when the temperature approaches 125°; at 190°, complete carbonisation occurs. The colour is destroyed by the addition of water to the sulphuric acid solution. It has been found impossible to isolate the colouring matter formed, as it is insoluble in ether, amyl alcohol, acetone, chloroform, and benzene.

With other phenols, similar colour reactions are obtained; thus phloroglucinol gives a red, pyrogallol a fine violet, coloration.

These reactions are not given by succinic, malic, citric, or benzoic acids; hence tartaric acid may be readily detected in a mixture with any of these; 0·01 milligram of tartaric acid can be characterised by operating as follows:—

The solution supposed to contain tartaric acid is evaporated to dryness in a small porcelain capsule, 1 c.c. of the resorcinol solution added, and gradually heated to about 125°, reddish streaks first appear, and then the sulphuric acid becomes coloured throughout.

If sugars, gums, or other organic substances which char in contact with sulphuric acid are present, the tartaric acid is precipitated as lead tartrate, the precipitate treated with nitric acid to destroy traces of the organic matter, and the nitric acid driven off; the residue then gives the colour reaction as above.

It is necessary to avoid the presence of nitrates and nitrites, as they give an intense blue coloration with resorcinol, which masks the tartaric acid reaction.

W. T.

Estimation of Soluble and Insoluble Fatty Acids in Butter.

By W. JOHNSTONE (*Chem. Zeit.*, 14, 671).—The author claims priority as regards the method of estimating fatty acids in butter described by Bondzynski and Ruff (Abstr., 1890, 838).

D. A. I.

New Method of Testing the Purity of Butter. By G. FRIEDSCH (*Chem. Centr.*, 1891. 1, 283—284; from *Ding. Polytech. J.*, 278, 422—429).—The method depends on the solubility of the barium salts of the volatile fatty acids of butter-fat. From 0.99—1.01 gram of the clarified fat is heated in a strong flask of 150 c.c. capacity with 50 c.c. of $\frac{1}{16}$ N. barium hydroxide for 6—8 hours at 140° by means of a paraffin-bath. It is frequently advisable to allow the flask to cool at the end of 3 hours in order to bring the little fat, which adheres to the sides of the flask, into the reaction, which is assisted by the frothing up which takes place when the heating is resumed. When the saponification is complete, the contents are passed as rapidly as may be through a filter into a half-litre flask, and washed with boiling water until the flask is full. The separation of the soluble from the insoluble barium salts is perfect excepting in the case

	Per cent. of total combined barium.	
	Ba in insol. salts.	Ba in sol. salts.
Butters I	68.47	31.53
" II	66.48	33.52
" III	65.84	34.16
" IV	68.99	31.01

" 50 " " 50 "	74.02	25.98
" 80 " " 70 "	78.37	21.16
Cocoa-nut oil	66.98	33.02
Palm oil	73.24	26.76

of cocoa-nut oil, which contains lauric acid. The insoluble barium salts are decomposed with 25 c.c. $\frac{1}{3}$ N. hydrochloric acid and warmed on the water-bath, filtered, washed, and weighed.

In the solution of the soluble barium salts, the excess of barium is determined by means of $\frac{1}{10}$ N. hydrochloric acid, as also the total amount of barium as sulphate. From the three determinations, the amounts of the insoluble fatty acids, the soluble fatty acids calculated as butyric acid, and the respective amounts of barium combined with them are obtained. The author's results are given in the table on the preceding page.

By distilling the solution containing the acids from the soluble barium salts, figures were obtained which did not agree with those obtained by the Reichert-Meissl method. The weight of the acids of the insoluble barium salts agreed with those obtained by Hefner's method. J. W. L.

Analysis of Butter. By M. VIOLETTE (*Chem. Centr.*, 1891, 1, 286—287, from *Milch-Zeit.*, 19, 905—906).—After separating the volatile from the non-volatile fatty acids, the author calculates, by means of Duclaux's formula, the ratio of butyric to caproic acid, and the results, as in the table, show that the greater part of the volatile acids consist of butyric and caproic acids.

	Butter [best] (3 samples).	Butter [2nd quality] (5 samples).	Margarin.	Suet.
Butyric acid.....	5.33—6.07	4.62—5.05	0.47	0.273

J. W. L.

Iodine-number for Cocoa-butter. By F. FILSINGER (*Chem. Zeit.*, 14, 716).—The following are the mean iodine-numbers for cocoas of various origins calculated from the results of numerous determinations:—

Arriba, I.....	35.1
Arriba, II.....	36.8
Carracas, I.....	34.4
Carupano.....	35.2
Ceylon.....	35.9
Machala Guajaquil.....	33.4
Puerto Cabello.....	34.1
Surinam.....	34.0
St. Thomé.....	33.5
Trinidad.....	34.5

Kauka, Bahia, and Porto Plata cocoas have been shown to range between 34.0—37.5; hence it follows the iodine-number for pure cocoa-butter varies between 33.4 and 37.5.

D. A. L.

Fat Analysis. By R. BENEDIKT (*Chem. Zeit.*, 14, 835—836).—In course of a very extensive experience and in conjunction with numerous collaborateurs, the author has never obtained an acetyl number in the absence of hydroxy-fatty acids; he therefore unhesitatingly condemns Lewkowitsch's (*Proc.*, 1890, 72—91) results as erroneous, and asserts the correctness of his own.

In a few remarks on the method in question it is pointed out that the alcoholic potash, for the saponification in the estimation of the acetyl number, may be replaced by semi-normal soda in the following manner; the acetylated fatty acid is dissolved in alcohol, titrated with semi-normal soda and phenolphthalein, then $1\frac{1}{2}$ or twice as much of the same soda is run in, the whole heated on a water-bath and titrated back with hydrochloric acid. Numbers below the theoretical are obtained for the acetyl acid number of oils containing hydroxy-fatty acids; this has to be taken into consideration when making determinations, and methods of calculation for the purpose are given. The formation of internal anhydrides is suggested as the cause of this depression of the acid number.

As regards the estimation of glycerol, the author recognises the superiority of permanganate over the acetin method, but, nevertheless, regards the latter as of value especially for technical purposes. Attempts to estimate the glycerol by conversion into allyl and isopropyl iodides have not proved successful. D. A. L.

The Elaidin Reaction with Fatty Oils. By C. WELLMAN (*Landw. Versuchs-Stat.*, 38, 447—451).—In testing olive and earthenut oils by the elaidin reaction, it was found that the mass solidifies sooner at a lower than at a higher temperature, 13—15 min. at 14°, 2 hours 17 min.—1 hour 7 min. at 18—19°; also if the surface of separation of the strata of oil and mercury and acid be not disturbed at the commencement of the testing, then a longer time is required for solidification. E. W. P.

Resin Oil in Oil of Turpentine. By E. BAUDIN (*J. Pharm.* [5], 23, 279—280).—A drop of the suspected oil is placed on a thin slip of unsized paper, and allowed to evaporate spontaneously. After one or two hours, the liquid has disappeared without leaving a sensible stain if pure, but if adulterated with resin oil, a distinct oily stain is left. With 5 per cent. of impurity, no mistake is possible. In doubtful cases, 20 to 30 drops is evaporated to 6 or 8 drops in a porcelain capsule, and this concentrated solution is tested as above. By comparison with known mixtures, an approximate estimation of the amount of impurity present may be made. J. T.

Estimation of Tannin in Hops. By E. KOKOSINSKI (*Chem. Centr.*, 1891, i, 377; *Zeit. ges. Brauwesen, München*, 13, 571—574).—The method depends on the property of tannin of absorbing iodine in presence of alkaline carbonates.

The solution is prepared by boiling 10 grams of hops, the solution being diluted to 500 c.c. If the hops have been sulphured, a few

drops of hydrogen peroxide is added to the water before commencing to boil. The extract is filtered from the hops. The solutions required are: (1) normal solution of sodium carbonate; (2) normal sulphuric acid; (3) $\frac{1}{10}$ N. iodine; (4) $\frac{1}{10}$ N. solution of sodium thio-sulphate 9.920 gram in 1 litre; (5) a solution of pure tannin prepared from galls which contains 0.05 gram tannin in 100 c.c.; (6) a freshly prepared solution of starch.

Three flasks of about 100 c.c. capacity, are employed; into the first is put 10 c.c. of water, into the second 10 c.c. of the tannin solution, into the third 10 c.c. of the hop extract. To each flask 4 c.c. of the normal sodium carbonate solution is added, and immediately afterwards 20 c.c. of the standard iodine solution. Flasks 2 and 3 are then tested for free iodine by placing a drop of the solution on to a piece of starch paper, and if free iodine is not present, more of the standard iodine must be added to each flask. The iodine is allowed to react for five minutes, then to each flask 4 c.c. of the normal sulphuric acid is added to neutralise the sodium carbonate, and 10 c.c. of the sodium thiosulphate solution is added to reduce the excess of iodine present. A few drops of starch paste are now added to each flask, and the excess of thiosulphate determined with the iodine solution. The number of c.c. of iodine required to titrate the thio-sulphate in flask 1 represents the amount of iodine which has entered into combination with the sodium carbonate, the starch, and other errors which may be inherent to the titration; the amount of iodine used by flask 2 represents that absorbed by the solution of tannin = 0.005 gram plus the amount absorbed in the blank experiment; the iodine used by flask 3 represents that which was absorbed by the tannin of the hops *plus* the amount absorbed in the blank experiment. From these figures, the amount of tannin in the hops may be readily calculated.

J. W. L.

Detection of Coniine in a Case of Poisoning. By L. W. ANDREWS (*Amer. Chem. J.*, 13, 123—128).—A stomach and a jar of soup were submitted to the author for analysis for "strychnine and other poisons." The stomach was immersed in a preservative sold as "bromo-chloralum" (a solution of magnesium and aluminium chlorides with a little bromide), and with this the contents had become mixed, but this did not interfere with the examination. The interior of the stomach was coated with a coffee-coloured scum, and exhibited near the pyloric end some large inflamed patches and numerous small pin-head dots of intense inflammation.

162 grams of the stomach (and contents) were cut up finely, digested for some time with 96 per cent. alcohol and 10 drops of sulphuric acid, filtered, and washed with alcohol. The filtrate and washings were evaporated to one-third at 50°. Light petroleum, benzene, and chloroform, applied successively, failed to extract any alkaloidal substance from this liquid; it was then made alkaline with sodium hydroxide and filtered, the precipitate being washed with a little alcohol. A portion of this solution and washing (B) was shaken with light petroleum; on subsequent evaporation with a drop of strong hydrochloric acid, the latter turned red and then violet-

blue (a reaction of impure coniine), and a crystalline hydrochloride was left. The following reactions were obtained with this residue:— With phosphomolybdic acid, pale-yellow, amorphous precipitate; with potassio-mercuric iodide, the same; with mercuric iodide, white, amorphous precipitate; with gold chloride, pale-yellow, micro-crystalline precipitate; with strong sulphuric acid and potassium dichromate, no colour except from gradual reduction of chromic acid; with picric acid, no change; with platinum tetrachloride, no change; with potassium dichromate, no precipitate; with iodine in potassium iodide solution, brown precipitate, which disappeared and was reproduced on further addition of the reagent.

The rest of the solution B was shaken, a part of it with chloroform and part with ether. The hydrochloride from the former solvent was hypodermically administered to a cat; great dilation of the pupils, a blue nose, violent trembling, laboured and irregular respiration, and partial paralysis of the hind-legs were the symptoms that ensued; after a nearly complete torpor had set in, recovery followed in four hours. From the ether solution, microscopic, oily globules smelling of coniine were obtained.

By working up a further portion of the stomach especially for the purpose, sufficient of the hydrochloride was obtained for a quantitative determination of the hydrochloric acid, which was found to agree with that calculated for the known formula of coniine hydrochloride.

The usual plea that the alkaloïd detected was an unnamed ptomaine was set up by the defence.

A. G. B.

Addition of Phenolphthaleïn to Margarin. By E. HOLM (*Bied. Centr.*, 1891, 138—139).—Small quantities of phenolphthaleïn added to milk, which was afterwards churned, were readily detected, and appeared to be evenly distributed throughout the mass of butter produced, and could be recognised even after the butter had been kept for three months. Phenolphthaleïn introduced into margarin was also easy of detection, although the colour reaction was somewhat feebler than with butter. The quantity capable of detection in this case was one of phenolphthaleïn in 50,000 parts of margarin.

E. W. P.

A New Test for Proteïds. By J. A. MACWILLIAM (*Brit. Med. J.*, 1, 1891, 837—840).—Salicylsulphonic acid is recommended as a powerful precipitant for proteïds. It precipitates all varieties of these substances; and solutions containing only 1 part of proteïd in 100,000 of water still show an opalescence when treated with a few drops of the reagent. The precipitate produced with albumins and globulins is not soluble on heating; that produced with albumoses and peptones is dissolved, reappearing when the liquid cools. The test is further recommended as a means of detecting minute quantities of proteïd in urine. No normal or other abnormal constituent of the urine is precipitated by the reagent.

General and Physical Chemistry.

Boiling Point Determination with Small Amounts of Material. By A. SCHLEIERMACHER (*Ber.*, 24, 944—949).—The boiling point of a substance, the amount of which is so small that the ordinary method of distillation cannot be applied, can be determined by measuring the temperature at which the pressure of the saturated vapour of the substance in question is equal to that of the atmosphere. The method described in this paper is based on the above principle.

A glass tube is taken, about 50 cm. long and 6—8 mm. in diameter, and is drawn out at one end to a thickness of 1—2 mm. in diameter. This end is then again drawn out to a fine capillary of about 50 mm. in length, and cut off so as to leave a small portion of the wider tube at the end of the capillary. The tube is then bent into U-form, the open limb being left about twice as long as the closed limb. For this purpose the tube is heated until it contracts to about half its original diameter, and is then bent so that the two limbs are parallel, and nearly touching each other. The substance experimented with is introduced into the open limb, and by inclining the tube, transferred to the closed limb, mercury being then added in like manner. The substance, which is now in the closed end of the tube, is gently warmed, until it commences to boil, the vapour driving any air which may remain in the tube out at the capillary.

The capillary is then sealed. At the end of this operation, the tube should contain nothing but the substance experimented with and mercury. Any mercury remaining in the open end of the tube is now removed, and the tube is placed in a bath for the purpose of heating, the whole arrangement being that shown in the drawing. The thermometer is placed in the open tube, and its temperature will indicate that of the heated substance.

On heating, the substance will, after a time, commence to volatilise, and the mercury will rise in the open tube. When the mercury, in both tubes, stands at the same level, the vapour pressure of the substance is equal to that of the atmosphere, and the temperature, therefore, will be that of the boiling point of the substance under the barometric pressure at the time of the experiment. This may be corrected in the ordinary manner, and the normal boiling point thus obtained; or by roughly graduating the tube the apparatus itself may be employed for obtaining directly the boiling point under normal atmospheric pressure. Thus, if the barometric pressure were 750 mm., the mercury would be allowed to rise in the open tube until its level was 10 mm. higher than that in the closed tube. The thermometer would now indicate the normal boiling point. Another advantage of this apparatus is that the correction for that portion of the thermometer which ordinarily escapes heating becomes unnecessary. For the apparatus can obviously be taken of such a size that both bulb and thread of the thermometer shall be below the level of the liquid in the bath, and, therefore, both be uniformly heated.

In carrying out an experiment it is advisable to take several readings, both when the tube is being heated and when it cools. The mean of these determinations gives the boiling point with great accuracy. This is illustrated by experiments performed with substances of known boiling point. The vapour pressure of the mercury itself does not appear to influence the results, even at as high a temperature as 300° . The minimum quantity of substance that can be taken for a determination is given by the condition that the vapour must be saturated, so that a trace of liquid must always remain in the vessel on vaporisation. If v is the volume occupied by the vapour, d its density, and l the specific gravity of air at the boiling temperature (about 0.0012), the minimum quantity of substance necessary is given by vd/l . H. C.

Note.—The author appears to have completely overlooked the fact that H. Chapman Jones (*Trans.*, 1878, 175) has described in full detail an apparatus practically identical with the above.

Theory of Dissociation. By J. TRAUBE (*Ber.*, 24, 1321—1327; compare this vol., pp. 390 and 638).—The author compares the determinations of the freezing point of aqueous sugar solutions made by Raoult and Arrhenius, those of the former being preferred on account of the more numerous precautions observed. An account is also given of the manner in which the author's own determinations were conducted; the results obtained agree closely with those of Raoult, and confirm the statement that "the osmotic coefficient of all organic

substances, in sufficiently dilute solutions, is identical, or almost so, with that of many salts ; " the only difference is one of degree, or, in other words, the dissociation of the molecular aggregates of organic compounds in solution usually commences at concentrations where that of salts is completed. Pickering and Raoult, in private communications to the author, express similar views.

Upholders of the theory of electrolytic dissociation have, therefore, to consider whether it can be extended so as to include solutions of all organic substances, and, if so, into what ions these are resolved.

J. B. T.

Precipitation. By G. WATSON (*Chem. News*, 63, 109—111).—In a previous communication (Abstr., 1890, 847), the author expressed an opinion that the transition of certain precipitates from the amorphous to the crystalline form was due to the combined influence of the surface energy of abraded glass and condensation of the precipitated material. A series of new experiments with antimony chloride, sodium antimonate, calcium hydrogen orthophosphate, and calcium carbonate, have led to the conclusion that the change in question is due to the lower solubility of the crystalline form as compared with the amorphous form, and, in fact, the latter can be avoided by using sufficiently dilute solutions. As it is, the amorphous form is first precipitated, then dissolves in the circumambient solution, until the latter is supersaturated; crystallisation then sets in, liberating mother liquor, ready to dissolve more of the amorphous precipitate: the solution, supersaturation or saturation, and crystallisation continue until all the amorphous salt is converted into crystals.

Similar cycles of phenomena have been pointed out by C. Winkler (Abstr., 1885, 871) in the case of arsenious oxide, and by H. Le Chatelier (Abstr., 1883, 712; 1885, 304; 1888, 1030) in connection with gypsum, sodium sulphate, and calcium silicates and aluminates.

The author has attempted, unsuccessfully, to obtain arragonite crystals from amorphous calcium carbonate at ordinary temperatures (below 30°) by introducing these crystals into the liquid.

A practical bearing, in the case of the antimony salt, is pointed out, inasmuch as fresh antimony does not pass into solution until that already in solution has been removed; it is suggested that cotton impregnated with tannin would serve to remove the antimony from solution, and so set the cycle of changes at work; the amorphous antimoniacal precipitate in this way would serve, in dyeing operations, as a substitute for the more expensive tartar emetic.

D. A. L.

Automatic Sprengel Pump. By H. L. WELLS (*Ber.*, 24, 1037—1041).—In the Sprengel pump described in this paper, the mercury is raised automatically by means of water pressure. Water enters at A (Fig. 1) into the small bottle, from which it flows out again through the tube B. M contains mercury, which can flow into the bottle through the tube ending in the valve V. This valve allows the passage of liquid from the inside, but is closed by outside pressure. Its construction is shown in Fig. 2. The glass tube is filed down until a small opening, *b*, has been made, and over this a small

piece of indiarubber tubing is placed, with an incision, *a*, on the opposite side to the opening *b*. When mercury flows into the bottle, it is forced by the water pressure into the tube B. In this it will rise until the level is very nearly that of the mercury in M, when its pressure will close the valve. The water pressure will then force the mercury up the tube B, and out at the top, when, the pressure being released, the valve will again open, and the above operations will be repeated.

FIG. 1.

FIG. 2.

FIG. 3.

In Fig. 3, this method of raising mercury is shown, attached to the Sprengel pump. Water enters at E, carries the mercury up the tube H, and flows out at F, whilst the mercury passes through the side tube into the reservoir C of the Sprengel pump. The downward bend in the tube H lengthens the column of mercury which is periodically carried up this tube. The distance from B to A determines the total length of the mercury column, but this distance will itself depend on the water pressure at command. Usually a distance of 500–600 mm. will be found sufficient, and the tube K of the

Sprengel pump being about 1500 mm. long, the whole apparatus will have a height of about 2 metres.

Inorganic Chemistry.

Silent Discharge and Chlorine. By H. M. VERNON (*Chem. News*, 63, 67).—When subjected to the influence of the silent electrical discharge, chlorine, either alone or saturated with bromine, showed no tendency to condensation. The author regards this insensibility as a function of univalency, and states reasons for supposing that of all the elements probably oxygen is the only one capable of undergoing such condensation.

D. A. L.

Magnus' "Black Sulphur." By F. KNAPP (*J. pr. Chem.* [2], 43, 305—320; compare *Abstr.*, 1887, 110; 1888, 1163).—Magnus' "black sulphur" is best obtained by suddenly heating a mixture of sulphur and oil, certain precautions being taken in order to obtain the maximum yield. The author dissolves almond oil (5—10 drops = 0.2—0.4 gram) in ether, mixes the solution with flowers of sulphur (50 grams) in a mortar, and evaporates the ether. A portion of the mixture thus prepared is dropped from the point of a knife on to the bottom of a red-hot platinum crucible; almost immediately the bulk of the mixture disappears, and a loose, black residue is left; the crucible is at once cooled on an iron plate, and the residue emptied into another vessel. The crucible is again heated to redness, and another portion introduced, the process being thus repeated until the whole mixture has been heated; it is best to keep one hand on the gas-cock to alternately raise and lower the flame, as the decomposition takes place more rapidly on the sides than on the bottom of the crucible. Neglect of the points here mentioned greatly diminishes the yield, which in any case is very variable and small; as a mean of 23 experiments, the author obtained 0.685 gram of "black sulphur" from 100 grams of sulphur and 10 drops of oil. 10 drops of oil similarly treated by itself gave only 0.011 gram of residue, or 1.60 per cent. of the "black sulphur."

"Black sulphur" generally contains a little yellow sulphur and, unless pure materials have been used, a considerable quantity of ash, amounting in one case to 9.7 per cent.; it is very slightly hygroscopic. The difficulty of regulating the temperature of the platinum crucible makes it difficult to obtain a homogeneous product, so that

its density varies between 2.622 and 1.843, even when prepared from ash-free substances and previously heated to expel yellow sulphur. It is insoluble in hot and cold water, alcohol, ether, hydrochloric acid, nitric acid, aqua regia, ammonia, caustic alkalis even when concentrated, and potassium cyanide. When evaporated with an alkaline hydroxide solution, it is attacked just as the hydroxide is becoming solid, and dissolves to a humus-brown mass, soluble in water with a deep-brown colour; acids precipitate a brown substance from the solution. When heated in air, it first loses moisture and yellow sulphur, but undergoes no other change until a temperature of 200—300° is reached, when sulphurous anhydride is formed; at a red heat the residue takes fire. When heated in the absence of air, no sulphurous anhydride is evolved, but the "black sulphur" slowly loses weight, and does not cease to do so until it has been exposed for many hours to a red heat; the empty space in the tube remains clear and colourless throughout the heating, no empyreumatic vapours or brown vapour of sulphur being evolved; the residue obtained when the weight is constant burns entirely away in the air, and is not influenced in quantity if the heating is conducted in carbonic anhydride; the mean of all experiments gave 43.59 per cent. as the amount of this residue. If the delivery tube of the vessel in which the "black sulphur" is heated dips under potash, much potassium sulphide is formed, although no ordinary brown vapour of sulphur is seen.

The sulphur was estimated in the "black sulphur," previously gently heated to expel moisture and yellow sulphur, by evaporating a portion with potassium hydroxide and potassium nitrate solutions, and heating the residue until it was white; three determinations gave 53.77, 56.76, and 57.07 per cent. of sulphur respectively. The residue left at a red heat contained 22.78 per cent. of sulphur as a mean of three determinations. Thus 44—46 per cent. of the total sulphur is expelled at a red heat, whilst the residue contains some 10 per cent. of sulphur and 33—34 per cent. of carbonaceous matter. Potassium dichromate and bromine dissolve only some 13—14 per cent. of the total sulphur.

Magnus' "black sulphur" is evidently not in itself a modification of sulphur, but consists of such adhering to, or condensed with, a carbonisation product of the oil, itself containing sulphur. This carbonisation product is essential to the production of the modification as affording a surface for condensation or adhesion. The new form of sulphur does not vaporise below a temperature far above the boiling point of yellow sulphur; its vapour is colourless instead of brown; it gives off sulphurous anhydride below a visible heat without combustion.

If it be granted that "black sulphur" contains a modification of sulphur, many other phenomena are brought to mind as probably due to such, especially as the chief manifestation of the modification in question is the production of a blue colour. When "black sulphur" is rubbed with levigated kaolin, a light-blue colour is developed; when it is evaporated with potassium hydroxide and potassium nitrate solutions, a blue ring is formed in the dish; the

same is the case when the solution of the sulphur vapour in potassium hydroxide (see above) is evaporated.

The new modification of sulphur is evidently unstable in the free state, but can readily exist in contact with any surface which affords a substratum for its development. As examples, the author quotes the blue colour developed by sulphur on platinum, silver, and lead sulphide; the blue colour of ultramarine, which is so readily destroyed by acids because the substratum of silicates is disturbed, and the sulphur changed into the yellow modification; the momentary blue colour produced when hydrogen sulphide is added to ferric chloride, only wanting permanency, because there is no surface for adhesion; the solution of sulphur in sulphuric anhydride, and other phenomena. The blue-coloured modification of sulphur *en masse* would appear to be a dull black, in which form it may exist in Spence metal, made by fusing sulphur with ferrous sulphide, and may play a part in the vulcanising of rubber. In conclusion, the author expresses the opinion that Schützenberger's compound $\text{Pt}_2\text{S}_2\text{C}$, obtained by the action of carbon bisulphide vapour on platinum sponge at a dark-red heat (this vol., p. 19), is nothing more than a manifestation of this sulphur.

A. G. B.

Thiosulphates. By A. FOCK and K. KLÜNS (*Ber.*, **24**, 1351—1355). —*Potassium Mercuric Thiosulphates.*—The salt $5\text{K}_2\text{S}_2\text{O}_3 \cdot 3\text{HgS}_2\text{O}_3$, which has already been prepared by Rammelsberg (*Ann. Phys. Chem.*, **56**, 315) and by Herschel (*Gmelin-Kraut*, Bd. 3, 852), is obtained when freshly precipitated mercuric oxide is dissolved in a solution of potassium thiosulphate and the alkaline liquid evaporated on the water-bath; it separates from an aqueous solution in colourless crystals belonging to the monosymmetric system; $a : b : c = 0.332 : 1 : 0.318$, $\beta = 88^\circ 9'$; these do not blacken on exposure to light. The compound $3\text{K}_2\text{S}_2\text{O}_3 \cdot \text{HgS}_2\text{O}_3 + 3\text{H}_2\text{O}$ is prepared by adding an excess of potassium thiosulphate to a solution of the last-mentioned salt, and evaporating over concentrated sulphuric acid; it forms small, colourless crystals also belonging to the monosymmetric system; $a : b : c = 1.4843 : 1 : 0.9463$, $\beta = 78^\circ 55'$; these are stable in the air and towards light, but become opaque on treatment with water. When potassium thiosulphate is added in very large excess, and the solution evaporated at about 35° , small, prismatic crystals, having the composition $5\text{K}_2\text{S}_2\text{O}_3 \cdot \text{HgS}_2\text{O}_3 + \text{H}_2\text{O}$, separate; they belong to the asymmetric system; $a : b : c = 0.7034 : 1 : 0.6761$; $A = 88^\circ 42'$, $B = 93^\circ 39'$, $C = 88^\circ 32'$; $\alpha = 88^\circ 36'$, $\beta = 93^\circ 41'$, $\gamma = 88^\circ 27'$; they were not sufficiently perfect for a complete optical investigation.

The salt $\text{K}_2\text{S}_2\text{O}_3 \cdot \text{Hg}(\text{CN})_2 + \text{H}_2\text{O}$, which, according to Kessler (*Ann. Phys. Chem.*, **74**, 274), exists also in an anhydrous modification, is prepared by dissolving equal weights of potassium thiosulphate and mercuric cyanide in water, and adding alcohol, or evaporating the solution over concentrated sulphuric acid, when it separates in large, colourless prisms which become yellowish to brown in the air, and develop the odour of hydrogen cyanide; they belong to the quadratic system; $a : c = 1 : 0.54635$, but were too opaque for complete optical investigation.

A. R. L.

The Soluble Phosphoric Acid Compounds of Superphosphates. By J. STOKLASA (*Landw. Versuchs-Stat.*, 38, 401—410; compare *ibid.*, 197—225, and Abstr., 1890, 695).—*Action of Dicalcium on Monocalcium Phosphate.*—Dicalcium phosphate, $\text{Ca}_2\text{HPO}_4 + 2\text{H}_2\text{O}$, is prepared from the decomposed monocalcium salt by precipitating the solution of sodium phosphate and acetic acid with calcium chloride. The washed precipitate is slowly dried over sulphuric acid. It forms microscopic, rhombic plates. When dicalcium phosphate (5.49 grams) and orthophosphoric acid (3.86 grams) in 2 litres of water are kept for 48 hours, the free acid disappears and the monocalcium salt is formed. A solution of pure monocalcium phosphate (1 : 200) dissolves 0.025 to 0.03 gram of dicalcium phosphate; if the monocalcium salt contains free acid, this reacts with the dicalcium salt with formation of monocalcium phosphate until the solution is saturated. In presence of much monoferric phosphate, free phosphoric acid acts on dicalcium phosphate, monocalcium phosphate being produced. The so-called soluble phosphoric acid contained in solutions of superphosphates is derived from the soluble dicalcium salt as well as from the monocalcium salt. Dicalcium phosphate is a chief product of the decomposition of monocalcium phosphate in superphosphates and in the soil. Monocalcium phosphate is not decomposed by dicalcium phosphate.

Action of Tricalcium Phosphate.—Tricalcium phosphate, $\text{Ca}_3(\text{PO}_4)_2 + 2\text{H}_2\text{O}$, decomposes monocalcium phosphate with formation of dicalcium phosphate. The action is very slow; after 240 days, 0.59 gram of phosphoric acid as monocalcium salt was found. The action is quicker when the finely-powdered and well-mixed salts are heated at 100° ; after six hours, 54.3 per cent. of soluble phosphoric acid was found.

Free phosphoric acid and tricalcium phosphate (eq. mol. wt.) have no action on monocalcium phosphate; dicalcium phosphate is formed. If an excess of tricalcium phosphate is present, this will react with the monocalcium salt as described above. The amount of free acid present is of great importance.

When superphosphate contains 15.4 per cent. of soluble phosphoric acid, of which 8.2 per cent. is free acid, there may be 4 per cent. of phosphoric anhydride as $\text{Ca}_3(\text{PO}_4)_2$; the amount of monocalcium salt will increase until at last all the phosphoric acid of the tricalcium phosphate has become soluble.

When dilute sulphuric acid, or only a slight excess of sulphuric acid, is used, free phosphoric acid is formed; when stronger acid, or when an excess of acid, is used, a small amount of phosphoric acid is produced, and reactions can take place with formation of dicalcium phosphate. Calcium sulphate plays an important part in these processes; it frequently causes the monocalcium phosphate to become coated with the tricalcium salt and hinders the action of free phosphoric acid. These processes are influenced by the degree of concentration of the sulphuric acid, by the amount of acid used, by the degree of fineness of the material (when coarsely-ground, more tricalcium phosphate is formed), by the amount of chalk, calcium fluor-

ide or chloride present, by the length of time the heaps are left, and by the degree of temperature. N. H. M.

Beryllium. By G. KRÜSS and H. MORAHT (*Annalen*, 262, 38—61).—This paper gives a detailed description of the methods employed in the preparation of pure beryllium sulphate (compare Abstr., 1890, 697), and in the determination of the atomic weight of beryllium by the conversion of the sulphate into the oxide. The value which the authors consider to be the most correct is $\text{Be} = 9.027$, $\text{O} = 15.96$ (compare Abstr., 1890, 1375). F. S. K.

Behaviour of Preparations of Zinc Sulphide. By J. CAWLEY (*Chem. News*, 63, 88—89).—Zinc sulphate or chloride, previously freed from iron, manganese, lead, tin, &c., is precipitated by an alkaline or alkaline earthy sulphide, the precipitate is dried, ignited at a red heat, thrown while hot into water, levigated, washed, dried, and finely pulverised. The pigment prepared in this manner is excellent for whiteness, body, and covering power, and is comparatively innocuous; it is, moreover, not discoloured by hydrogen sulphide; it has, however, the disadvantage of blackening in sunlight, but recovers its original whiteness in a more permanent condition when placed in the dark. The darkening does not take place in the perfectly dry pigment hermetically sealed in a glass tube, nor when pure material is exposed to sunlight; if, however, the pure material is calcined even slightly, it becomes sensitive. The darkening is accelerated by moisture, and augmented by damping the zinc-white with zinc sulphate solution. Attempts were made to remove any sulphate from the zinc-white by treatment with potassium, sodium, barium, calcium, or magnesium hydroxide; about 0.5 per cent. of freshly precipitated magnesium hydroxide proved the most effective, but increased the tendency of the zinc-white to frit when ignited, and consequently impaired its value as a pigment, this difficulty being overcome by the use of salt. The author ultimately succeeded in preparing a pigment which as a rule does not darken, in the following manner:—Boiling hot, concentrated solutions of the zinc salt and barium sulphide are used; the precipitate is mixed with 0.5 per cent. of fresh magnesium hydroxide and with pulverised sodium chloride, filtered, dried, coarsely crushed, and mixed with 3 per cent. of ammonium chloride before ignition. The reason for the immunity of this preparation is open to investigation, which the author invites; it was at first suggested that the blackening was due to liberation of metallic zinc in accordance with the reactions $\text{ZnS} + 2\text{ZnO} = 3\text{Zn} + \text{SO}_2$ and $\text{ZnS} + \text{ZnSO}_4 = \text{Zn}_2 + 2\text{SO}_2$; but this explanation is, in the face of the more recently observed facts, untenable. D. A. L.

Atomic Weight of Lanthanum. By B. BRAUNER (*Ber.*, 24, 1328—1331).—Lanthanum is probably a trivalent metal with an atomic weight of 138.21 ($\text{O} = 16$); this number was found by the author, and is identical with the results of Cleve and of Bettendorff. Winkler (this vol., p. 802) describes the metal as quadrivalent with the

atomic weight 160; the lower equivalent of 45 was obtained by Rammelsberg, Zschiesche, and Erk, but their material was almost certainly contaminated with yttrium compounds, which would fully account for the difference. With an atomic weight of 180, the atomic heat of lanthanum is 8.07, which makes it unique in its variation from the law of Dulong and Petit. From its position between cerium and thorium, and ytterbium and tantalum, the molecular volume of the oxide should not exceed 26; with the higher atomic weight, the molecular volume is 33; with the lower, 25.0. Lanthanum is the most positive metal of the rare earths; an element occurring between those above mentioned, and forming an oxide RO_2 , should only exhibit feebly basic properties.

The hydrogen compound of lanthanum described by Winkler (*loc. cit.*) is probably a mixture of 3 mols. LaH_3 and 1 atom of lanthanum, or it may be a compound, La_3H_3 , the composition of which agrees almost exactly with Winkler's analysis. In this case the type of the hydrogen compounds of lanthanum and cerium is a periodic function of the atomic weight.

J. B. T.

Atomic Weight of Chromium. By C. MEINKE (*Annalen*, 261, 339—371).—The author has made a careful determination of the atomic weight of chromium by estimating (1) the quantity of silver and of chromium in silver chromate and in silver chromate ammonia, $\text{Ag}_2\text{CrO}_4 \cdot 4\text{NH}_3$; (2) the quantity of oxygen in these two compounds; (3) the quantity of oxygen in potassium dichromate; and (4) the quantity of oxygen and of chromium in ammonium dichromate.

The silver chromate ammonia was prepared by treating an aqueous solution of pure silver nitrate with a solution of pure potassium chromate, and crystallising the precipitate twice from hot ammonia; the silver chromate was obtained by evaporating an aqueous solution of the ammonia compound.

The potassium dichromate was prepared from pure potash and pure chromic acid; it was free from sulphuric acid, alkaline earths, and metals of the iron group. The ammonium dichromate was obtained by repeatedly recrystallising the purest commercial salt; it contained 0.2 per cent. of potash.

In estimating the silver and the chromium in the silver salts, a weighed quantity was placed in a porcelain crucible, covered with dilute alcohol, and digested with hydrochloric acid, first at the ordinary temperature, and then at $60-70^\circ$. The precipitated silver chloride was washed by decantation until free from chromium, dried, and weighed in the original crucible. The filtrate and washings from the silver chloride contain, besides chromium chloride, a considerable quantity of silver chloride, which is kept in solution by the chromium chloride; the silver was precipitated from this solution with hydrogen sulphide and weighed as sulphate.

The oxygen determinations were made by a modification of the method described by Zulkowski (*J. pr. Chem.*, 103, 351) as follows:—The salt (about 0.5 gram) was dissolved in dilute ammonia, the silver precipitated with potassium iodide, the solution warmed and filtered,

and the precipitate washed with water; the filtrate and washings were mixed with solid potassium iodide (5 to 6 grams), then with a solution of pure phosphoric acid (containing about $2\frac{1}{2}$ grams of phosphoric anhydride) and dilute (1 : 1) sulphuric acid (1 c.c.), and titrated with sodium thiosulphate. A special form of burette for use in very accurate analysis is described; the titration was carried out in phosphoric acid instead of in sulphuric acid solution, as the end reaction is then more sharply defined. Instead of using iodine for standardising the thiosulphate solution, the author found it advantageous to employ potassium diiodate in the iodometric analyses of the dichromates, as it is more convenient to weigh, and its solutions are less liable to undergo change. This salt was prepared by evaporating a solution of commercial potassium iodate with a slight excess of iodic anhydride, the product being purified by recrystallisation; it is soluble in 18.63 parts of water at 17° , and its sp. gr. is 3.955. On adding potassium iodide to a neutral solution of the diiodate, the following reaction takes place:— $6\text{KHI}_2\text{O}_6 + 5\text{KI} = 11\text{KIO}_3 + 6\text{I} + 3\text{H}_2\text{O}$, 1 atom of iodine being liberated from 1 mol. of the diiodate. In presence of an acid, the reaction is expressed by the equation $\text{KHI}_2\text{O}_6 + 10\text{KI} + 11\text{HCl} = 11\text{KCl} + 6\text{H}_2\text{O} + 12\text{I}$. Taking the atomic weights of oxygen, chlorine, and silver as 15.96, 35.37, and 107.66 respectively, the atomic weight of chromium, calculated from the proportion $4\text{AgCl} : \text{Cr}_2\text{O}_3$, was found to be 51.99 (maximum, 52.12; minimum, 51.92) as the average of nine experiments. From the average of four estimations of the oxygen in silver chromate, the atomic weight was found to be 52.00, the result of the complete analysis of this salt being on the average $\text{Ag}_2\text{O} = 69.856$ per cent., $\text{Cr}_2\text{O}_3 = 22.930$ per cent., and $\text{O} = 7.228$ per cent. (total 100.14 per cent.). The iodometric estimations in the case of silver chromate ammonia gave $\text{O} = 6.007$ per cent. as the average of six experiments, from which the atomic weight of chromium is found to be $52.0 \pm$.

The average of 12 determinations of the oxygen in potassium dichromate gave $\text{Cr} = 51.91$, and nine experiments with ammonium dichromate, $\text{Cr} = 51.94$; five gravimetric determinations of the chromium in ammonium dichromate gave as the average result $\text{Cr} = 51.99$.

The extreme values, calculated from 36 experiments, are 52.12 and 51.83; excluding those values which are above 52 or below 51.9, there remain 28 lying between these limits. The iodometric determinations, which are probably very accurate, give as the average result of 21 analyses $\text{Cr} = 51.94$, four experiments, which gave values below 51.9, not being taken into account. All the weights from which the above results are calculated are reduced to 0° and a vacuum.

The author concludes with a criticism of the methods employed by other chemists for determining the atomic weight of chromium; he considers Rawson's result ($\text{Cr} = 52.01$, *Trans.*, 1889, 213), is highly trustworthy, but points out that when the weights are reduced to 0° and a vacuum the above value becomes 51.98.

F. S. K.

Molybdovanadates. By C. FRIEDHEIM (*Ber.*, **24**, 1173—1184; compare Abstr., 1890, 1066).—The analogous behaviour of the compounds of tungsten and molybdenum make it probable that the molybdovanadates can be considered as double salts like the tungstovanadates. The author discusses the work of Gibbs (Abstr., 1884, 161, 560, 713) and Milch (*Dissertation*, Berlin, 1887), who have described a list of salts of so-called complex acids obtained by the action of molybdic acid on normal ammonium vanadate, or of vanadic acid on acid ammonium molybdate. He shows that the salts of these complex acids can also be considered as double salts. Thus, Milch, by the action of molybdic acid on normal ammonium vanadate, obtained the compound $3(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 4\text{MO}_3 + 11\text{H}_2\text{O}$. The author also obtained a compound of the same composition, together with ammonium divanadate. He considers that the first stage of the reaction is the production of $2(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5$ and $2(\text{NH}_4)_2\text{O} \cdot 2\text{MO}_3$. These two compounds then act on one another, 1 mol. of the former combining with 2 mols. of the latter to form the double salt or isomorphous mixture $(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 + 2[(\text{NH}_4)_2\text{O} \cdot 2\text{MO}_3] + 11\text{H}_2\text{O}$, which is the so-called complex salt described by Milch. Experiments under varying conditions are described, and equations are given expressing the products of the reactions as double salts. The free acid of these salts could not be obtained.

The author finally discusses the constitution of salts of complex acids and double salts in general. E. C. R.

Vanadium Fluorides. By E. PETERSEN (*Ber.*, **24**, 1307).—A note regarding the priority of the discovery of three vanadium fluorides, which were first described by Piccini and Giorgio in 1888, and, shortly afterwards, independently by the author. J. B. T.

Atomic Weight of Osmium. By K. SEUBERT (*Annalen*, **261**, 257—272).—In a series of experiments carried out some time ago, the atomic weight of osmium was found to be 191 as the average of several not very closely-agreeing determinations (compare Abstr., 1888, 921); the author has undertaken a fresh investigation of the subject with a different sample of the metal and with improved apparatus, but employing the same method as before, namely the analysis of potassium osmiochloride, K_2OsCl_6 . Ammonium osmiochloride, $(\text{NH}_4)_2\text{Os}_2\text{Cl}_6$, was also analysed.

Three samples of the potassium salt were used: one was prepared directly in the manner described below, another was obtained from the sodium salt, and the third was a portion of the salt remaining from the previous experiments. The ammonium osmiochloride was prepared from the sodium salt.

In preparing potassium osmiochloride and the corresponding sodium salt, it was found advantageous to heat the mixture of finely-divided metal and alkaline chloride in a stream of hydrogen immediately before passing the chlorine; when this precaution is adopted, only a very small quantity of osmium chloride sublimes on to the cooler portions of the tube; whereas, when it is neglected, volatile products, such as perosmic acid, are formed in much larger quantities,

owing to the metal having undergone oxidation by exposure to the air.

Fusion with sodium chloride in a stream of chlorine proved to be the easiest method of preparing a pure double salt; the chlorine is so rapidly absorbed that, unless care is taken to provide a rapid stream of the gas, air is drawn into the apparatus. After keeping the mixture at a dull-red heat for some time, it is allowed to cool, and the dark carmine-red mass dissolved in pure water; the concentrated solutions of the osmiochloride do not change very quickly, but dilute solutions soon become greenish, a black powder being deposited, and an odour of perosmic acid observed; solutions of potassium and ammonium osmiochloride show a like behaviour. It is necessary, therefore, to employ for analysis only those crystals which are deposited from the hot, saturated solution in the course of 12 hours, and to use only small quantities of ice-cold water in washing the salt.

In preparing the potassium and ammonium salts from the sodium salt, a concentrated solution of the latter is mixed with 50 per cent. alcohol (1 vol.) and a solution of pure potassium chloride or ammonium chloride in 50 per cent. alcohol added in slight excess; the potassium or ammonium salt, as the case may be, is precipitated, almost immediately, as a dark-red, crystalline powder, and is first washed with dilute alcohol, and then recrystallised from hot water. The salts were dried over phosphoric anhydride under reduced pressure at the ordinary temperature; in this way they are not obtained perfectly anhydrous, but they cannot be dried at higher temperatures on account of their instability.

The analysis was carried out as previously described in the case of the platinum salts (compare Abstr., 1881, 514), except as regards the estimation of the osmium in the potassium osmiochloride; these determinations were made by first reducing the salt in a stream of hydrogen, and then igniting the mixture of metal and potassium chloride in a platinum boat in a platinum tube in a stream of hydrogen, until the whole of the potassium chloride is volatilised.

The average of the 16 analyses of the potassium salt gives $Os = 190.3$ ($O = 15.96$). The two determinations of the percentage of metal in the ammonium salt gave $Os = 190.76$; as this result is, in all probability, too high, owing to the presence of oxychloride in the salt employed, it may be neglected. The atomic weight of osmium is, therefore, to be taken as 190.3; its true value is not known within about 0.2 per cent., but it is certainly less than that of iridium.

F. S. K.

Atomic Weights of the Platinum Metals. By K. SEUBERT (*Annalen*, 261, 272–279; compare Abstr., 1888, 1043).—The latest determinations of the atomic weights of gold, and of the metals of the platinum group account for the anomalies previously observed in the classification of these metals according to the natural system; the order in which they are now to be placed is the following:—

Ruthenium	101.4	Rhodium	102.7
Osmium	190.3	Iridium	192.5
Palladium	106.35	Silver	107.66
Platinum	194.3	Gold	196.7

F. S. K.

Mineralogical Chemistry.

Aurichalcite. By S. L. PENFIELD (*Amer. J. Sci.*, 41, 106—109).—As some question still exists regarding the composition of aurichalcite, the author has analysed a specimen of unusual purity from an unknown locality in Utah. The mineral occurs in small, flattened, prismatic crystals in narrow seams in an impure limonite. Analysis gave the following results:—

CO ₂	CuO.	ZnO.	H ₂ O.	CaO.	Total.	Sp. gr.
16.50	20.88	52.18	9.91	0.86	100.33	3.52

The formula is $2\text{RCO}_3, 3\text{R}(\text{OH})_2$, in which R is Zn and Cu. This is the same as that proposed by Büttger in the original description of aurichalcite from the Altai.

B. H. B.

Powellite, a New Mineral Species. By W. H. MELVILLE (*Amer. J. Sci.*, 41, 138—141).—This new mineral was found with bornite at a mine in Western Idaho, in crystals belonging to the pyramidal system, closely allied in habit and development to scheelite. It has a yellow colour, a hardness of 3.5, and a sp. gr. of 4.526. Analysis yielded:—

MoO ₃	WO ₃	SiO ₂	CaO.	MgO.	Fe ₂ O ₃	Total.
58.58	10.28	3.25	25.55	0.16	1.65	99.47

Calcium molybdate has never before been observed in nature. It fills a gap existing in the series of isomorphous minerals, of which scheelite is the type. The new mineral is named in honour of the Director of the U.S. Geological Survey.

B. H. B.

Columbite and Tantalite from the Black Hills of South Dakota. By W. P. HEADDEN (*Amer. J. Sci.*, 41, 89—102).—Since 1884, when the occurrence of columbite in the Black Hills was first noticed, the mineral has been found at a number of localities in Pennington Co., and in the Nigger Hill district in Lawrence Co. The author gives the results of analyses of specimens of columbite from different localities in the Black Hills. In eight specimens from the Etta mine, the amount of tantalite increases with the specific gravity. This emphasises the fact that these various isomorphous mixtures not only occur at the same locality, but may even form the individual members of groups of crystals. They all have the form of columbite,

but the ratio of Nb : Ta gradually changes from 6 : 1 to 6 : 2. Of the 20 specimens analysed, 7 of them contain the Nb and Ta in the ratio of 3 : 2, 4 in the ratio of 1 : 1 and 1 in the ratio of 1 : 1½. The well-known tantalite from North Carolina gives the formula $6\text{RTa}_2\text{O}_6 + 4\text{RNb}_2\text{O}_6$, while the columbite from Northfield, Massachusetts, and from the Yolo mine, South Dakota, gives the formula $5\text{RTa}_2\text{O}_6 + 4\text{RNb}_2\text{O}_6$. If these specimens are real tantalites and columbites respectively, there is an overlapping of specific gravity and chemical composition which destroys their value as guides in determining these minerals, when the columbite and tantalite molecules are nearly equal in number. There is probably, chemically, no sharp line between them; but the author has so far been unable to determine the superior limit of tantalic acid compatible with the columbite form.

A mineral from Turkey Creek, Colorado, gave, on analysis, the following results :—

Nb ₂ O ₅ .	Ta ₂ O ₅ .	SnO ₂ .	FeO.	MnO.	CaO.	WO ₃ .
73.45	2.74	0.21	11.32	9.70	0.61	1.14

This is an almost typical columbite, but is, like the Dakota columbites, rich in manganese.

Manganese columbite occurs on the Advance Claim, in Pennington Co., South Dakota, in a vein of granite. It has a sp. gr. of 6.170. An analysis of one of the largest crystals gave the following results :—

Nb ₂ O ₅ .	Ta ₂ O ₅ .	SnO ₂ .	FeO.	MnO.	Total.
47.22	34.27	0.32	1.89	16.25	99.95

B. H. B.

Artificial Formation of Amphibole. By K. CROUSTCHOFF (*Compt. rend.*, 112, 677—679).—The following substances are introduced successively into glass flasks: an aqueous solution of dialysed silica, containing 3 per 100, an aqueous solution of dialysed aluminium hydroxide, an aqueous solution of dialysed ferric hydroxide, ferrous hydroxide, lime-water, magnesium hydroxide suspended in water, and a small quantity of a solution of potassium and sodium hydroxides. The flasks are then made vacuous, and are sealed up and heated at 550° for three months. The glass is strongly attacked, and on the sides of the flask are seen small, very brilliant, almost black, flattened prisms of hornblende, with the face (010) predominant, (110) often well developed, and (100) and (011) sometimes distinctly visible, the angle (011) (011) being 148° 28'. The optical sign is negative, the extinction (001) (010) = 17° 58', and the polychroism is not intense. The crystals had the composition :—

SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	FeO.	MgO.	CaO.	Na ₂ O.	K ₂ O.	Loss.
42.35	8.11	7.91	10.11	14.33	13.21	2.18	1.87	0.91 = 100.98

Four other minerals were formed at the same time, namely, small, pale-green prisms, which seem to be a pyroxene; colourless, iso-

tropic, rounded grains of a zeolite: small, distinct, limpid crystals of quartz; thin, colourless, rhombic lamellæ, with the optical properties of orthose (adularia).

Organic Chemistry.

The Reaction Capacity of Chlorotrimethylene and some Allied Compounds. By G. GUSTAFSON (*J. pr. Chem.* [2], 43, 396—402).—The author has isolated *chlorotrimethylene* from the product of the action of chlorine on trimethylene; it is a liquid of pleasant, sweet odour, lighter than water, in which it is insoluble, and boils at 43° (744 mm.); it is to be treated of in a future communication.

Chlorotrimethylene and dichlorotrimethylene were sealed up in tubes with bromine in the proportions $C_3H_5Cl + Br_2$ and $C_3H_4Cl_2 + Br_2$, after the manner previously described by the author (*Ann. Chim. Phys.* [5], 2). Several such tubes were prepared and kept in the dark at 16—18°; from time to time a tube was broken by being shaken in a stoppered vessel containing potassium iodide solution, the liberated iodine was estimated, and the amount of uncombined bromine remaining in the tube thus determined. In this way the progress of the two reactions could be watched under similar conditions. The results given show that chlorotrimethylene combines more rapidly with bromine under these conditions than dichlorotrimethylene does; thus, after 81 days, 31.63 per cent. of bromine was still uncombined in the chlorotrimethylene tube, while, after 84 days, 51.32 per cent. remained uncombined in the dichlorotrimethylene tube; moreover, in the former only 1.2 per cent. of the bromine which had disappeared was found as hydrogen bromide, whereas as much as 12 per cent. was so found in the latter. Similar experiments with trimethylene showed that it combines more rapidly with bromine than either of the above chloro-substitution products.

Wislicenus has shown (*Annalen*, 248, 308) that of the two chloropropylenes that which has the formula $\begin{array}{c} H \cdot C \cdot Me \\ | \\ H \cdot CCl \end{array}$ is much more stable towards alcoholic potash than its isomeride; the author has treated chlorotrimethylene and allyl chloride under similar conditions with alcoholic potash, and finds that the former is much more stable towards this reagent than the latter. All the experiments hitherto made show that of the isomerides of the formula C_3H_5Cl chlorotrimethylene is the most stable towards alcoholic potash.

Chlorotrimethylene is somewhat more easily decomposed by water than dichlorotrimethylene.
A. G. B.

Dimolecular Ethyl Cyanide. By P. S. BURNS (*J. pr. Chem.* [2], 43, 406—408; compare *Abstr.*, 1889, 114, 577).—*Benzoylimidopropionylethyl cyanide*, $COPh \cdot N : CEt \cdot C_2H_5 \cdot CN$, is obtained by warming

a mixture of benzoic chloride with imidopropionylethyl cyanide, in molecular proportion, in ether on the water-bath, evaporating the ether, neutralising the aqueous solution of the residue with ammonia, and recrystallising the precipitate from alcohol; it forms beautiful needles melting at 198° , and sparingly soluble in cold alcohol and ether. The *hydrochloride* crystallises in slender needles.

α -Imidopropionylbenzoyl ethyl cyanide, $\text{NH}\cdot\text{Cet}\cdot\text{CMe}(\text{CN})\cdot\text{COPh}$, isomeric with the above, is obtained when the product of the action of sodium on ethyl cyanide, that is, the mixture of NaCN and $\text{C}_2\text{H}_5\text{NaN}$, is suspended in light petroleum and acted on by benzoic chloride; it separates from the filtrate as a pale-yellow oil. It is decomposed by hydrochloric acid, and this proves that it is not identical with the foregoing compound.

When phthalic anhydride is melted with imidopropionylethyl cyanide in molecular proportion, phthalimide and propionylethyl cyanide (α -cyanodiethyl ketone) are formed.

Oximidopropionylethyl cyanide, $\text{NOH}\cdot\text{Cet}\cdot\text{CHMe}\cdot\text{CN}$, obtained by shaking the aqueous solutions of hydroxylamine and imidopropionylethyl cyanide, in molecular proportion, and extracting with ether, crystallises in slender needles, and melts at 42° . The *hydrochloride* and *zincchloride* were obtained. A. G. B.

Boiling Point of Diisopropylcarbinol. By G. POLETAEFF (*Ber.*, 24, 1308—1314).—Diisopropyl ketone, prepared by the distillation of calcium isobutyrate, does not reduce ammoniacal silver solution, as stated by Münch. Diisopropylcarbinol is best obtained from the ketone by treatment with sodium amalgam in considerable excess; the liquid is at first cooled, but, as the reaction approaches completion, the application of heat is necessary; the operation extends over two months. The alcohol boils at 140° under a pressure of 760 mm.; not at 131.5° , as stated by Münch. The sp. gr. is 0.8445 at $0^{\circ}/4^{\circ}$, and the coefficient of expansion between 0° and $20^{\circ} = 0.00094$; the refractive index for H_α 1.42047, and for $\text{H}_\gamma = 1.43156$. On oxidation with chromic anhydride, diisopropyl ketone, isobutyric acid, acetone, and acetic acid are formed. *Diisopropylcarbinyl acetate* is prepared by heating the alcohol with acetic anhydride in a sealed tube for 12 hours at 120° ; it boils at 159.7° under a pressure of 752 mm., has a sp. gr. of 0.8856 at $0^{\circ}/4^{\circ}$, and an expansion coefficient, from $0-20^{\circ}$, of 0.00101. The alcohol is regenerated by heating with alcoholic potash.

Applying the above boiling point to the expression $\text{MeOH} + 2\text{Pr}^{\text{iso}}\text{OH} - \text{CHPr}^{\text{iso}}_2\cdot\text{OH} = 2\text{H}_2\text{O}$, that is to say, $60^{\circ} + (82.8 \times 2) - 140^{\circ} = 85.6^{\circ}$, 42.8° is obtained as the equivalent for 1 mol. of water; the value previously obtained from methylisopropylcarbinol is 40.3° , therefore 41.5° , the mean of these two numbers, may be considered to be the constant for calculating the boiling point of secondary alcohols with secondary radicles. J. B. T.

Eulyte. By A. ANGELI (*Ber.*, 24, 1303—1305).—Eulyte, $\text{C}_6\text{H}_4\text{N}_4\text{O}_7$, which is formed by the action of nitric acid on citraconic acid, is not altered by treatment with acetic anhydride and benzoic chloride, VOL. LX.

or with hydroxylamine or phenylhydrazine. When heated with sulphuric acid, or hydrochloric acid, under pressure, decomposition takes place; by the action of alkalis at the ordinary temperature, nitrous acid is eliminated, and on the addition of iodine to the solution, iodoform is deposited in considerable quantity.

By the distillation of enlyte with hydrogen potassium sulphate and a little powdered pumice, nitrous fumes are evolved, and a yellow, viscid liquid is obtained; this is probably a *diketone* of the formula $C_6H_6N_2O_8$; it does not react with orthophenylenediamine. On treatment with phenylhydrazine in dilute acetic acid solution, a *diphenylhydrazone*, $C_{18}H_{18}N_6O_4$, is deposited, which crystallises from alcohol in orange-yellow plates melting at 110–111°. J. B. T.

Solvent for Cellulose. By C. F. CROSS and E. J. BEVAN (*Chem. News*, 63, 66).—The authors find that, by dissolving zinc chloride in twice its weight of hydrochloric acid, a solution of sp. gr. 1.44 is obtained, which dissolves cellulose instantly without sensible modification, and hence provides a useful solvent, especially suitable for the chemical or microscopical investigations of the vegetable fibres.

D. A. L.

Action of Nitric Acid on Acetonylacetone. By A. ANGELI (*Ber.*, 24, 1305–1306).—On warming acetonylacetone with 5 parts of concentrated nitric acid, an energetic reaction occurs, and, on cooling, large, colourless crystals are deposited which melt at 128–129°. The compound has the formula $C_6H_8N_2O_8$, and is readily soluble in benzene, acetone, or ethyl acetate; it is not acted on by alkaline carbonates, but dissolves in aqueous alkalis with a yellow colour, and does not give the nitroso-reaction. The *phenylhydrazone*, $C_{12}H_{12}N_4O_8$, crystallises from alcohol, on the addition of light petroleum, in small, yellow needles and melts at 161° with decomposition. The author suggests one or other of the following formulæ for the ketone:—

J. B. T.

Dibutylryl and Di-isovaleryl. By H. KLINGER and L. SCHMITZ (*Ber.*, 24, 1271–1276).—The results of the investigation of the constitution of isobenzila, which have shown it to be diphenylacetylene benzate (this vol., p. 931), make it probable that the supposed dibutylryl of Freund (*Annalen*, 118, 33) and the di-isovaleryl of Brühl (*Abstr.*, 1879, 520) have a similar constitution. It has already been pointed out by V. Meyer that they cannot be really α -diketones, as they are colourless substances (*Ber.*, 21, 809, footnote). The authors have, therefore, re-examined these compounds, and the results already obtained show that in all probability they are also ethereal salts of glycols.

Dibutylryl was obtained in the manner described by Münchmeyer (*Abstr.*, 1886, 350), namely, by acting on an ethereal solution of butyric chloride with sodium wire. It is obtained as an oil, and boils at 155–165° under a pressure of 12 mm. On warming with alcoholic

potash, it yields butyric acid, and a yellowish oil which boils at 180—190° and has the composition $C_8H_{16}O_2$. This has in all probability the constitution $OH \cdot CHPr^a \cdot COPr^a$, and may be termed *butyrolin*. It combines with phenylhydrazine, forming a *hydrazone* crystallising in straw-yellow needles and melting at 135°. The supposed dibutyrylmonoxime obtained by Münchmeyer (*loc. cit.*) is probably butyrolinmonoxime. When butyrolin is boiled with aqueous potash in presence of air, it yields *dipropylglycollic acid*, $OH \cdot CPr^a \cdot COOH$, just as benzoin yields benzoic acid. The new acid crystallises from water in long, white needles, melts at 72—73°, and yields a *barium salt*,

crystallising in white scales. From these results there can be little doubt that dibutyryl is in reality *dipropylacetylene dibutyrate*, $CH_3 \cdot [CH_2]_2 \cdot COO \cdot CPr^a \cdot CPr^a \cdot OOC \cdot [CH_2]_2 \cdot CH_3$.

Di-isovaleryl is obtained in a similar manner to dibutyryl from isovaleric chloride. It distils with slight decomposition at 155—165° under 12 mm. pressure, and is resolved by alcoholic potash into valeric acid and an oil which boils at 85—95° under a pressure of 12 mm., has the composition $C_{10}H_{20}O_2$, and is in all probability *isovaleroïn*, $C_4H_9 \cdot CO \cdot CH(OH) \cdot C_4H_9$. It combines with phenylhydrazine, and on heating with potash in presence of air, forms a new acid, apparently *di-isobutylglycollic acid*, $OH \cdot C(C_4H_9)_2 \cdot COOH$, which crystallises from water in long, white needles melting at 114°. Hence it appears that di-isovaleryl is *di-isobutylacetylene di-isovalerate*,

$$C_4H_9 \cdot COO \cdot \overset{\overset{C_4H_9}{|}}{C} \cdot C_4H_9,$$

H. G. C.

Angelic Acid. By E. SCHMIDT (*Arch. Pharm.* [2], 29, 68—71).—Finding that a sample of angelic acid 25 years old was pure methylcrotonic acid, the author supposed that the conversion had come about simply by long keeping, especially as Demarçay (*Compt. rend.*, 10, 83, 906) has shown that the application of heat causes the change. Further examination of other samples, even 50 years old, shows, however, that angelic acid can be preserved unchanged. Notwithstanding the assertions made in text-books that this acid exists in angelica root, either in the free state or as an ethereal compound from which distillation with water sets it free, it is probable that the acid is a decomposition product of some unknown compound occurring in the root.
J. T.

Substitution Derivatives of Succinic Acid. By C. A. BISONOFF (*Ber.*, 24, 1064—1074).—No isomeride of succinic acid could be obtained by dissolving succinic anhydride in water at low temperatures. An attempt to isolate isomerides of methyl- and ethylsuccinic acids by fractional crystallisation from benzene and chloroform also gave negative results. In order to ascertain whether derivatives of glutaric acid are formed as secondary products in the preparation of substituted succinic acids from ethyl malonate, ethyl ethylpropenyltricarboxylate was prepared as formerly described (Abstr., 1890, 743), and then hydrolysed. No ethylglutaric acid was

obtained, but the two symmetrical ethylmethylsuccinic acids were again found in the distillate, the anhydrides of these acids having very nearly the same boiling points. In the preparation of the two symmetrical diethylsuccinic acids also no glutaric acid was obtained. The anhydrides of these two acids have nearly the same boiling point. Attempts to obtain an optically active diethylsuccinic acid were not successful.

The author gives a list of the substitution products of succinic acids which have up to the present been prepared, together with their melting points. The monosubstitution derivatives all melt at 91—114°, the symmetrical di-derivatives at 115—138°, the asymmetrical dimethyl- and all tri-derivatives at 139—141°, the parasy-mmetrical di-derivatives at 154—197°, and tetramethylsuccinic acid at 200°. The only exceptions to this rule are the monobenzyl-, diphenyl-, and Zelinsky's mesoethylmethylsuccinic acid, and also succinic acid itself. H. C.

Theoretical Results of Studies in the Succinic Acid Group. By C. A. BISCHOFF (*Ber.*, 24, 1074—1085).—To explain the isomerism of derivatives of succinic acid, the author formerly put forward a theory of dynamical isomerism (*Abstr.*, 1890, 723), according to which the rotation of singly bound carbon atoms may be limited, owing to the vibrations of the atomic complexes in the molecule causing interference with one another. If this interference, or, as the author terms it, "collision," takes place between carboxyl groups, it will probably be attended with loss of water and the formation of an anhydride. On the other hand, collision between alkyl groups might result in limitation of the free rotation of the carbon atoms with which they were united, and the consequent occurrence of isomerides.

On the latter assumption, the occurrence of isomeric trimethylsuccinic acids, said to have been recently obtained by Zelinsky and Besredka, would be in perfect accordance with the theory. Careful consideration of Zelinsky and Besredka's results leads, however, to the conclusion that the isomeric trimethylsuccinic acid was in reality dimethylglutaric acid, and that up to the present only one trimethylsuccinic acid has been obtained. H. C.

Dynamical Hypothesis in its Application to the Succinic Acid Group. By C. A. BISCHOFF (*Ber.*, 24, 1085—1095).—The dynamical hypothesis, explained in a former paper (*Abstr.*, 1890, 723), is applied to the cases of isomerism among the succinic acid derivatives. It is necessary to assume with Wislicenus that carboxyl is repelled by carboxyl, with Baeyer that methyl is only slightly repelled or even attracted by methyl, and also that carboxyl repels methyl. The influence of the attraction of methyl or alkyl groups for one another would bring about a proximity of the carboxyl groups. From this would result the ready formation of anhydrides and increased conductivity noticed in the higher substituted succinic acids. If under any influence, such as that of a dehydrating agent, carboxyl were brought into proximity with carboxyl, and the agent then removed, the two carboxyl groups would repel one another, unless the

counter-attraction of two alkyl groups for one another overcame the repulsion. This repulsion also would be counteracted by the tendency of an alkyl group to repel carboxyl, and therefore the separation of carboxyl from carboxyl could only be effected with difficulty. This explains the fact that asymmetrical dimethylsuccinic acid only exists in one modification, and trimethylsuccinic acid exists probably in two active enantiomorphous forms, the ordinary acid being a mixture of the two.

The further application of the hypothesis to the succinic acids is fully discussed by the author with the aid of diagrams. It has the advantage over that of Meyer and Riecke (*Abstr.*, 1888, 549) that no assumptions are made as to so-called positive or negative groups, and the conception of affinity is as far as possible excluded in favour of a purely mechanical attraction or repulsion. H. C.

Oxidation Products of Brominated Thiophens. By G. CIAMICIAN and A. ANGELI (*Ber.*, 24, 1347—1351).—The dibromomaleic anhydride obtained from tetrabromothiophen and nitric acid (this vol., p. 427) melts at 117—118°, even after repeated distillation in a stream of dry carbonic anhydride and crystallisation from a mixture of benzene and light petroleum, whereas that obtained from maleic acid melts at 114—115°. When the supposed dibromacetylacrylic acid prepared from α -tribromothiophen (*loc. cit.*) is reduced with sodium amalgam in the presence of sulphuric acid, ether extracts an oily product which, on dissolving in chloroform and treating with bromine, yields a compound which crystallises from chloroform in colourless needles, melts at 114—115°, and has all the properties of dibromolevulinic acid. When tetrabromothiophen (3 grams) is dissolved in 90 per cent. acetic acid (50 c.c.), and boiled with chromic anhydride (5 grams), bromine is evolved, and a reddish-yellow, crystalline powder separates, which is very sparingly soluble in the ordinary solvents, and is purified by crystallisation from a large quantity of boiling xylene; it has the composition represented by the formula $C_4Br_4S_2O_2$, does not melt at 310°, but sublimes without decomposition when heated on platinum foil; it dissolves in alkalis with a brown colour, and hydrogen sulphide is evolved on heating with phenylhydrazine. A second compound separates in yellow flocks on adding light petroleum to the xylene filtrate from the red compound. A red compound closely resembling that above described is also obtained by treating α -tribromothiophen with chromic anhydride. When $\alpha\alpha'$ -dibromothioxylene and $\alpha\alpha'$ -methylphenyltribromothiophen are oxidised with nitric acid, semi-solid or amorphous substances are formed whose purification is difficult; better results may, however, be obtained by varying the conditions of the experiments.

The concluding portion of the paper is devoted to a discussion of the configuration of thiophen, pyrroline, and furfuran. A. R. L.

So-called Isothiocyanoethylsulphine. By A. MIOLATI (*Annalen*, 262, 61—81).—The compound obtained by Glutz (*Annalen*, 153, 313) by treating ethylenethiocarbimide with tin and hydrochloric acid, and named by him isothiocyanoethylsulphine chloride, has the con-

stitution $\begin{matrix} \text{CH}_2\cdot\text{S} \\ \text{CH}_2\cdot\text{S} \end{matrix} > \text{C}\cdot\text{NH}_2\cdot\text{HCl}$, and should therefore be called μ -imidomethylene ethylene bisulphide hydrochloride; its formation from ethylenethiocarbimide is most easily explained by assuming that an intermediate product of the constitution $\text{SH}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{S}\cdot\text{CO}\cdot\text{NH}_2$ is first formed by the addition of 1 mol. H_2O .

μ -Imidomethylene ethylene bisulphide hydrochloride is obtained when ethylenethiocarbimide is boiled for a long time with concentrated hydrochloric acid, but it is best prepared by heating ethylenethiocarbimide with excess of tin and concentrated hydrochloric acid; the *stannochloride*, $(\text{C}_2\text{H}_4\text{S}_2\text{N})_2\cdot\text{H}_2\text{SnCl}_4$, is deposited from the cold filtered solution, and can be purified by recrystallisation from hot water. The hydrochloride, obtained by decomposing the *stannochloride* with hydrogen sulphide and evaporating the filtered solution, crystallises from hot alcohol in nacreous scales, but it cannot be freed from ammonium chloride without considerable loss; the preparation employed in the experiments described below contained a little ammonium chloride. When the hydrochloride is oxidised with nitric acid of sp. gr. 1.52, it is converted into ethylenedisulphonic acid (m. p. 104° , corr.), and when treated with potassium carbonate, it yields ammonia and diethylene tetrasulphide.

The free imidomethylene ethylene bisulphide can be obtained by shaking the hydrochloride with potassium carbonate and ether, and then evaporating the ethereal solution; it is a colourless oil, having a slight mercaptan-like odour, and it decomposes on exposure to the air, with formation of diethylene tetrasulphide. It is insoluble in water, gives with silver nitrate a colourless silver derivative, and is quickly decomposed by cold dilute alkalis. The *hydriodide*, $\text{C}_2\text{H}_4\text{S}_2\text{N}\cdot\text{HI}$, is obtained when the hydrochloride of the base is warmed with methyl iodide in alcoholic solution; it crystallises in colourless needles, turns brown, and melts at $182\text{--}184^\circ$ with complete decomposition, and is very readily soluble in water and hot alcohol.

Methylimidomethylene ethylene bisulphide, $\begin{matrix} \text{CH}_2\cdot\text{S} \\ \text{CH}_2\cdot\text{S} \end{matrix} > \text{C}\cdot\text{NMe}$, prepared by decomposing the hydriodide with alkalis, is an oil; it quickly decomposes with evolution of methylamine, being converted into a colourless, amorphous compound, probably diethylene tetrasulphide.

Acetylimidomethylene ethylene bisulphide, $\begin{matrix} \text{CH}_2\cdot\text{S} \\ \text{CH}_2\cdot\text{S} \end{matrix} > \text{C}\cdot\text{N}\cdot\text{Ac}$, is formed when the hydrochloride of the base is boiled with excess of acetic anhydride; it crystallises from alcohol and benzene in thin plates, melts at 69° , and is readily soluble in alcohol and benzene, but only sparingly in ether, and almost insoluble in water; it is decomposed by alkalis, and when warmed with benzoic chloride it is converted into a crystalline compound, probably the benzoyl derivative, which melts at $141\text{--}143^\circ$.

Oximidomethylene ethylene bisulphide, $\begin{matrix} \text{CH}_2\cdot\text{S} \\ \text{CH}_2\cdot\text{S} \end{matrix} > \text{C}\cdot\text{N}\cdot\text{OH}$, can be obtained by warming the hydrochloride with hydroxylamine hydro-

chloride in faintly alkaline solution, and then allowing the filtered solution to cool; it crystallises in long, colourless needles, melts at 126° (corr.), and is almost insoluble in cold water, but readily soluble in hot water, alcohol, glacial acetic acid, alkalis, and acids; it is not decomposed by boiling concentrated hydrochloric acid. The *hydrazone*, $C_6H_{10}S_2N_2$, prepared by warming an aqueous solution of the hydrochloride with phenylhydrazine hydrochloride and sodium acetate, and then adding sodium carbonate, crystallises from hot alcohol in greyish plates, melts at 88° , and is insoluble in hot water, and only sparingly soluble in ether, but readily in alcohol.

Ethylimidomethylene ethylene bisulphide, $\begin{matrix} CH_2S \\ | \\ CH_2S \end{matrix} > C:NEt$, is formed when a 33 per cent. solution of ethylamine is added, drop by drop, to a hot, concentrated solution of the hydrochloride of the base; after boiling until the evolution of ammonia is at an end, and then adding stannous chloride, the stannochloride $(C_2H_5S_2N)_2 \cdot H_2SnCl_4$, is deposited in crystals. The stannochloride of the *allyl* derivative was prepared in like manner; it has the composition $(C_6H_9S_2N)_2 \cdot H_2SnCl_4$. The *puratolyl* derivative is precipitated as an oil on treating a solution of the imido-base with paratoluidine; the *hydrochloride*, $C_{10}H_{11}S_2N \cdot HCl$, separates from ether in colourless needles, melts at about 168° with decomposition, and is decomposed by water. The *parahydroxyphenyl* derivative, prepared by treating a solution of the imido-base with paramidophenol, separates from hot alcohol in large, dirty-brown crystals, melts at $204-205^{\circ}$, and is soluble in alkalis, but insoluble in acids.

When the hydrochloride of the imido-base is dissolved in alcoholic carbon bisulphide, and the solution gradually treated with alcoholic potash, ethylene thiocarbonate, $\begin{matrix} CH_2S \\ | \\ CH_2S \end{matrix} > CS$ (m. p. $40-41^{\circ}$, corr.), is formed; when this substance is treated with hydroxylamine, it is converted into the oxime described above, and on oxidation with moderately dilute nitric acid, it yields ketomethylene bisulphide, $\begin{matrix} CH_2S \\ | \\ CH_2S \end{matrix} > CO$, and not ethylene thioxy carbonate, as was supposed by Husemann (*Annalen*, 123, 83).

μ -Imidomethylene propylene bisulphide, $\begin{matrix} CHMeS \\ | \\ CH_2-S \end{matrix} > C:NH$, is formed when propylenethiocarbimide is boiled with tin and hydrochloric acid; the *stannochloride*, $(C_4H_7S_2N)_2 \cdot H_2SnCl_4$, crystallises from water in plates, and is readily soluble. The *hydrochloride*, $C_4H_7S_2N \cdot HCl$, forms well-defined plates, melts at $172-175^{\circ}$, and is readily soluble in water. The *acetyl* derivative, $C_6H_5S_2NO$, prepared by boiling the hydrochloride with acetic anhydride, is a crystalline powder which melts at 59.5° , and is almost insoluble in water and ether, but very readily soluble in alcohol.

When trimethylenethiocarbimide is boiled with tin and hydrochloric acid, it yields trimethylenemercaptan, and not imido-methylenetrimethylene bisulphide.

F. S. K.

Preparation of Pyromucic Acid from Furfuraldehyde. By J. VOLHARD (*Annalen*, 261, 379—380).—A better method for the preparation of pyromucic acid than that described by Schiff (compare this vol., p. 676) is to oxidise furfuraldehyde with potassium permanganate. For this purpose furfuraldehyde (9.6 grams) is mixed with water (400 c.c.) and potassium hydroxide (26 grams), and a solution of potassium permanganate (10.5 grams) in water (400 c.c.) gradually added, the temperature being kept below 20° ; the solution is then boiled, filtered, the filtrate evaporated to a small volume, mixed with hydrochloric acid, and extracted with ether. The yield of the crude acid is about 8.9 grams; it is most easily obtained in a pure condition by sublimation, the acid being heated at 130 — 140° in a glass tube through which is passed a stream of air under a pressure of about 50—60 mm. F. S. K.

Furazancarboxylic Acid. By L. WOLFF and P. F. GANS (*Ber.*, 24, 1165—1172).—Diisonitrosovaleric acid, when treated with concentrated sulphuric acid, loses a molecule of water, and is converted into furazanpropionic acid. The latter, under the action of cold sodium hydroxide or ammonia, is converted into the isomeric cyanonitrosobutyric acid, $\text{CN}\cdot\text{C}(\text{NOH})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, and on oxidation it yields furazancarboxylic acid, which is converted by alkali into cyanonitrosoacetic acid.

Furazancarboxylic Acid.—The oxidation of furazanpropionic acid by means of potassium permanganate is a somewhat difficult operation, as the action either goes too far, or not far enough, unless special care is taken. The following conditions give a good yield. Furazanpropionic acid (2 grams) is dissolved in a mixture of concentrated sulphuric acid (20 grams) and water (100 c.c.), heated at 85 — 90° , and mixed with a hot saturated solution of permanganate (20 grams) in four portions. The oxidation at first proceeds rapidly, afterwards more slowly, and is complete in 8—9 hours. The acid is extracted with ether, and purified by crystallisation from benzene. It is very easily soluble in water, ether, and alcohol, somewhat easily in boiling chloroform and benzene, and sparingly in carbon bisulphide and light petroleum. From benzene, it crystallises in long leaflets or needles of satiny lustre, and melts at 107° to a colourless oil. It dissolves in aqueous alkalis with a deep yellow coloration, and is immediately converted into the isomeric cyanonitrosoacetic acid; on boiling with water it is slowly decomposed with formation of hydrocyanic acid. The aqueous solution reddens litmus, and with carbonates yields well characterised salts, which are unstable to boiling water. The calcium salt, $(\text{C}_3\text{HN}_2\text{O}_3)_2\text{Ca} + \text{H}_2\text{O}$, obtained by saturating the cold acid solution with calcium carbonate, crystallises in small needles, and is easily soluble in water. By boiling the aqueous solution, it is slowly converted into calcium cyanonitrosoacetate, hydrocyanic acid being formed at the same time. The silver salt, $\text{C}_3\text{HN}_2\text{O}_3\text{Ag}$, is obtained as a white, crystalline precipitate on adding silver nitrate to a solution of the calcium salt. It dissolves somewhat easily in boiling water, crystallises in shining needles, and decrepitates when quickly heated. By prolonged boiling with water, it is converted into a sparingly soluble, yellow crystalline salt.

Cyanonitrosoacetic acid, $\text{NC}\cdot\text{C}(\text{NOH})\cdot\text{COOH}$, is obtained by treating furazancarboxylic acid with excess of sodium hydroxide, strongly acidifying the solution with sulphuric acid, and extracting with ether. The acid is purified by crystallisation from a mixture of benzene and ether, and then from water. It is very easily soluble in water, ether, and alcohol, sparingly so in benzene, petroleum, and carbon bisulphide, crystallises in colourless prisms containing $\frac{1}{2}$ mol. H_2O , and melts at 103° . The anhydrous acid melts at 129° with violent frothing, and is converted into a crystalline compound, which is probably cyanuric acid. The aqueous solution reacts strongly acid; with ferric chloride it gives a red coloration, which disappears on the addition of a mineral acid. When boiled with water, it evolves hydrocyanic acid, and when boiled with potassium hydroxide, is converted into ammonia and nitrosomalonic acid. Towards alkaline carbonates it behaves as a bibasic acid, and yields salts of the formula $\text{NC}\cdot\text{C}(\text{NOM})\cdot\text{COOM}$, which are yellow when dry. The acid salts are colourless. The *normal calcium salt*, $\text{CN}\cdot\text{C}\begin{smallmatrix} \text{NO} \\ \diagup \\ \text{COO} \end{smallmatrix} \text{Ca} + 7\text{H}_2\text{O}$, is obtained by saturating an aqueous solution of the acid with calcium carbonate, and evaporating over sulphuric acid. It crystallises in colourless, six-sided tablets, and is easily soluble in hot water, less so in cold water. When dried in a desiccator, it loses 4 mols. H_2O , and is converted into a lemon-yellow powder; the remaining water of crystallisation is not lost at 100° , and at a higher temperature the salt turns brown. The yellow salt takes up water to form the colourless salt, and dissolves in water to a yellow solution, which, on the addition of ferric chloride, turns deep red. The *normal silver salt* is obtained as a yellow, crystalline precipitate on adding silver nitrate to a solution of the normal calcium salt. It is sparingly soluble in water, easily so in excess of nitric acid or ammonia, and decrepitates when gently heated. The *acid salt*, $\text{C}_3\text{HN}_2\text{O}_3\text{Ag}$, is obtained by careful addition of nitric acid to the normal salt, and also as a white crystalline precipitate by adding silver nitrate to an aqueous solution of the free acid. It crystallises from boiling water containing nitric acid in long, colourless needles, decrepitates when heated, and is converted by prolonged boiling with water, more easily by warming with ammonia, into the yellow normal salt.

Nitrosomalonic acid is obtained in theoretical quantity by boiling 1 part of cyanonitrosoacetic acid or furazancarboxylic acid with potash (2 parts) and water (6 parts) in a reflux apparatus as long as ammonia is evolved. It melts at 139° , decomposes when strongly heated, with a hissing sound, and on heating in aqueous solution, decomposes into carbonic anhydride, hydrocyanic acid, and water. It has the properties ascribed to it by Baeyer (*Annalen*, 131, 292). E. C. R.

Constitution of Benzene. By A. CLAUS (*J. pr. Chem.* [2], 43, 321—343).—A reply to Zincke's paper in *Annalen*, 261, 208, as far as it concerns the author's diagonal formula for benzene.

A. G. B.

Cymene. By O. WIDMAN (*Ber.*, 24, 1362—1363).—A reply to R. Meyer (this vol. p. 688).

Oxidation of Cymene and Isopropylbenzene by Chromyl Chloride. By W. v. MILLER and RONDE (*Ber.*, 24, 1356—1362).—The authors obtained an aldehyde on treating cymene with chromyl chloride (*Abstr.*, 1890, 978), and this was likewise obtained by Errera (*ibid.*, 1254), together with a second compound which he has recently shown to be paratolyl methyl ketone (*Gazzetta*, 21, 65). They now find that, under similar conditions, isopropylbenzene yields hydratropaldehyde and acetophenone.

Hydratropaldehyde, $C_9H_{10}O$, is obtained from that portion of the product which combines with sodium hydrogen sulphite. It is an almost colourless oil, having an odour resembling that of the aldehyde obtained from cymene, and boils at $203-204^\circ$ (thermometer in the vapour) under a pressure of 716 mm.; it colours a sulphurous acid solution of rosaniline, reduces an ammoniacal silver solution in the cold, and gives an oily compound with phenylhydrazine; it does not appear to oxidise, or only does so very slowly, in the air. Taking the above in conjunction with Widman's recent discovery (this vol., p. 656) that cymene is paramethylisopropylbenzene, there can be no doubt that the aldehyde obtained from the latter is paramethyl-hydratropaldehyde as suggested (*loc. cit.*). A. R. L.

Action of Halogens on Aromatic Compounds in presence of Light. By J. SCHRAMM (*Ber.*, 24, 1332—1337).—By the action of bromine on parethyltoluene in molecular proportion in sunlight, 1 atom of hydrogen in the ethyl group is displaced; the resulting product is liquid, and readily decomposes on distillation or by treatment with potash, paramethylcinnamene being obtained. The latter combines directly with 1 mol. of bromine to form *paramethylcinnamene dibromide*, $C_9H_9Me-CHBr-CH_2Br$, which crystallises from alcohol in long, slender needles melting at 44.5° . The same substance may be more readily prepared by heating the above liquid bromo-derivative with 1 mol. proportion of bromine on the water-bath in darkness.

Parethyltoluene also reacts with 2 mol. proportions of bromine in sunlight; the product is liquid and probably consists of paramethyl- β -cinnamene dibromide. Ethylbenzene may be readily prepared by the interaction of benzene, ethyl bromide, and aluminium chloride, at 0° ; on treating the crude product with 1 mol. proportion of bromine in sunlight, and afterwards with the same quantity in darkness at higher temperatures, *parabromocinnamene dibromide*, $C_9H_7Br-CHBr-CH_2Br$, is formed, crystallising from alcohol in long, slender needles melting at 60° ; the compound is identical with that obtained by the addition of bromine to parabromocinnamene, and yields parabromobenzoic acid on oxidation. By boiling with aqueous potassium carbonate solution, *parabromophenylethylene glycol* is formed; this crystallises from benzene or water in needles, melts at 102° , and readily decolorises potassium permanganate solution.

Bromopropylbenzene behaves towards bromine like the corresponding ethyl derivative. *Parabromo- $\alpha\beta$ -dibromopropylbenzene*,

crystallises from alcohol in lustrous needles and melts at 61° ; long,

prismatic crystals are deposited on slowly evaporating a dilute alcoholic solution.

Parabromobutylbenzene is prepared by the action of bromine on butylbenzene in presence of iodine, and boils at 240—242°. It reacts with bromine in a manner similar to the propyl and ethyl derivatives, and yields *parabromo-β-γ-dibromobutylbenzene*,

which crystallises from alcohol in highly lustrous plates and melts at 76.5°. J. B. T.

Thymol. By A. CLAUß and E. KRAUSE (*J. pr. Chem.* [2], 43, 344—355).—Engelhardt and Latschinoff's α -thymolsulphonic acid is the para-acid, as they themselves showed by oxidising it to thymoquinone (this Journal, 1871, 1053); their β -acid has been shown by the authors to be thymolorthosulphonic acid; the γ -acid is, therefore, thymolmetasulphonic acid.

Orthobromothymolparasulphonic acid (brom- α -sulphothymolic acid of Engelhardt and Latschinoff)

is best obtained by adding a solution of bromine (1 mol.) in three times its weight of glacial acetic acid, by drops, to an aqueous solution of potassium thymolparasulphonate with continuous shaking; the liquid is then neutralised with potash and evaporated. The free acid cannot be crystallised by evaporation over the water-bath, as, after a certain degree of concentration, it decomposes into bromothymol and sulphuric acid; over sulphuric acid it crystallises in small, colourless columns (with 1 mol. H_2O) which melt in their water of crystallisation at 55° (uncorr.). The *potassium* (with 1 mol. H_2O), *sodium* (with 2 mols. H_2O), the *barium*, the *lead* (with 3 mols. H_2O), and the *silver* salts are described.

Orthobromothymol [$\text{OH} : \text{Pr} : \text{Br} : \text{Me} = 1 : 6 : 2 : 3$] separates as an oily layer when potassium orthobromothymolpara-sulphonic acid is heated with dilute hydrochloric acid in a tube at 150°. It is a clear, yellow oil which boils at 240° (uncorr.) undecomposed, and does not solidify in a freezing mixture.

2-Bromothymoquinone [$\text{O}_2 : \text{Br} : \text{Me} : \text{Pr} = 1 : 4 : 2 : 3 : 6$] is obtained when orthobromothymolparasulphonic acid is oxidised with chromic acid; it crystallises in beautiful, red, prismatic columns which melt at 48° (uncorr.); it is identical with the bromothymoquinone obtained by action of hydrogen bromide on thymoquinone (compare Kehrman, Abstr., 1890, 367). The action of concentrated nitric acid on orthobromothymolparasulphonic acid yields orthoparadinitrothymol (m. p. 54—55°, uncorr.).

The *potassium* (with 1 mol. H_2O), *barium* (with 4 mols. H_2O), *silver* (with 2 mols. H_2O), *copper*, *nickel*, and *cobalt* salts of thymol-orthosulphonic acid are described. *Potassium parabromothymolorthosulphonate* [$\text{OH} : \text{Pr} : \text{Br} : \text{Me} : \text{SO}_3\text{K} = 1 : 6 : 4 : 3 : 2$] is obtained by the action of bromine on potassium thymolorthosulphonate; the

barium salt is described; the free acid cannot be crystallised, being so easily decomposed into sulphonic acid and *parabromothymol*, which is a clear yellow oil; by the action of bromine it yields orthoparadi-bromothymol, which is characterised by its oxidation into 2-bromo-thymoquinone.

The authors doubt whether Mazzara's bromothymol is the para-compound (Abstr., 1890, 602, 753, 884); investigations are being made into this question.

A. G. B.

Action of Sunlight on Organic Compounds. By H. KLINGER and O. STÄNDKE (*Ber.*, 24, 1340—1346; compare Abstr., 1886, 888; 1889, 405).—When a mixture of finely powdered quinone (5 grams) and benzaldehyde (10 c.c.) is exposed in a sealed tube to direct sunlight, the yellow solution becomes darker, and greenish-black crystals separate, which increase in quantity as the quinone dissolves. No pressure is observed on opening the tube; the crystals are collected, washed with ether, and, after crystallising from dilute alcohol, identified as quinhydrone. *Dibenzoylquinhydrone*, $C_{22}H_{14}O_6$, is obtained when the filtrate and ethereal washings from the quinhydrone are allowed to evaporate in the sun. The black, semi-crystalline residue is spread upon a porous tile, and dissolved in dilute alcohol, when it separates in long, black, flat needles, having a bluish-violet lustre, and a brown colour by transmitted light; it melts at 116—117°, and dissolves in alcohol, ether, and benzene, with a yellow colour, splitting up into its components (see below); heated with water, it melts, the brown drops gradually become lighter, and quinone passes off with the steam.

Benzoylquinol (*dihydroxybenzophenone*), $C_6H_5Bz(OH)_2$, is obtained, together with quinol, when dibenzoylquinhydrone is heated with sulphurous acid; it separates in yellow oily drops which solidify on cooling, whereas quinol remains in solution: it forms long, yellow needles from dilute alcohol, and is very readily soluble in ether, benzene, and alcohol; it melts at 125°, and yields dibenzoylquinhydrone when a dilute alcoholic solution is mixed with one of quinone. The *tribenzoyl derivative*, $C_6H_5Bz(OBz)_2$, which crystallises from alcohol in glistening, white needles, melts at 118°, and is sparingly soluble in cold alcohol, readily in ether and benzene, is formed on treating benzoylquinol with benzoic chloride; by hydrolysis with alcoholic potash, benzoylquinol is regenerated.

Isovaleroquinhydrone, $C_{17}H_{16}O_6$, is formed together with quinhydrone from quinone and isovaleraldehyde; it crystallises from dilute alcohol in beautiful, red tables with a metallic lustre, which gradually undergo change in the air and become yellow; it dissolves with a yellow colour in alcohol, ether, benzene, and glacial acetic acid, and melts at 103°.

Isovaleroquinol, $C_6H_5\cdot CO\cdot C_6H_5(OH)_2$, is obtained, together with quinol, when isovaleroquinhydrone is treated with sulphurous acid; it separates from dilute alcohol in yellow needles, and from benzene, in prisms, which become dull in the air, melts at 115°, and dissolves in alkalis with a yellowish-red colour; it combines with quinone to form isovaleroquinhydrone; the *dibenzoyl derivative*, $C_6H_5\cdot CO\cdot C_6H_5(OBz)_2$,

crystallises from alcohol in white needles, melts at 105° , and yields isovaleroquinol on hydrolysis.

The above-mentioned aldehydes have scarcely any action on quinone in the dark, less quinhydrone being formed after a month's action than by an hour's exposure to light.

A. R. L.

Action of Aniline on Chloride and Bromide of Arsenic. By R. ANSCHÜTZ and H. WEYER (*Annalen*, 261, 279—297).—*Arsenanilidodichloride*, $\text{AsCl}_2\cdot\text{NHPh}$, is formed, with development of heat, when a dry ethereal solution of aniline (1 mol.) is gradually added, with constant shaking, to a dry ethereal solution of pure arsenic trichloride; the mixture is boiled for some time, then allowed to cool, and the intense yellow solution of the arsenic compound separated from the precipitated aniline hydrochloride, moisture being carefully excluded. The solution is partially evaporated on the water-bath, and then kept over phosphoric anhydride, when a crystalline mixture of arsanilidodichloride, aniline hydrochloride, and arsendianilidochloride is deposited; the first-named compound can be isolated in a pure condition by repeated recrystallisation from ether, in which the two impurities are very sparingly soluble; the yield is very small. Arsanilidodichloride is a yellow, crystalline powder; it melts at $87\text{--}88^{\circ}$, decomposes at a higher temperature, and is readily soluble in warm ether and chloroform, but only very sparingly in benzene; it quickly decomposes on exposure to moist air, being converted into arsenious oxide, hydrochloric acid, and aniline hydrochloride.

Arsendianilidochloride, $\text{AsCl}(\text{NHPh})_2$, can be prepared by gradually adding an ethereal solution of arsenic trichloride (1 mol.) to an ethereal solution of aniline (6 mols.); as soon as the reaction is at an end, the colourless solution is separated from the precipitated aniline hydrochloride and allowed to cool, when the arsenic compound is deposited in transparent, rhombic crystals, which immediately become cloudy on exposure to the air. It is purified by recrystallisation from hot ether containing a little aniline. It melts at $127\text{--}128^{\circ}$, decomposes at a higher temperature, and is insoluble in benzene, and almost insoluble in cold ether and chloroform, but more readily in hot xylene, and readily in aniline; it is quickly decomposed by warm water and by cold alkalis.

Arsenunilidobromide, $\text{AsBr}_2\cdot\text{NHPh}$, prepared from arsenic tribromide, as described in the case of the corresponding dichloride, separates from ether in small, yellow crystals, melts at $111\text{--}113^{\circ}$, and decomposes at a higher temperature; it is more sparingly soluble in ether and chloroform, and more sensitive to moisture than the dichloride.

Arsenanilidodimethoxide, $\text{NHPh}\cdot\text{As}(\text{OMe})_2$, is formed when the dibromide is boiled with an ethereal solution of the theoretical quantity of sodium methoxide; it is a colourless, highly refractive liquid, which boils at 55° under a pressure of about 12 mm., and at $159\text{--}162^{\circ}$ under the ordinary atmospheric pressure with slight decomposition; it turns yellow on keeping.

Arsenanilidodiethoxide, $\text{NHPh}\cdot\text{As}(\text{OEt})_2$, prepared in like manner, boils at 78° under a pressure of about 12 mm., and at $178\text{--}181^{\circ}$ under

the ordinary atmospheric pressure with slight decomposition. The two compounds just described are very readily decomposed by water, yielding arsenious oxide, aniline, and the corresponding alcohol.

Arsendianilidobromide, $\Delta_2\text{Br}(\text{NHPh})_2$, can be prepared as described in the case of the corresponding chloride; it separates from hot ether containing a little aniline in well-defined, transparent, seemingly rhombic crystals, which soon turn red and become cloudy on exposure to the air; it decomposes at $170-180^\circ$, is insoluble in benzene, and only sparingly soluble in ether and chloroform, and is quickly decomposed by water and alkalis.

The compound of the composition $\text{As}(\text{NHPh})_3\cdot 3\text{HCl}$, described by Schiff (*Compt. rend.*, **56**, 1095) and by Leeds (*Amer. Chem. J.*, **3**, 134), could not be obtained; it is most probably a mixture of arsenianilidodichloride, arsendianilidochloride, and anilino hydrochloride. Landau (*Inaug. Diss. Berlin*, 1888) has described two compounds of the composition $\text{AsCl}_3\cdot 4\text{C}_6\text{H}_5\cdot \text{NH}_2 + \text{H}_2\text{O}$ and $\text{AsBr}_3\cdot 3\text{C}_6\text{H}_5\cdot \text{NH}_2 + \text{H}_2\text{O}$, which he obtained by treating aniline with arsenic trichloride and arsenic tribromide respectively in benzene solution; the authors find that Landau's bromo-compound is simply aniline hydrobromide, so that his results are not trustworthy. F. S. K.

Combination of Ethyl Oxalate with Anilides. By W. WILKENUS and W. SÄTZLER (*Ber.*, **24**, 1245—1256).—By the action of sodium ethoxide on a mixture of ethyl oxalate and acetanilide in benzene solution, these two compounds unite in a manner similar to ethyl oxalate and ethyl acetate (Abstr., 1888, 1178), forming *ethyl sodoxalacetanilide*, $\text{COOEt}\cdot\text{CO}\cdot\text{CHNa}\cdot\text{CO}\cdot\text{NHPh}$. This separates out from the benzene solution, and is purified by recrystallisation from hot alcohol. It forms stellate groups of small plates, which slowly dissolve in cold, and are decomposed by hot water. When heated to boiling with water, acidified, and quickly cooled, it yields *ethyl oxalacetanilide*, $\text{COOEt}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{NHPh}$, as an oil which quickly solidifies, and may then be recrystallised from light petroleum. It is very readily soluble in alcohol, ether, benzene, and alkalis, sparingly in light petroleum, and insoluble in water, melts at $87-88^\circ$, and decomposes at 130° . Its alcoholic solution is coloured red by ferric chloride.

The above sodium compound is not formed in very large quantities in the reaction, several other products being obtained; one of these is a sodium compound of the formula $\text{C}_{10}\text{H}_8\text{NO}_3\text{Na}$, which is exceedingly difficult to purify, and possibly consists of *sodium oxalacetanilide*, $\text{C}(\text{NHPh})\cdot\text{CO}$

$\text{CHNa}\cdot\text{CO}$ > NHPh . By the action of acids, it quickly undergoes alteration, forming complicated products, one of which is anilidomaleic phenylimide (Abstr., 1890, 379); the chief product, however, is a yellow compound of unknown composition and constitution, termed by the authors *xanthoxalanil*, which is also the chief constituent of the original product of the reaction of sodium ethoxide on ethyl oxalate and acetanilide. It is best prepared from the latter by adding water, shaking well, acidifying, and warming the aqueous solution. The yellow, crystalline product obtained is boiled with acetic acid, which removes anilidomaleic phenylimide. Xanthoxal-

anil remains as a yellow, crystalline product which is insoluble in the ordinary solvents, and decomposes, on heating with alkalis, into aniline, oxalic acid, and volatile organic acids.

Sodium ethoxide acts on a mixture of ethyl oxalate and acetoparatoluidide in a similar manner. The sodium compound formed could not be recrystallised, and was therefore at once acidified and cooled. *Ethyl oxalacetoparatoluidate*, $\text{COOEt} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NH} \cdot \text{C}_6\text{H}_4\text{Me}$, is thus obtained as an oil which quickly solidifies, and on recrystallisation from benzene forms yellowish plates, melts at $134-135^\circ$, and is readily soluble in alcohol and ether. In this case also the chief product of the reaction is a yellow, insoluble compound, for which the name *xanthoxalotoluidil* is proposed. It forms microscopic plates and melts at 259° .

When a mixture of ethyl acetanilide and ethyl oxalate is heated with sodium ethoxide, the reaction proceeds in a normal manner, without the formation of condensation products. No sodium compound could be isolated, but the chief portion of the ethyl oxalethylacetanilate was found in the ethereal solution. It is purified by conversion into the copper salt, $(\text{C}_{14}\text{H}_{16}\text{NO}_4)_2\text{Cu}$, which crystallises from alcohol in slender, pale-green needles, and melts at $137-139^\circ$. The free *ethyl oxalethylacetanilate*, $\text{COOEt} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NEtPh}$, is obtained from it by acidifying and extracting with ether, and crystallises from the latter in large, lustrous, oblique prisms melting at $67-69^\circ$. It decomposes at 160° , and is soluble in the usual solvents with the exception of water and dilute soda, the alcoholic solution giving a dark-red coloration with ferric chloride.

When propionanilide is substituted for ethylacetanilide in the above reaction, the corresponding ethyl oxalpropionanilate is not obtained, but a compound containing the elements of alcohol less, which

is probably *methyl oxalacetophenylimide*, $\begin{array}{c} \text{CO} - \text{CO} \\ | \quad \quad | \\ \text{CHMe} - \text{CO} \end{array} > \text{NPh}$. It may be recrystallised from benzene, and then melts at $191-192^\circ$, becoming yellow at the same time; it is readily soluble in alcohol, ether, and benzene, sparingly in water and light petroleum, and gives with ferric chloride in alcoholic solution a dirty, brownish-red coloration.

H. G. C.

Action of Alkalis and Amines on Halogen-substituted Quinones. By F. KEHRMANN (*J. pr. Chem.* [2], 43, 260-267).—In his previous paper (Abstr., 1890, 136), the author stated that, by reduction with stannous chloride under certain conditions, the β -series of the halogen-substituted quinones yield the α - as well as the β -series of corresponding quinols. This is a mistake; experiments upon carefully purified β -dimethoxydichloroquinone show that the α -quinol cannot be obtained from it by reduction.

Chlorethoxydianilidoquinone. $\text{C}_{20}\text{H}_{17}\text{N}_2\text{ClO}_3$, is obtained by dissolving the crude mixture of α - and β -diethoxydichloroquinones (*loc. cit.*) in alcohol, adding aniline equal in weight to that of the mixed quinones, and leaving the mixture for half an hour in the cold; the precipitated chloranilanilide is then filtered off, and more aniline added to the filtrate, which is then boiled for a quarter of an hour; the liquid is

filtered while hot, the precipitate washed with hot benzene, and the mixed filtrate and washings evaporated to crystallisation. Chlor-ethoxydianilidoquinone crystallises in long, steel-blue needles, melts at 232—233°, and partially sublimes undecomposed; it is insoluble in water and aqueous potash, which shows the absence of the hydroxyl group; it dissolves in alcoholic potash with an intense, brownish-red colour, and in concentrated sulphuric acid with a violet colour, like other dianilidoquinones and unlike anilidoquinols, which dissolve with an emerald-green colour, boiling alcohol, glacial acetic acid, and benzene dissolve it slightly, with an olive-green colour.

When aniline acts on α -diethoxydichloroquinone, both ethoxy-groups are eliminated (*loc. cit.*) from their para-positions, while the chlorine atoms remain. In the β -compound, one ethoxy-group and one chlorine atom are removed; hence neither the ethoxy-groups nor the chlorine atoms in the β -compound are in the para-positions; whether they are in the ortho- or meta-positions remains undecided. The constitution of chlorethoxydianilidoquinone is

Tetramethyldiamidochlorethoxyquinone, $[O_2 : (NMe_2)_2 : OEt : Cl = 1 : 4 : 2 : 5 : 3 : 6]$, is prepared by heating an alcoholic solution of β -diethoxydichloroquinone with a slight excess of dimethylamine, adding much water, and recrystallising the precipitate from dilute alcohol. It forms long, dark brownish-green needles, melts at 90—91°, is insoluble in cold, but slightly soluble in hot, water, and very soluble in alcohol, glacial acetic acid, ether, and benzene. *Dimethylidiumidochlorethoxyquinone*,

is formed when methylamine is substituted for dimethylamine; it crystallises in brownish-green leaflets melting with decomposition at 210°, and dissolves sparingly in boiling alcohol, but not at all in water. *Diunilochlorethoxyquinone*, formed when alcoholic ammonia is used, crystallises in long, dark-violet needles.

Chlorethoxypuradihydroxyquinone,

is obtained by boiling a weak aqueous alcoholic solution of β -diethoxydichloroquinone with excess of potash for some minutes, adding hydrochloric acid, and shaking with ether; it forms chocolate-brown, leafy crystals, melts at 168—170°, and partially sublimes in slender needles; it is very soluble in alcohol, ether, and hot benzene, with a brownish-red colour, slightly soluble in cold water and cold benzene, insoluble in strong hydrochloric acid, and soluble in alkalis with a blue-violet colour. When hydrochloric acid is added to a strong solution of it in an alkali, it crystallises gradually in thick, lustrous, dark-brown, rhombohedric tables (with 1 mol. H_2O). Several metallic compounds of this quinone were obtained. *Anilidohydroxychlorethoxyquinone*, $[O_2 : OH : NHPh : OEt : Cl = 1 : 4 : 5 : 3 : 6]$, is obtained by evaporating an alcoholic solution of the quinone with aniline, adding water, acidifying with hydrochloric acid, collecting the

precipitate and treating it with dilute ammonia to dissolve the anilide and leave the dianilide; on adding dilute sulphuric acid to the ammoniacal liquid, the anilide is precipitated in steel-blue needles. It melts with complete decomposition at about 180° , and dissolves easily in alcohol and glacial acetic acid with an ultramarine-blue colour.

The alkyl chloranilates are shown to be quinone derivatives, in that they form molecular compounds with the corresponding hydrochloranilates. *Tetrachlorotetramethoxyquinhydrone* crystallises in brilliant, ruby-red tables and prisms with a faint-green, metallic lustre, when dimethyl chloranilate and dimethyl hydrochloranilate, in molecular proportion, are dissolved in a boiling mixture of equal volumes of alcohol and glacial acetic acid. *Tetrachlorotetramethoxyquinonehydrone*, similarly obtained, forms long, dark blood-red needles. A. G. B.

Symmetrical Trinitrosophenylparabromazobenzene. By C. WILLGERODT (*Ber.*, 24, 1320).—*Trinitrosophenylparabromazobenzene*, $C_6H_2(NO)_3 \cdot N_2 \cdot C_6H_4Br$ [$N : (NO)_3 = 1 : 2 : 4 : 6$; $N : Br = 1 : 4$], is prepared by the reduction of picrylparabromophenylhydrazine, trinitrosophenylparabromazobenzene, dinitronitrosophenylparabromazobenzene, or nitrodinitrosophenylparabromazobenzene with potassium iodide in acetic acid solution; the compound crystallises from glacial acetic acid in yellow needles melting at 215° ; it is soluble in alcohol, benzene, or chloroform, but dissolves very sparingly in ether, and is insoluble in water. J. B. T.

Picrylchlorophenylhydrazine and Related Compounds. By C. WILLGERODT and A. BÖHM (*J. pr. Chem.* [2], 43, 482—496).—*Picrylparachlorophenylhydrazine*, $C_6H_2(NO_2)_3 \cdot NH \cdot NH \cdot C_6H_4Cl$, exists in two distinct modifications. A red, stable variety is obtained by warming together molecular proportions of 4-chlorophenylhydrazine and picryl chloride, in alcoholic solution. It crystallises from organic solvents in well-formed prisms, and decomposes at 174 — 175° . The other variety is formed by dissolving the chlorophenylhydrazine and picryl chloride in cold chloroform, and shaking the mixed solutions in the cold, when the compound separates as an amorphous, yellow mass. On recrystallisation from cold chloroform, slender, yellow needles which decompose at 170 — 171° are obtained. The yellow modification is rapidly converted into the red modification when boiled for a short time with alcohol, ether, or water.

Picrylparachlorazobenzene, $C_6H_2(NO_2)_3 \cdot N_2 \cdot C_6H_4Cl$, is obtained by the oxidation of picrylparachlorophenylhydrazine with an alcoholic solution of iodine or a solution of chromic acid in acetic acid. It crystallises from alcohol in reddish-yellow needles, and melts at 138 — 139° .

Dinitronitrosophenylparachlorazobenzene, $NO \cdot C_6H_2(NO_2)_2 \cdot N_2 \cdot C_6H_4Cl$.—This compound is obtained when picrylparachlorophenylhydrazine is boiled in a reflux apparatus with glacial acetic acid, until the red colour at first formed is changed to a bright yellow. On cooling the solution, soft, slender, yellow needles separate; these dissolve in acetic acid, benzene, and alcohol, and melt at 242 — 243° .

Dinitronitrosoparachlorazobenzene, $NO \cdot C_6H_2(NO_2)_2 \cdot N_2 \cdot O \cdot C_6H_4Cl$,
VOL. LX. 3 p

results on further oxidation of the corresponding azo-compound with a mixture of chromic and acetic acids. It crystallises from acetic acid in yellow needles, melts at $223-224^{\circ}$, and is readily soluble in benzene and chloroform.

Dinitrosonitrophenylparachlorazobenzene, $\text{NO}_2 \cdot \text{C}_6\text{H}_3(\text{NO})_2 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4\text{Cl}$, crystallises in greyish-yellow needles, and melts at 200° . It is obtained by heating picrylparachlorophenylhydrazine with alcohol for two hours at $110-120^{\circ}$.

Picrylnitroparachlorazobenzene, $\text{C}_6\text{H}_2(\text{NO}_2)_3 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{NO}_2$. This compound is prepared by boiling picrylparachlorazobenzene with three times its weight of a mixture of nitric and sulphuric acids for 3-4 hours. It crystallises best from alcohol in reddish-yellow scales, and melts with decomposition at $184-185^{\circ}$.

Dinitronitrosophenylparachlorazobenzene,

obtained on nitration of dinitronitrosophenylparachlorazobenzene with a mixture of nitric and sulphuric acids, crystallises from benzene or acetic acid in slender, yellow needles, and melts with decomposition at $180-181^{\circ}$. When this compound is heated for several hours with a very large excess of fuming nitric acid (sp. gr. 1.5) in presence of concentrated sulphuric acid, *dinitronitrosophenyl*dinitroparachlorazobenzene, $\text{NO} \cdot \text{C}_6\text{H}_2(\text{NO}_2)_3 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{NO}_2$, is formed, which crystallises in whitish-yellow needles, and decomposes at $160-161^{\circ}$, some 20° lower than the compound containing one nitro-group less. On continued boiling with a mixture of the acids, further nitration does not take place.

2:4-Dinitrophenylparachlorophenylhydrazine is formed on heating together, in alcoholic solution, α -dinitrochlorobenzene (1 mol.) and parachlorophenylhydrazine. It crystallises from alcohol or benzene in beautiful, blood-red prisms, decomposes at $148-149^{\circ}$; and, on oxidation with chromic acid in acetic acid, forms the corresponding *dinitrophenylparachlorazobenzene*, $\text{C}_6\text{H}_3(\text{NO}_2)_2 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4\text{Cl}$, which is dissolved by organic solvents, crystallises in reddish needles, and melts at $151-152^{\circ}$.

Nitronitrosophenylparachlorazobenzene, $\text{NO} \cdot \text{C}_6\text{H}_3(\text{NO}_2) \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4\text{Cl}$, is obtained on heating a mixture of 2:4-dinitrophenylparachlorophenylhydrazine and acetic acid in a reflux apparatus for $\frac{1}{2}$ to 1 hour. It crystallises from acetic acid in beautiful, greenish-yellow needles, and melts at $217-218^{\circ}$.

2:4-Dinitrosophenylparachlorazobenzene, $\text{C}_6\text{H}_3(\text{NO})_2 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4\text{Cl}$, is formed when the corresponding dinitrophenylparachlorophenylhydrazine is reduced by boiling it with alcohol; or more rapidly by heating together the two substances in a sealed tube at $115-120^{\circ}$ for 2-3 hours. On evaporation of its alcoholic solution, dark-red crystals are deposited, which decompose at $126-127^{\circ}$.

2:4-Dinitrophenylnitroparachlorazobenzene, obtained by heating for one hour a mixture of 2:4-dinitrophenylparachlorazobenzene with three times its weight of a mixture of nitric with sulphuric acid. It crystallises from acetic acid in yellow needles, and melts at $122-123^{\circ}$.

Trinitronitrosoazobenzenephenylhydrazine,

is prepared by heating together in a reflux apparatus phenylhydrazine (2 mols.) and trinitronitrosoparachlorazobenzene (1 mol.). It crystallises in dark-brown, microscopic scales which decompose at 115—116°.

Tetranitrosoazobenzeneparachlorophenylhydrazine,

obtained in a similar way to the last-described compound, crystallises in imperfect, dark-red, microscopic prisms, decomposes at 117—119°, and, on boiling 4—5 hours with acetic acid, gives *trinitronitrosoazobenzeneparachlorazobenzene*, $\text{C}_6\text{H}_4\text{Cl}\cdot\text{N}_2\cdot\text{C}_6\text{H}_3(\text{NO})\cdot\text{N}_2\cdot\text{C}_6\text{H}_2(\text{NO}_2)_3$, which forms reddish-yellow crystals, and decomposes at 202—203°.

Trinitronitrosoazobenzeneparachlorophenylhydrazine,

is formed by the action of trinitrosophenylparachlorazobenzene (1 mol.) on parachlorophenylhydrazine (2 mols.). It has a dark-red colour, and decomposes at 110—112°; on oxidation with chromic and acetic acids, it gives *trinitronitrosoazobenzeneparachlorazobenzene*, $\text{C}_6\text{H}_4\text{Cl}\cdot\text{N}_2\cdot\text{C}_6\text{H}_3(\text{NO}_2)_2\cdot\text{N}_2\cdot\text{C}_6\text{H}_2(\text{NO}_2)_3\cdot\text{NO}$, which crystallises in yellow needles, and decomposes at 217—218°; and on reduction by heating for 4—5 hours with alcohol in sealed tubes at 120°, furnishes *trinitrosunitrosoazobenzeneparachlorazobenzene*,

which only crystallises imperfectly, and decomposes at 146—147°.

Trinitronitrosoazobenzenenitroparachlorazobenzene,

is obtained when trinitronitrosoazobenzeneparachlorazobenzene is boiled for 2—3 hours with three times its weight each of nitric acid (sp. gr. 1.5) and concentrated sulphuric acid. It forms whitish-yellow crystals, only slightly soluble in alcohol, and decomposes at 189—190°.

Tetranitronitrosodisazobenzeneparachlorophenylhydrazine,

This compound is obtained by adding parachlorophenylhydrazine (2 mols.) to trinitronitrosoazobenzenenitroparachlorazobenzene (1 mol.) suspended in alcohol. It forms an almost amorphous, dark-red product, and decomposes at 120—122°.

That the above-described nitroso-compounds are simple azo-compounds, and not polymerides, is shown by the fact that their molecular weights, as determined by Raoult's method, agree with those calculated from the above-given formulæ.

G. T. M.

Amidotolyloxamethane. By H. SCHIFF and A. VANNI (*Ber.*, 24, 1315—1317; compare this vol., p. 702).—*Toluylenediozoxamethane*,

$C_6H_5Me(NH\cdot CO\cdot COOEt)_2$ [$Me : NH : NH = 1 : 2 : 4$], is prepared by heating amidotolylloxamethane with ethyl oxalate and a little alcohol; it is also found in the mother liquors obtained in the preparation of amidotolylloxamethane from ethyl oxalate and toluylenediamine; the compound is sparingly soluble in ether, from which it crystallises in needles melting at 130° ; the alcoholic solution is fluorescent.

Oramethanetolyloramide, $NH_2\cdot CO\cdot CO\cdot NH\cdot C_6H_5Me\cdot NH\cdot CO\cdot COOEt$ [$= 4 : 1 : 2$], is formed from amidotolylloxamide and ethyl oxalate in a similar manner to the preceding compound; it crystallises from dilute alcohol in tufts of colourless needles, and melts at 210° with decomposition. By the action of alcoholic ammonia on either of the preceding compounds, *toluylloxamide*, $C_6H_5Me(NH\cdot C_2O_2\cdot NH_2)_2$, is obtained as a white, crystalline powder decomposing above 220° without melting. *Toluylenedioramic acid*, $C_6H_5Me(NH\cdot CO\cdot COOH)_2$, is found in the aqueous mother liquors of the dioxamide; it is an unstable, viscid liquid, excessively sweet to the taste; the barium salt crystallises with $1H_2O$, and, like the silver and lead salts, readily undergoes decomposition.

Uramidotolyloramethane, $NH_2\cdot CO\cdot NH\cdot C_6H_5Me\cdot NH\cdot CO\cdot COOEt$, is prepared by the action of potassium cyanate on amidotolylloxamide sulphate in aqueous solution; it crystallises from alcohol, and melts at 218° . On treatment with ammonia, or by the action of potassium cyanate on amidotolylloxamide sulphate, *uramidotolyloramide*, $C_6H_5Me(NH\cdot CO\cdot NH_2)_2$, is formed; this is sparingly soluble in alcohol, and melts at 239° with partial decomposition. J. B. T.

Ethyl Acetoacetate Aldehydeuramide. By P. BIGINELLI (*Ber.*, 24, 1317—1312).—On boiling an alcoholic solution of ethyl acetoacetate, benzaldehyde, and carbamide in molecular proportion for two hours in a reflux apparatus, a compound is obtained crystallising in colourless, lustrous plates and melting at $207\text{--}208^\circ$; its constitution is expressed by one or other of the following formulæ, of which the second appears to be the more probable:—

The same substance is also formed by the interaction of ethyl uramidocrotonate and benzaldehyde. It is very stable, and is not affected by concentrated acids or alkalis in the cold; on boiling with dilute sulphuric acid, benzyl alcohol is produced, whilst, by heating with potash, it decomposes into benzyl alcohol, benzaldehyde, ammonia, and potassium carbonate; a yellow substance is also formed in small quantity, and is being further investigated. Salicylaldehyde, cinnamaldehyde, furfuraldehyde, cumaldehyde, and other aldehydes react in a manner similar to benzaldehyde, whilst the ethyl acetoacetate may be replaced by acetophenone or acetone; the resulting products are, however, less stable. J. B. T.

Formyl and Oxalyl Derivatives of Orthamidobenzamide. By E. KNAPE (*J. pr. Chem.* [2], 43, 209—231).—The orthamidobenz-

amide employed in this work was prepared from isatoic acid, itself prepared from isatin as described by Kolbe (Abstr., 1885, 665). Concerning the preparation of isatin, the author remarks that oxidation of indigo by chromic acid yields a purer product, whilst oxidation by nitric acid yields a larger quantity; he gives directions for obtaining a yield of 30—35 per cent. of pure isatin by Sommargau's method with nitric acid (*Ber.*, 17, 976). The orthamidobenzoic acid was prepared by reducing orthonitrobenzoic acid with tin and hydrochloric acid in alcohol; the yield was 47—50 per cent.

Formylorthamidobenzamide (Weddige, Abstr., 1885, 661) is best obtained by stirring orthamidobenzamide (1 mol.) with 95 per cent. formic acid ($1\frac{1}{2}$ mols.) until the mass is solid, evaporating the excess of acid on the water-bath, and crystallising from hot alcohol. It forms colourless, lustrous, rhombohedral crystals, sometimes needles; it dissolves in all hot solvents, and in most of them when cold; it melts at 123°, and when heated at 170°, or for some time with water or alkalis, it loses water and forms 2-oxyquinazoline (*loc. cit.*); this substance crystallises in long, slender, white needles, melts at 211—212°, and dissolves in the usual solvents, including acids and alkalis, except light petroleum; its solutions, especially the aqueous, fluoresce blue; its *platinochloride* forms an orange-red, microcrystalline precipitate.

γ -Methyl-2-oxyquinazoline, $C_6H_4 \begin{smallmatrix} \text{CO} \cdot \text{NMe} \\ \text{N} = \text{CH} \end{smallmatrix}$, is obtained by dissolving 2-oxyquinazoline in the calculated quantity of a solution of potash in methyl alcohol, and adding the calculated quantity of methyl iodide; it crystallises in long, lustrous needles, melts at 71°, and dissolves in the usual solvents, but will not crystallise from light petroleum. The *platinochloride* is described.

When orthamidobenzamide and 95 per cent. formic acid are stirred together in molecular proportion, *formyldiorthamidobenzamide*, $OH \cdot CH(NH \cdot C_6H_4 \cdot CONH_2)_2$, is obtained; it crystallises in thin, nearly quadratic, rhombic leaves or tables, melts at 135°, and dissolves freely in water, alcohol, benzene, ether, acetone, and hot chloroform; prolonged heating with water, alcohol, or dilute alkalis converts it into 2-oxyquinazoline; when heated at 150° until no more water is evolved, it yields a crystalline mass which gradually melts between 170° and 180°, and is so readily converted into 2-oxyquinazoline and orthamidobenzamide that it could not be analysed. Attempts to obtain a methyl derivative of formyldiorthamidobenzamide resulted in the formation of γ -methyl-2-oxyquinazoline and orthamidobenzamide. The *platinochloride* forms long, slender, lustrous, yellowish-red needles, which dissolve in alcohol with a blue fluorescence. A substance melting at 107—108° was obtained during the preparation of formyldiorthamidobenzamide, but in quantity insufficient for analysis.

Formylorthamidobenzomethylamide, $CHO \cdot NH \cdot C_6H_4 \cdot CO \cdot NHMe$, is obtained by mixing orthamidobenzomethylamide (Abstr., 1887, 1043) with formic acid in molecular proportion, evaporating on the water-bath, and crystallising from benzene; it forms clusters of needles, melts at 111—112° and dissolves in warm ether and benzene, less easily in

water and alcohol, and not at all in light petroleum; when heated at 190—200° for some hours, it is converted into γ -methyl- δ -oxyquinazoline. The *methiodide*, $C_{10}H_{11}N_2OI$, is obtained by heating formylorthamidobenzomethylamide with the calculated quantity of methyl iodide in methyl alcohol at 100° in a sealed tube for one hour; it crystallises in needles and leaflets; its *platinochloride*, for obtaining which it is converted into chloride by double decomposition with silver chloride, is an orange-yellow, crystalline powder insoluble in alcohol and ether; the corresponding *hydroxide* forms very slender crystals which are very soluble in water.

Weddige (Abstr., 1887, 1044) treated orthamidobenzamide with methyl iodide in alcohol in order to obtain orthomethamidobenzamide; the author substituted methyl for ethyl alcohol, and obtained dimethamidobenzamide at the same time. Orthamidobenzamide is dissolved in methyl alcohol, and heated with the calculated quantity of methyl iodide in a sealed tube at 100° for some hours; the mass is extracted with ether, the residue dissolved in as little water as possible, the solution filtered, the bases precipitated by ammonia, washed with cold water, and then treated with water at 70—80°; dimethamidobenzamide and unaltered orthamidobenzamide are thus dissolved, and on cooling, the former crystallises out. *Dimethamidobenzamide*, $NMe_2 \cdot C_6H_4 \cdot CONH_2$, forms needles, melts at 139—140°, and dissolves easily in acids; its *platinochloride* was obtained.

Formylorthomethamidobenzamide, $CHO \cdot NMe \cdot C_6H_4 \cdot CONH_2$, is prepared by heating orthomethamidobenzamide with the calculated quantity of formic acid in a tube at 100° for three hours; after decolorising with animal charcoal in alcohol, it crystallises in feathery, flat needles which soften about 100° and melt at 113°. When heated at 150—160° for some time, it yields a thick, yellow oil which solidifies after some days to small needles melting at 123—124°; the quantity obtained was insufficient to allow of this substance being identified as α -methyl- δ -oxyquinazoline, but it is certainly distinct from γ -methyl- δ -oxyquinazoline. The identity of the methyl derivatives obtained from formylorthamidobenzomethylamide and from δ -oxyquinazoline proves that the constitution of the latter is

The author has prepared Griess' carbimidoamidobenzoyl (Abstr., 1885, 1227), and finds that it melts at 211—212°, not 214°; he therefore concludes that it is identical with δ -oxyquinazoline, and that Griess' formula for it is incorrect.

Ethylorallylorthamidobenzamide, $COOEt \cdot CO \cdot NH \cdot C_6H_4 \cdot CONH_2$, was obtained once in several experiments, when the calculated quantities of orthamidobenzamide and ethyl oxalate were gradually heated together to 170°, alcohol being evolved. An amorphous precipitate separated from the alcoholic solution of the product; this was a mixture of several substances, from which, by fractional crystallisation, small, prismatic crystals of this ethyl derivative, melting at 158—159°, were obtained. From the mother liquor, a substance, $C_{15}H_{15}NO_2$, was obtained in needles melting at 140—141°; the amount

was insufficient for further investigation. A fibrous substance of uncertain composition melting at 177—178° was obtained when methyl oxalate was substituted for ethyl oxalate.

An *additive product* is obtained when orthamidobenzamide and ethyl oxalate are heated in alcohol; it forms thick, flat prisms, melts at 87—90°, and dissolves in cold alcohol, water, ether, acetone, and warm chloroform; it is decomposed into ethyl oxalate and orthamidobenzamide when heated at 80° for some time, or by the action of hydrochloric acid. A similar product is obtained with methyl oxalate; it forms short, slender needles, melts gradually between 80° and 90°, and dissolves in the usual solvents. A. G. B.

Alkyl Ketones from Halogen Derivatives of Aromatic Hydrocarbons. By A. CLAUS (*J. pr. Chem.* [2], 43, 355—363; compare Schweitzer, this vol., p. 684).

Orthochlorometamethyltolyl methyl ketone (orthochlorometacetyltoluene) [Me : Cl : COMe = 1 : 2 : 5] is obtained by the action of acetic chloride on orthochlorotoluene in carbon bisulphide in the presence of aluminium chloride; it is a colourless, strongly refractive liquid of agreeable aromatic odour, boiling at 238—242° (uncorr.); its *oxime* crystallises in thick, yellowish needles and melts at 112° (uncorr.). By oxidation with potassium permanganate in alkaline solution, it yields parachlorometatoluic acid [COOH : Me : Cl = 1 : 3 : 4] (m. p. 209°, uncorr.; Abstr., 1885, 1052), whose *calcium* salt crystallises with 3½ mols. H₂O, and 4-chlorisophthalic acid [(COOH)₂ : Cl = 1 : 3 : 4], which does not melt below 340°; this oxidation shows that in the ketone the acetyl group must occupy the para-position to the chlorine atom, and the meta-position to the methyl group.

Orthobromometamethyltolyl methyl ketone [Me : Br : COMe = 1 : 2 : 5] is prepared in like manner, and is a colourless, strongly refractive oil of agreeable, aromatic odour; it boils at 262—264° (uncorr.); its *oxime* crystallises in thick, white needles, and melts at 104° (uncorr.). When oxidised with permanganate, it yields parabromometatoluic acid (m. p. 209°, uncorr.; Abstr., 1882, 185), whose *barium* salt crystallises with 4 mols. H₂O, and 4-bromisophthalic acid (m. p. 287°, uncorr.), whose *barium* salt (with 1 mol. H₂O) is described.

When parachlorotoluene and parabromotoluene are acetylated in this way, the products seem to be mixtures; in the former case, the product boils at 235—240° (uncorr.), in the latter, at 261—265°.

Metachlororthomethyltolyl methyl ketone [Me : COMe : Cl = 1 : 2 : 5], similarly obtained, is a colourless, agreeably aromatic liquid which boils at 239—240° (uncorr.); its *oxime* crystallises in long, colourless, lustrous needles melting at 116° (uncorr.). By oxidation with permanganate, it yields parachlororthotoluic acid (m. p. 166°, uncorr.) and parachlorophthalic acid (m. p. 148°).

Metabromorthomethyltolyl methyl ketone is a colourless oil of agreeable aromatic odour which boils at 257—258° (uncorr.); its *oxime* forms long, soft, filamentous needles, and melts at 97° (uncorr.). By oxidation with permanganate it yields parabromorthotoluic acid (m. p. 187°, uncorr.) and parabromophthalic acid (m. p. 168°), whose anhydride melts at 106°.

4-Chlorometaxylyl methyl ketone is a colourless, aromatic oil, boiling at 26° (uncorr.); its oxime forms colourless needles, and melts at 103° (uncorr.).
A. G. B.

Action of Ammonia on Derivatives of the Ethyl and Methyl Salts of Orthamidobenzoic Acid. By E. ZACHARIAS (*J. pr. Chem.* [2], 43, 432–450; compare Hübner, *Annalen*, 195, 34).—Ethyl amidonitrobenzoate [$\text{COOEt} : \text{NH}_2 : \text{NO}_2 = 1 : 2 : 3$] is obtained by heating in a sealed tube at 130 – 150° a mixture of ethyl nitroethoxybenzoate [$\text{COOEt} : \text{OEt} : \text{NO}_2 = 1 : 2 : 3$] and alcoholic ammonia. It crystallises from 90 per cent. alcohol in beautiful, dark-yellow needles, and melts at 109° . On continued digestion with baryta-water, and subsequent addition of hydrochloric acid to the sparingly soluble barium salt thus obtained, a substance identical with amidonitrobenzoic acid [$\text{COOH} : \text{NH}_2 : \text{NO}_2 = 1 : 2 : 3$] separates.

Ethyl acetamidonitrobenzoate [$\text{COOEt} : \text{NHAc} : \text{NO}_2 = 1 : 2 : 3$] is obtained by heating together a mixture of ethyl amidonitrobenzoate and acetic chloride. It crystallises from water in white needles, melts at 102° , and is exceedingly soluble in cold alcohol, ether, benzene, chloroform, and light petroleum. On digestion with aqueous ammonia, it forms the corresponding ammonium salt, but, on heating in a sealed tube at 170° with alcoholic ammonia, the compound $\text{NO}_2 \cdot \text{C}_6\text{H}_3 < \begin{smallmatrix} \text{CO} \cdot \text{NH} \\ \text{N} = \text{C} \text{Me} \end{smallmatrix}$ is obtained. This compound is insoluble in ordinary solvents, except hot alcohol, from which it separates in small, brownish crystals; it melts with decomposition at 264° , gives a potassium salt crystallising in yellowish-red needles, and a methyl salt crystallising in white needles which melt at 175° ; it forms insoluble salts with the heavy metals; and, on reduction with tin and hydrochloric acid or stannous chloride, gives a base which crystallises in colourless needles, and melts at 230 – 232° . On acetylation of ethyl amidonitrobenzoate, a yellow compound is obtained, which appears to be an isomeride of the ethyl acetamidonitrobenzoate melting at 102° .

Ethyl nitrobenzoylamidobenzoate [$\text{COOEt} : \text{NHBz} : \text{NO}_2 = 1 : 2 : 3$] is obtained by warming ethyl amidonitrobenzoate (m. p. 109°) with benzoic chloride. It forms yellowish-white crystals, melts at 85.5° , and is readily soluble in alcohol, ether, benzene, and chloroform. On heating it with alcoholic ammonia, it yields the compound

which crystallises in slender, white needles, not melting at 250° , and forms a methyl salt crystallising from alcohol in slender, white needles which melt at 138° .

On treating ethyl diazobenzoate chloride, $\text{COOEt} \cdot \text{C}_6\text{H}_4 \cdot \text{N}_2\text{Cl}$ [$\text{COOEt} : \text{N} : \text{NCl} = 1 : 2$], obtained from ethyl orthamidobenzoate, with cold aqueous ammonia, benzazimide, $\text{C}_6\text{H}_4 < \begin{smallmatrix} \text{CO} \cdot \text{NH} \\ \text{N} = \text{N} \end{smallmatrix}$, is formed; but the author has not succeeded in producing a similarly constituted

closed-chain compound by the action of aqueous ammonia on ethyl methylnitrosoamidobenzoate [$\text{COOEt} : \text{N(NO)Me} = 1 : 2$]. When the last-named compound is heated at $140\text{--}150^\circ$ with aqueous ammonia, a mixture of orthonitrosomethylamidobenzamide and *methylamidobenzoic acid*, $\text{COOH} \cdot \text{C}_6\text{H}_4 \cdot \text{NHMe}$ [$\text{COOH} : \text{NHMe} = 1 : 2$], is obtained. The latter softens at 165° , melts at 170° , is soluble in all ordinary solvents, but does not form well-characterised salts.

G. T. M.

Diethylcarbобензоник Acid. By R. ANSCHÜTZ and W. BERNs (*Annalen*, 261, 298—309).—The acid first prepared by Limpricht and Schwanert (*Annalen*, 155, 63), by the action of alcoholic potash on deoxybenzoin, and named by Zagoumenny (this Journal, 1877, ii, 194) diethylcarbобензоник acid, has the composition $\text{C}_{15}\text{H}_{18}\text{O}_2$, but its constitution has not yet been ascertained. It distills under greatly reduced pressure with slight decomposition, and is insoluble in ammonia and alkaline carbonates, but soluble in concentrated potash; it seems not to contain a carboxyl group, and it does not combine with hydroxylamine, phenylhydrazine, or acetic anhydride. When treated with hydrogen chloride in alcoholic solution, it is converted into a colourless, liquid, *diethyl* derivative, which boils at $207\text{--}209^\circ$ (11 mm.) and has the composition $\text{C}_{20}\text{H}_{22}\text{O}_2$. It is not acted on by sodium amalgam, but when distilled over zinc-dust it yields stilbene, and when boiled with hydriodic acid and amorphous phosphorus it is converted into a colourless, crystalline compound melting at $132\text{--}134^\circ$, which the authors name *isodiethylcarbобензоник acid*; this substance is probably identical with the compound obtained by Limpricht and Schwanert (*loc. cit.*) by heating diethylcarbобензоник acid at 100° with hydrochloric acid.

When diethylcarbобензоник acid is boiled with excess of nitric acid of sp. gr. 1.18 until oxidation is at an end, it is converted into a compound of the composition $\text{C}_{15}\text{H}_{16}\text{O}_3$, which melts at 120° . On fusing it with potash in the manner described by Zagoumenny, an inflammable gas is evolved, and on dissolving the melt in water and acidifying with hydrochloric acid, there is produced a precipitate which is completely soluble in ammonia: when this product is distilled under greatly reduced pressure (12 mm.), it yields a small quantity of a colourless liquid with an odour of butyric acid, benzoic acid, and a thick, colourless oil boiling at about 176.5° (15 mm.), which has the composition $\text{C}_{11}\text{H}_{14}\text{O}_2$. On treating this oil with potassium permanganate, it is converted into benzoic acid; it is, therefore, a phenylvaleric acid, and not diethylbenzoic acid as was supposed by Zagoumenny; it is not identical with either of the known phenylvaleric acids, both of which, namely, the normal acid and phenylethylpropionic acid (benzylethylacetic acid), have been prepared by Baeyer and Jackson.

Ethyl phenylvalerate, $\text{C}_{13}\text{H}_{18}\text{O}_2$, prepared by treating the acid obtained from diethylcarbобензоник acid with hydrogen chloride in alcoholic solution, is a colourless liquid boiling at $144\text{--}146^\circ$ under a pressure of about 15 mm. The *chloride*, $\text{C}_{11}\text{H}_{13}\text{OCl}$, is obtained when the acid is treated with phosphorus pentachloride; it is a colourless liquid boiling at $129\text{--}131^\circ$ under a pressure of about 11 mm. The *anilide*,

$C_{17}H_{19}NO$, prepared from the chloride, separates from alcohol in rhombic crystals, $a : b : c = 0.68451 : 1 : 0.60844$, melting at $101-102^\circ$.

Benzylethylacetic acid (phenylethylpropionic acid) can be prepared by hydrolysing ethyl benzylethylacetoacetate; it boils at $172-174^\circ$ under a pressure of about 15 mm. The chloride is a colourless liquid boiling at $145-150^\circ$ under a pressure of about 24 mm. The anilide, $C_{17}H_{19}NO$, separates from alcohol in large, well-defined, monosymmetric crystals, $a : b : c = 0.81716 : 1 : 1.1885$, $\beta = 70^\circ 28'$, melting at $88-89^\circ$.
F. S. K.

Additive Products of Ethyl Sodacetoacetate and Sodiummalonate with Etheral Salts of Unsaturated Acids. By A. MICHAEL and P. C. FREER (*J. pr. Chem.* [2], 43, 390-395; compare Auwers, this vol., p. 546).—The first product of the reaction of ethyl sodacetoacetate on ethyl cinnamate (Abstr., 1887, 672) is an additive compound of one molecule of the latter with two molecules of the former. The compound $C_{18}H_{18}O_4$ is obtained when this additive product is heated with alcohol; it melts at $144-145^\circ$, not 140.5° (*loc. cit.*), and gives an amorphous, white *hydrazone*, $C_{18}H_{18}O_3 \cdot N \cdot NHPH$, which melts at $74-75^\circ$. When the compound $C_{18}H_{18}O_4$ is saponified with alcoholic potash, a *potassium* salt is obtained; the corresponding *acid* melts at 95° with evolution of carbonic anhydride, yielding a compound $C_{12}H_{12}O_3$, which crystallises in long, lustrous needles, melts at $184-185^\circ$, and dissolves in alcohol and ether, but not in light petroleum.

The substance $C_{12}H_{12}O_3$ yields two *oximes*, the one, $C_{24}H_{22}O_3 \cdot NOH$, when a neutral (*sic*) solution of the substance in ammonia is mixed with hydroxylamine hydrochloride, as a white, amorphous precipitate which melts with decomposition at $129-131^\circ$; the other, $C_{12}H_{12}O_3 \cdot NOH$, when hydroxylamine is added to an aqueous or alcoholic solution of the substance, as a white, amorphous compound melting at 172° and soluble in alcohol and ether but not in light petroleum; it is thus proved that $C_{12}H_{12}O_3$ contains a carbonyl group. The compound $C_{24}H_{22}O_3 \cdot NPh$, obtained by heating $C_{12}H_{12}O_3$ with aniline (equal mols.) in alcohol, crystallises in white octahedra, melts at $237-238^\circ$, and is insoluble in aqueous sodium carbonate and hydroxide.

When the compound $C_{12}H_{12}O_3$ is heated for some time with aqueous alkalis, a new substance $C_{12}H_{14}O_3$ is obtained; it crystallises from light petroleum in concentric groups of needles, from water and carbon bisulphide in large, hard prisms, melting at $83-84^\circ$; it behaves as an acid but not an unsaturated one; with iodine in an alkaline solution, it yields iodoform; its *silver salt* (with $\frac{1}{2}$ mol. H_2O) forms a white precipitate; its *oxime* is an amorphous substance, melts at $93-94^\circ$ with decomposition, and dissolves in alcohol and ether. Dilute potassium permanganate solution oxidises the substance $C_{12}H_{14}O_3$, with formation of benzoic acid and an unidentified, volatile acid. When reduced with sodium amalgam in alcohol, $C_{12}H_{14}O_3$ yields a thick oil, $C_{12}H_{14}O_3$, which distils undecomposed at $271-273^\circ$ (17 mm.) and behaves as a lactone, thus indicating that $C_{12}H_{14}O_3$ is a carboxy-acid of the constitution $COMe \cdot CH_2 \cdot CHPh \cdot CH_2 \cdot COOH$.

the lactone being a δ -lactone of the constitution

The substance $\text{C}_{12}\text{H}_{12}\text{O}_2$ has the same empirical formula as cinnamyl-acetone (m. p. 84°), but is not identical with it. A. G. B.

Derivatives of Phenyl Salicylate (Salol). By W. KNEBEL (*J. pr. Chem.* [2], 43, 378—389; compare Abstr., 1890, 1284).—*Phenyl acetylsalicylate* (*acetylsalol*), $\text{OAc} \cdot \text{C}_6\text{H}_4 \cdot \text{COOPh}$, is obtained by heating acetic chloride or acetic anhydride with dry phenyl salicylate and pouring the liquid into absolute alcohol; it forms stellate crystals and melts at 97° .

α -Phenyl nitrosalicylate [$\text{NO}_2 : \text{OH} : \text{COOPh} = 5 : 2 : 1$] has been already described (Abstr., 1890, 1284); it is also obtained by heating 5-nitrosalicylic acid (m. p. 222° ; compare Hübner, Abstr., 1879, 380) with phenol and phosphorus oxychloride at 120 — 130° for several hours (compare Nencki and Rasinsky, *J. pr. Chem.* [2], 31, 472).

β -Phenyl nitrosalicylate [$\text{NO}_2 : \text{OH} : \text{COOPh} = 3 : 2 : 1$] is prepared by heating 3-nitrosalicylic acid with phenol and phosphorus oxychloride at 100° ; it crystallises in prisms which melt at 101° .

α -Phenyl acetylnitrosalicylate, prepared from α -phenyl nitrosalicylate and acetic anhydride, crystallises in slender, white needles melting at 118° . The nitration of phenyl acetylsalicylate with nitric acid only yields α -phenyl nitrosalicylate. β -Phenyl nitracetylsalicylate, prepared from β -phenyl nitrosalicylate and acetic anhydride, melts at 95° .

Phenyl dinitrosalicylate (Abstr., 1890, 1284), is sparingly soluble in alcohol, more so in benzene and chloroform, and most so in glacial acetic acid. *Phenyl dinitracetylsalicylate* crystallises in slender, white needles and melts at 118° .

Orthonitrophenyl dinitrosalicylate (phenyl trinitrosalicylate, *loc. cit.*) is obtained by acting on phenyl salicylate with a mixture of nitric acid (sp. gr. 1.525) and strong sulphuric acid; it crystallises in silvery leaflets and melts at 100° . By saponification it yields orthonitrophenol. *Paramitrophenyl dinitrosalicylate* is similarly obtained, but the reaction mass is extracted with glacial acetic acid instead of alcohol; it forms yellowish needles and melts at 176° ; it yields paramitrophenol on hydrolysis. *Paramitrophenyl dinitracetylsalicylate* melts at 156° .

The author's attempts to obtain a trinitrosalicylic acid failed. An isomeride of dinitrosalicylic acid was obtained; it melts at 95° and is converted into the known acid (m. p. 173°) when recrystallised.

A. G. B.

Action of Ammonia and Methylamine on Derivatives of the Ethyl and Methyl Salts of Nitrohydroxybenzoic Acids. By P. THIEME (*J. pr. Chem.* [2], 43, 451—482).—When a mixture of ethyl nitrohydroxybenzoate [$\text{COOEt} : \text{NO}_2 : \text{OH} = 1 : 3 : 4$] and alcoholic ammonia is heated together for 8—16 hours, at 180° , in sealed tubes, the compound $\text{COOEt} \cdot \text{C}_6\text{H}_3(\text{NO}_2) \cdot \text{ONH}_4$ is formed, without the least trace of a nitrohydroxybenzamide.

Ethyl nitrethoxybenzoate [$\text{COOEt} : \text{NO}_2 : \text{OEt} = 1 : 3 : 4$] crystallises from alcohol in nearly colourless needles or scales, melts at 64° ,

is insoluble in water, but dissolves readily in alcohol, ether, benzene, and chloroform. On digestion with alcoholic ammonia at 130—140°, it is converted almost quantitatively into *ethyl nitramidobenzoate* [$\text{COOEt} : \text{NO}_2 : \text{NH}_2 = 1 : 5 : 4$], which crystallises from alcohol in long, yellow needles, melts at 136°, and readily sublimes. If aqueous ammonia is employed instead of alcoholic ammonia, *ammonium nitramidobenzoate* is formed.

Nitramidobenzamide [$\text{CONH}_2 : \text{NO}_2 : \text{NH}_2 = 1 : 3 : 4$] is obtained when the above-described ethyl nitramidobenzoate (m. p. 136°) is heated with aqueous ammonia. It crystallises from water in long, felted, yellow needles, melts with decomposition at 226°, and sublimes at a lower temperature.

Ethyl nitracetamidobenzoate [$\text{COOEt} : \text{NO}_2 : \text{NHAc} = 1 : 3 : 4$] crystallises in long, white, felted needles, melts at 95—96°, readily sublimes, and is converted on heating with aqueous ammonia into *ammonium nitramidobenzoate*.

Ethyl nitromethamidobenzoate [$\text{COOEt} : \text{NO}_2 : \text{NHMe} = 1 : 3 : 4$] is readily formed by heating ethyl nitrethoxybenzoate (m. p. 64°) with methylamine (2 mols.) in alcoholic solution. It crystallises from alcohol in orange-yellow, prismatic masses, melts at 100°, and, on treatment with potash and subsequent addition of hydrochloric acid, gives a corresponding *nitromethamidobenzoic acid*, which crystallises from alcohol in pale-yellow needles, and melts with decomposition at 295°.

Ethyl dinitrohydroxybenzoate [$\text{COOEt} : (\text{NO}_2)_2 : \text{OH} = 1 : 3 : 5 : 4$] is obtained on further nitration of the mononitro-compound (m. p. 64°) with a mixture of nitric and sulphuric acids. It crystallises from alcohol in long, stout, yellow needles (compare Salkowsky, *Annalen*, 163, 50), melts at 87°, and is converted by aqueous ammonia into the corresponding ammonium salt. *Ethyl dinitrethoxybenzoate* [$\text{COOEt} : (\text{NO}_2)_2 : \text{OEt} = 1 : 3 : 5 : 4$] crystallises in colourless needles melts at 56°, and is converted by alcoholic ammonia into the corresponding ethyl dinitramidobenzoate, which crystallises from alcohol in lemon-yellow, glistening scales, and melts at 114° (Salkowsky, *loc. cit.*).

Ethyl nitrethoxybenzoate [$\text{COOEt} : \text{NO}_2 : \text{OEt} = 1 : 4 : 5$] crystallises in white, prismatic needles, melts at 60—61°, and is converted, on heating at 180° with alcoholic ammonia, into the corresponding *nitrethoxybenzamide*, which crystallises from hot water in slender needles melting at 202°, and on hydrolysis with potash, and subsequent treatment with hydrochloric acid, gives the corresponding free *acid*, crystallising from alcohol in light-yellow needles, and melting at 216.5°. When heated with aqueous ammonia, ethyl nitrethoxybenzoate (m. p. 60—61°) is converted into *nitramidobenzoic acid* [$\text{COOH} : \text{NO}_2 : \text{NH}_2 = 1 : 4 : 5$], which crystallises from water in brick-red scales, and melts with decomposition at 290°.

Ethyl nitramidobenzoate [$\text{COOEt} : \text{NO}_2 : \text{NH}_2 = 1 : 4 : 5$] melts at 139° (compare Kayser, *Abstr.*, 1886, 149), and is converted by alcoholic ammonia, at 160—170°, into *nitramidobenzamide*

which crystallises from water in slender, reddish-yellow needles, and melts at 231—232°.

Ethyl nitrethoxybenzoate [$\text{COOEt} : \text{NO}_2 : \text{OEt} = 1 : 4 : 5$] is converted, by heating with methylamine, into *nitromethamidobenzo-methylamide* [$\text{CONHMe} : \text{NO}_2 : \text{NHMe} = 1 : 4 : 5$], which melts at 194°, and, on hydrolysis and subsequent treatment with acid, gives *nitromethylamidobenzoic acid* [$\text{COOH} : \text{NO}_2 : \text{NHMe} = 1 : 4 : 5$], crystallising from alcohol in rhombic plates or prisms, and melting with decomposition at 268°.

Nitrohydroxybenzoic acid [$\text{COOH} : \text{NO}_2 : \text{OH} = 1 : 2 : 3$] crystallises in yellow prisms containing 1 mol. H_2O , and, when anhydrous, melts at 178°. Its ethyl salt melts at 124°, and does not give a nitrohydroxybenzamide when heated with aqueous or alcoholic ammonia. The corresponding ethoxyethyl salt crystallises from alcohol in almost colourless, prismatic prisms or plates, melts at 53—54°, is not acted on by alcoholic ammonia, and gives, with aqueous ammonia, the original nitrohydroxybenzoic acid (m. p. 178°).

Ethyl nitrohydroxybenzoate [$\text{COOEt} : \text{NO}_2 : \text{OH} = 1 : 5 : 2$], which melts at 96°, gives Hübner's nitrohydroxybenzamide (m. p. 225°) on digestion with alcoholic ammonia. Under like conditions, the corresponding ethyl nitrethoxybenzoate (m. p. 68°) gives an ethyl nitramidobenzoate, which crystallises in slender, yellow needles melting at 145°, and corresponds in constitution with Hübner's nitroamidobenzoic acid (m. p. 263°).

Ethyl nitromethamidobenzoate [$\text{COOEt} : \text{NHMe} : \text{NO}_2 = 1 : 2 : 5$] is formed when the corresponding ethyl nitroethoxybenzoate (m. p. 194°) is heated in a sealed tube, at 150°, with methylamine (2 mols.). It crystallises in greenish-yellow needles, melts at 103°, and may be readily sublimed. The free acid crystallises in small, bright-yellow, pearly, rhombic plates, melts at 259°, and is easily soluble in alcohol and ether. *Nitromethamidobenzomethylamide*

crystallises in long, thin, yellow needles, melts at 204°, and readily sublimes.

Ethyl nitracetamidobenzoate [$\text{COOEt} : \text{NHAc} : \text{NO}_2 = 1 : 2 : 5$] forms long, colourless needles, melts at 153°, and is converted by alcoholic ammonia into *metanitro-β-methyl-β-oryquina-zoline*,

This compound crystallises from alcohol in almost colourless, four- or six-sided plates, turns brown at 280° without previously melting, and gives rise to salts, which are not well characterised, with the exception of the methyl salt, which melts at 165°; and may also be obtained by acting on ethyl nitracetamidobenzoate with ammonia.

Ethyl nitracetylmethamidobenzoate [$\text{COOEt} : \text{NMeAc} : \text{NO}_2 = 1 : 2 : 5$] forms large, colourless plates, and melts at 66°. On heating with alcoholic or aqueous ammonia, it furnishes *ethyl nitromethamidobenzoate* and ammonium nitromethamidobenzoate respectively.

The formation of the above-described compounds shows that the action of ammonia on the derivatives of the ethyl salts of nitrohydroxybenzoic acids is determined both by the relative position of the substituted groups in the nucleus, and by the temperature. In the case of the metanitrobenzoates, no acid amide is formed, whilst in that of the paranitrobenzoates, acid amides are readily formed. In the case of ethyl metanitro-orthoethoxybenzoate, only the ethoxyl attached directly to the nucleus is displaced by amidogen at 125°, whilst at 170—180° the ethoxyl of the carboxyl group is also replaced.

G. T. M.

Metanitrocoumarin. By C. TAEHE (*Arch. Pharm.*, 229, 71—83).—Nitrocoumarin, $\text{NO}_2 \cdot \text{C}_9\text{H}_6\text{O}_2$, obtained by the action of fuming nitric acid on coumarin, melted at 187°, but after sublimation between watch glasses this fell to 183°; Bleibtren (*Annalen*, 59, 191) gives the number as 170°. By oxidation with potassium permanganate in an alkaline solution, metanitrosalicylic acid was obtained, indicating that the carboxyl group is in the meta-position, and the nitrocoumarin is of the meta-type. Metamidocoumarin, $\text{C}_9\text{H}_7\text{NO}_2$, described by Frapoli and Chiozza (*Annalen*, 95, 253), was more simply prepared by dissolving nitrocoumarin in aqueous ammonia, heating nearly to boiling, and adding ferrous sulphate solution until the precipitate appeared pure black; this was filtered hot, washed a few times with hot water, and the filtrate was allowed to remain, when needles of the amidocoumarin crystallised out. This compound melts at 164°; Frapoli found 168°. The platinochloride was analysed. Dibromo-metanitrocoumarin, $\text{NO}_2 \cdot \text{C}_9\text{H}_4\text{Br}_2\text{O}_2$, was obtained by exposing powdered metanitrocoumarin in a thin layer to bromine vapour for some days. After washing with alcohol, and recrystallising from chloroform, the prisms obtained melted at 151°, dissolved readily in alcohol, chloroform, and ether, but with difficulty in carbon bisulphide and light petroleum. Nitrosalicylaldehyde (unsymmetrical, melting at 125°), when heated over the free flame with acetic anhydride and sodium acetate, is converted into metanitrocoumarin.

The Tannin of Algarobilla and Myrobalans. By G. ZÜLFEL (*Arch. Pharm.*, 229, 123—160).—The legumes of several Chilian plants of the genus *Caesalpinia* have been employed in Europe for tanning and dyeing. Two tanning principles are found in algarobilla: one, occurring to the extent of 8 to 10 per cent., is the glucoside of gallotannic acid, and by hydrolysis yields gallic acid and dextrose; the other, occurring in much larger quantity, is a sugar-free tannic acid which readily decomposes into ellagic acid, $\text{C}_{14}\text{H}_6\text{O}_8 + 2\text{H}_2\text{O}$. This new ellagotannic acid, $\text{C}_{14}\text{H}_{10}\text{O}_{10}$, has already been obtained in an impure form by Löwe, from the fruit of myrobalan and divi-divi. The dextrose noted above yields glucosazone when treated with phenylhydrazine (compare Fischer, *Abstr.*, 1885, 53). The molecule of ellagotannic acid contains five hydroxyl groups, replaceable by acetyl, and its constitution may be thus represented, $\text{C}_6\text{H}_3(\text{OH})_5 \cdot \text{COO} \cdot \text{C}_8\text{H}_3(\text{OH})_5 \cdot \text{COOH}$. Ellagic acid loses its water of crystallisation at 100°. This acid, when treated with acetic anhydride, yields a tetracetyl derivative, as Schiff also has shown. The tanning

principle of myrobalans is also a mixture of gallotannic glucoside with a much larger amount of ellagotannic acid. In both algarobilla and myrobalans, gallic acid exists in small quantity; the former also contains a little oxalic acid. J. T.

Shikimic Acid. By J. F. EYKMAN (*Ber.*, 24, 1278—1303).—Shikimic acid, $C_7H_{10}O_5$, the preparation of which has already been described (*Abstr.*, 1886, 95), forms a white, crystalline powder consisting of slender needles, melts at 184° , and has a sp. gr. of 1.599 at 14° . It dissolves in 5.5 parts of water, and in 20 parts of ordinary alcohol, readily forming supersaturated solutions, but is almost insoluble in absolute alcohol, ether, and benzene; it has a sp. rotation of -246.3° , and a conductivity constant of 0.0071. The ammonium salt, which crystallises in rhombic sphenoids ($a : b : c = 0.827 : 1 : 1.759$), has an even stronger rotatory power, and therefore these two substances are among the most powerfully active compounds at present known. The acid does not reduce silver or copper solutions, but immediately decolorises alkaline potassium permanganate.

When barium or calcium shikimate is heated to about 230° , it yields products which show the qualitative reactions of catechol and dihydroxybenzoic acid, whilst the acid on fusion with potash yields, in addition to these, two compounds which appear to be meta- and para-hydroxybenzoic acid. On distillation, the calcium salt yields considerable quantities of phenol, which is probably formed according to the equation $C_7H_{10}O_5 = C_6H_5O + CO_2 + 2H_2O$.

The anhydrides of fatty acids act upon shikimic acid at their boiling point with formation of tri-substituted derivatives, the triacetyl, tripropionyl, and tributryl compounds having been prepared. They are all yellowish, amorphous substances which could not be obtained crystalline; the number of acid radicles present was determined by titration, and in every case the result agreed with the supposition that three such groups have entered the molecule. Hence shikimic acid must contain 3 hydroxyl groups, and as it must, from its pronounced monobasic character, also contain a carboxyl group, the condition of all 5 atoms of oxygen is accounted for. Attempts were made to obtain ethereal salts of the acid, and of its triacetyl and tributryl derivatives, but in every case the etherification was only a partial one.

If shikimic acid is warmed with concentrated hydrochloric acid, partial carbonisation takes place; from the residue remaining on evaporation, ether extracts parahydroxybenzoic acid, which must be formed simply by the elimination of 2 mols. H_2O : $-C_7H_{10}O_5 - 2H_2O = C_6H_4(OH)COOH$. Other products are formed at the same time, but could not be identified.

Sodium amalgam reduces an acidified solution of shikimic acid, forming *dihydroshikimic acid*, $C_7H_{12}O_5$. This is separated by neutralising the solution with soda, adding slightly less than an equivalent of hydrochloric acid, and a large quantity of alcohol. After filtering off precipitated sodium chloride, the remainder of the chlorine is removed by silver oxide, the lead salt of dihydroshikimic acid pro-

precipitated by alcoholic lead acetate, and decomposed by hydrogen sulphide. The acid crystallises with great difficulty in hemimorphic, monosymmetric prisms ($a : b : c = 1.637 : 1 : 0.976$; $\beta = 46^\circ 0' 30''$), melts at 175° (uncorr.), and dissolves in 7 parts of water. It does not reduce silver or copper solutions, nor is it immediately oxidised by alkaline potassium permanganate. It dissolves in sulphuric acid on warming with evolution of carbonic oxide and formation of a brown solution, it has a sp. gr. of 1.47 at 9° , a conductivity constant of 0.0031, and a sp. rotation $[\alpha]_D = 18.2^\circ$; in the amorphous condition, however, it has a rotation four times as great. The amorphous acid is converted by hydrochloric acid, at 100° , into benzoic acid, but the crystallised acid must be more strongly heated before the decomposition takes place. The reaction takes place according to the equation $C_7H_{12}O_8 = C_6H_5 \cdot COOH + 3H_2O$.

When an equivalent of bromine is added to a supersaturated solution of shikimic acid, the *dibromide*, $C_7H_{10}Br_2O_8$, is formed, and crystallises from alcohol in rhombic sphenoids ($a : b : c = 0.933 : 1 : 1.010$). Its conductivity constant is about 100 times as large as that of shikimic acid, namely, 0.75, and it has a sp. rotation $[\alpha]_D = -58^\circ$. It reduces copper solution, and is reconverted by zinc and acetic acid into shikimic acid; on warming its aqueous solution, or, better, by the action of the theoretical quantity of silver oxide, it loses hydrogen bromide, forming *bromoshikimolactone*, $C_7H_8BrO_8$, which is also contained in the alcoholic and ethereal mother liquors of the dibromide. It is quite neutral, dissolves in water and ordinary alcohol, melts at 235° (uncorr.), and has a sp. gr. of 1.965 at 11° , and a sp. rotation $[\alpha]_D = +22^\circ$. It crystallises in hemimorphic hexagonal needles ($a : c = 1 : 2.4595$), and scarcely reduces copper solutions, but forms silver bromide on heating with silver nitrate.

When the bromolactone is treated with baryta-water, it is converted into *dihydroxyshikimic acid*, $C_7H_{12}O_7$, which crystallises in long, monosymmetric needles ($a : b : c = 2.021 : 1 : 1.407$; $\beta = 74^\circ 4'$), melts at 156° with formation of a lactone, is optically inactive, and has a conductivity constant 25 times as great as that of shikimic acid, namely, 0.072.

The author has also made certain observations with regard to quinic acid, $C_7H_{12}O_8$, and quinide, $C_7H_{10}O_8$, which are closely allied in constitution to shikimic acid. The sp. rotation of the former was found, in agreement with Hesse, to be $[\alpha]_D = -43.8^\circ$, and is therefore only one quarter of that found for shikimic acid, and varies much less with the concentration. Quinide was prepared according to Hesse's method (*Annalen*, 110, 335), and was found to have the properties ascribed to it by him. As it is completely neutral and optically inactive, it cannot be identical with shikimic acid. On boiling with milk of lime, it yields a calcium salt $(C_7H_{11}O_8)_2Ca + 4H_2O$, which, with acids, forms an inactive quinic acid. This has a conductivity constant of 0.022, compared with 0.0277 for the active acid.

The above results in the case of shikimic acid, although from lack of material not as complete as is desirable, show that it must be a *trihydroxytetrahydrobenzoic acid*, $C_6H_8(OH)_3COOH$. The position of the ethylene linkage and of the hydroxyl groups cannot be stated.

with certainty, but the author regards the following formula as the most probable:—

The stability of the compound towards alkalis renders it probable that the ethylene linkage is between the α - and β -carbon atoms (compare this vol., p. 452), and the above arrangement of the hydroxyl groups is the only one which readily explains the formation of the various benzene derivatives by the loss of water, unless the elimination takes place between groups in the para-position to one another, which is not at all probable. This formula is also in agreement with the relations between the conductivity constants of the different derivatives.

The constitution of quinic acid is regarded by the author as being probably represented by one of the following formulæ:—

H. G. C.

4 : 5-Dichlorophthalic Acid: Derivatives of Ortho-xylene.

By A. CLAUS and C. GRONWEG (*J. pr. Chem.* [2], 43, 252—259).—Experiments which will shortly be published show that the orientation of the dichlorortho-xylene which yields the dichlorophthalic acid melting at 183° (Abstr., 1885, 972) is [$\text{Me}_2 : \text{Cl}_2 = 1 : 2 : 4 : 5$]; the orientation of the acid is therefore also settled.

4 : 5-Dichlorophthalic anhydride, obtained by heating the acid at 130°, sublimes in long, colourless needles, and melts at 143° (uncorr.). The potassium, sodium, ammonium, barium (with 2 mols. H_2O), calcium (with 4 mols. H_2O), and copper salts are described. When the acid was distilled with the calculated quantity of soda-lime, it yielded a chlorobenzene which gave 4-nitro-1 : 2-dichlorobenzene (m. p. 43°) on nitration; this, taken in conjunction with the fact that neither of the chlorine atoms in this dichlorophthalic acid can be in the 3- or 6-position, is confirmatory of the above orientation.

4-Chloro-1 : 2-xylene boils at 195° (uncorr.), not 205° (Abstr., 1885, 972). 5-Nitro-4-chloro-1 : 2-xylene, obtained by mixing the chloro-xylene (1 vol.) with nitric acid, sp. gr. 1.5 (3—4 vols.) in the cold, and heating for half an hour on the water-bath, forms small needles which melt at 73° (uncorr.). 5-Bromo-4-chloro-1 : 2-xylene, obtained by brominating the chloro-xylene in chloroform in presence of iron, and distilling with steam, crystallises in long, colourless needles, and melts at 75° (uncorr.). Nitro-5-bromo-4-chloro-1 : 2-xylene, crystallises in small, colourless prisms, melts at 223° (uncorr.), and dissolves easily in acetone and in chloroform, sparingly in alcohol.

5-Bromo-4-chlorophthalic acid is obtained by heating the bromo-chloro-1 : 2-xylene with nitric acid (sp. gr. 1.1) for 5—6 hours in a sealed tube at 180—190°; it crystallises in aggregates of colourless, nacreous needles, melts at 205° (uncorr.), and is easily soluble in

water, alcohol, and ether. The *anhydride* sublimes when the acid is heated at 120° in the form of small needles; it melts at 185° (uncorr.). The *sodium* salt (with 3 mols. H_2O) and *barium* salt (with 3 mols. H_2O) are described.

4:5-Dichloro-3-bromo-1:2-xylene, obtained by brominating dichloro-ortho-xylene (m. p. 237° ?) with bromine in presence of iron, forms slender, colourless, felted crystals which melt at 90° (uncorr.).

A. G. B.

Benzeneazomalonic Acid. By R. MEYER (*Ber.*, 24, 1241—1245).—The author has already shown (*Abstr.*, 1888, 369) that the benzeneazomalonic acid obtained from diazobenzene chloride and ethyl sodiomalonate is identical with the compound prepared from phenylhydrazine and mesoxalic acid. In place of the method previously given, the author recommends the following:—16 grams of ethyl malonate is dissolved in 250 c.c. of alcohol, a solution of 14 grams of crystallised sodium acetate in 62 per cent. alcohol added, and then gradually a well-cooled solution of diazobenzene chloride, containing an excess of $\frac{1}{2}$ mol. hydrochloric acid, the temperature being kept below 0° during the addition, and the solution allowed to remain over night. The alcohol is then distilled off, solid soda added, and the precipitated sodium salt filtered off and decomposed with hydrochloric acid. To purify the acid it is dissolved in sodium carbonate solution, filtered, and the boiling solution again precipitated by hydrochloric acid. It then forms slender, yellow needles, melting at 163 — 164° with evolution of gas, which consists chiefly of carbonic anhydride and a little nitrogen, and also contains traces of ammonia and aniline. The *silver* salt, $PhN_2CH(COOAg)_2$, is a pale-yellow precipitate, and explodes on heating; it reacts very violently with ethyl iodide, and must be diluted with absolute alcohol in carrying out the reaction. The compound obtained is the *monethyl* salt, $PhN_2CH(COOH)(COOEt)$, which forms hair-like, yellow needles and melts at 114° . The author had hoped to obtain the *diethyl* salt, which would have one of the following formulae, according as it is an azo-compound or a hydrazone,

and examine whether it still contained a hydrogen atom replaceable by metals, in which case the first formula must be correct, whereas if no such replacement took place the compound must have the hydrazone constitution. At present this remains an open question.

H. G. C.

Ethyl Benzamidoxalacetate and Benzamidopyruvic Acid. By W. WISLIZIUS (*Ber.*, 24, 1257—1263).—When sodium ethoxide is added to a mixture of ethyl oxalate and ethyl hippurate, the action proceeds in the usual manner (*Abstr.*, 1888, 1178), *ethyl sodiobenzamidoxalacetate*, $COOEt\cdot CN_2(NHBz)\cdot CO\cdot COOEt$, being formed. It crystallises out in yellowish crusts, which become pure white when washed with ether; its aqueous solution gives a precipitate with silver nitrate, which blackens and yields a mirror on warming. Free *ethyl benzamidoxalacetate* (*ethyl oxalhippurate*),

is prepared by acidifying the aqueous solution of the sodium compound, extracting with ether, and evaporating in a vacuum. It is then obtained as an oil, which solidifies after a time; it crystallises from ether in slender, white, fascicular aggregates of needles, containing 1 mol. H_2O , which is partly evolved over sulphuric acid in a vacuum, with formation of the oily anhydrous ethyl salt. The hydrated compound melts at $73-74^\circ$, and gradually decomposes on continued heating, is readily soluble in hot water, ether, benzene, and alcohol, sparingly in light petroleum.

The crude ethereal solution in one instance deposited yellow crystals which melted at 164° with decomposition, had the composition $\text{C}_{11}\text{H}_{11}\text{NO}_3$, and gave a red coloration with ferric chloride in alcoholic solution. The constitution of this compound is unknown.

Ethyl benzamidoxalacetate readily yields a *hydrazone*, $\text{C}_{21}\text{H}_{23}\text{N}_3\text{O}_2$, which separates from ether in lustrous crystals, melts at $133-134^\circ$, and gives a deep violet coloration with ferric chloride in sulphuric acid solution. On boiling with acetic acid, it loses 1 mol. alcohol, and is converted into *ethyl phenylbenzamidopyrazolonecarboxylate*,

which forms yellow crystals and melts at $194-195^\circ$. On boiling with aqueous soda, the benzoyl group is not eliminated, but simple hydrolysis takes place, the corresponding acid being formed; the latter forms slender, yellowish, matted needles, melts at $185-190^\circ$ with decomposition, and is readily soluble in aqueous sodium carbonate, alcohol, and benzene, sparingly in water, ether, and light petroleum. The benzoyl group can only be eliminated by heating with hydrochloric acid at $160-170^\circ$, benzoic acid being then formed; the other products, however, form a resinous mass which could not be purified.

Ethyl benzamidoxalacetate is very readily decomposed by alkalis with formation of oxalic acid, hippuric acid and alcohol. On treatment with acids, however, an entirely different reaction takes place, benzamidopyruvic acid, alcohol, and carbonic anhydride being formed. The reaction is best carried out by treating the compound with fuming hydrochloric acid at the ordinary temperature, and allowing the mixture to remain for several days. The liquid is filtered from a little benzoic acid formed at the same time, and the filtrate evaporated in a vacuum; when a certain concentration is reached, the acid separates in reddish grains, which are purified by recrystallisation from ether. *Benzamidopyruvic acid*, $\text{NHBz}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{COOH}$, forms white, flocculent masses, which when quickly heated melt at 195° with sudden decomposition, and on slowly heating at $190-192^\circ$. It is soluble in hot water, alcohol, and aqueous sodium carbonate, and with phenylhydrazine, yields a *hydrazone* which cannot be readily purified. Its solutions give a dark bluish-green coloration with ferric chloride, and precipitate silver and copper from their solutions. On heating with hydrochloric acid, benzoic acid is formed, but the author has been unable to isolate amidopyruvic acid from the other products.

H. G. C.

Action of Iodine on Sodium Benzenesulphinate in the presence of Mercaptan. By R. OTTO and J. TRÖGER (*Ber.*, **24**, 1145—1146).—The authors undertook these experiments in the hope of obtaining disulphoxides by the action of iodine on a mixture of mercaptan and an alkali sulphinate. This reaction does not, however, take place. An alcoholic solution of sodium benzenesulphinate and sodium phenyl mercaptan when treated with iodine yielded phenyl bisulphide and benzenesulphoiodide. Sodium benzenesulphinate and sodium ethyl mercaptan, treated in a similar way, gave ethyl bisulphide and benzene sulphoiodide. E. C. R.

Thioanhydrides of Aromatic Thiosulphonic Acids and Polythiosulphonic Acids. By R. OTTO and J. TRÖGER (*Ber.*, **24**, 1125—1145).—*The Action of Iodine on Potassium Paratoluenethiosulphonate.*—When an aqueous solution of the thiosulphonate is mixed with a solution of iodine in aqueous potassium iodide until a slight excess of iodine is present, *toluenesulphothiosulphonic anhydride*, $(C_6H_4SO_2)_2S_2$, is formed. The mixture becomes milky, and a resinous compound is deposited, and is purified by extraction with ether; it crystallises from light petroleum in needles, sinters at 105° , and melts at 109° . This compound was the only product of the reaction: in all the other experiments a mixture was obtained of this compound and two others, namely, the *thioanhydride of toluenethiosulphonic acid*, $(C_6H_4SO_2)_2S$, and *toluenedisulphothiosulphonic anhydride*, $(C_6H_4SO_2)_2S_3$. For shortness sake these compounds are called the trithio-, the tetrathio-, and the pentathio-compound. Sulphonic acid and free sulphur are also formed by the action of iodine on the thiosulphonate; salts of toluenesulphonic acid were only obtained in insignificant quantity.

Potassium toluenethiosulphonate (40 grams) dissolved in water was gradually mixed with a 10 per cent. alcoholic solution of iodine (20 grams). The product is a white, crystalline mixture of the tetrathio- and pentathio-compounds with a little of the trithio-compound. By extraction with light petroleum, the trithio- and tetrathio-compounds are separated. The former is purified by crystallisation from alcohol, and melts at 133° . The product insoluble in light petroleum is crystallised from acetic acid, and yields the pentathio-compound which melts at 180 — 182° . Three other experiments gave a similar mixture. The tetrathio-compound is split up into the pentathio- and trithio-compounds when boiled for some time with acetic acid in a reflux apparatus. The trithio-compound (the thioanhydride of toluenethiosulphonic acid), $(C_6H_4SO_2)_2S$, is obtained by gradually adding a solution of iodine in potassium iodide to a solution containing potassium toluenesulphinate and potassium toluenethiosulphonate in molecular proportion. The product is purified by washing with a solution of potassium iodide and with water, and crystallisation from benzene. It melts at 133 — 134° . In a second experiment, the tetra- and pentathio-compounds were also obtained.

Action of Iodine on a mixture of Sodium Tolueneulphinate and Sodium Sulphide in molecular proportion.—W. Spring has stated that sodium thiosulphate is formed by the action of iodine on

a mixture of sodium sulphite and sodium sulphide (*Ber.*, 7, 1157). Hence it was of interest to study the action of iodine on a mixture of sodium toluenesulphinate and sodium sulphide. An alcoholic solution of iodine is gradually added to an aqueous solution of sodium sulphide and sodium toluenesulphinate in molecular proportion, until the yellow precipitate of sulphur which is first formed no longer redissolves; this shows that it no longer consists of sulphur, but of the thio-anhydrides of the thiosulphonic acid, that is, the products of the further action of iodine on the thiosulphonate first formed. The product was filtered, and the filtrate evaporated and extracted with alcohol. The alcoholic solution contains sodium toluenethiosulphonate. In a second experiment, enough iodine was added to convert all the thiosulphonate into thiosulphonic anhydride, and on crystallising the product from alcohol the trithio-compound (m. p. 134°) was obtained. Free sulphur was produced in all these experiments. From the production of free sulphur the authors conclude that the reaction takes place in two stages, as represented by the equations:— $\text{Na}_2\text{S} + \text{I}_2 = 2\text{NaI} + \text{S}$ and $\text{C}_7\text{H}_7\text{SO}_2\text{Na} + \text{S} = \text{C}_7\text{H}_7\text{SO}_2\text{SNa}$; and that the formation of sodium thiosulphate and sodium bisulphide observed by Spring is a similar reaction. For if a mixture of sodium sulphite and sodium sulphide in molecular proportion is carefully treated with an alcoholic solution of iodine, sulphur first separates, but redissolves on shaking or gently warming the mixture; and sulphur also separates when a small quantity of iodine solution is added to a solution of sodium sulphide.

Action of Chlorine on Potassium Toluethiosulphonate.—When the thiosulphonate dissolved in water is treated with an excess of chlorine, the pentathio-compound mixed with the tri- and tetrathio-compounds is formed; and from the mother liquors toluenesulphonic acid and toluenesulphochloride are obtained.

The thioanhydride of paratoluenethiosulphonic acid, $(\text{C}_7\text{H}_7\text{SO}_2)_2\text{S}$, crystallises in the monosymmetric system,

$$a : b : c = 2.8289 : 1 : 3.2212; \beta = 60^{\circ} 7'.$$

The pentathio-compound, $(\text{C}_7\text{H}_7\text{SO}_2)_2\text{S}_3$, crystallises from hot ethyl acetate in small, pointed prisms of adamantine lustre, $a : b : c = 1 : 1 : 2.732$. The crystals may belong either to the tetragonal or rhombic system.

The Action of Iodine on Potassium Benzenethiosulphonate.—An aqueous solution of the thiosulphonate is heated with a 10 per cent. alcoholic solution of iodine as long as precipitation takes place. The product is extracted with light petroleum and benzene, and the insoluble residue dissolved in acetic acid. The acetic solution deposited well-formed crystals of the *thioanhydride of benzenethiosulphonic acid*, $\text{S}(\text{PhSO}_2)_2$, melting at 133 – 134° . The petroleum extracts contain a mixture of the tetra- and pentathio-compounds, which could not be separated. Sulphuric acid and free sulphur are also formed in the reaction, as well as benzenesulphonic acid in inappreciable quantity. When potassium benzenethiosulphonate in aqueous solution is treated with chlorine, a product is obtained which smells faintly of benzenesulphochloride. On extraction with ether and crystallisation of the residue from alcohol, the pure *tetrathio-compound*, $(\text{PhSO}_2)_2\text{S}_2$, is

obtained, and melts at 76—77°. The ethereal extract contains a mixture of the tetrathio- and pentathio-compounds. Sulphuric and benzenesulphonic acids are also formed, and are found in the aqueous liquors. The tetrathio-compound when boiled with acetic acid is split up into the trithio- and pentathio-compounds, and by fractional crystallisation from ethyl acetate, the latter can be obtained pure and melts at 101—102°. Two other experiments on the action of chlorine gave no trace of the tetrathio-compound, but only the penta- and trithio-compounds, together with a substantial quantity of benzene sulphochloride, and sulphuric and benzenesulphonic acids. When a solution of 50 grams of the thiosulphonate, cooled with ice, is chlorinated, 25 grams of product insoluble in water are obtained, and this consists almost entirely of the trithio-compound (m. p. 128—132°).

The thioanhydride of benzenesulphonic acid, $(\text{PhSO}_2)_2\text{S}$, crystallises in the monosymmetric system, $a : b : c = 2.8320 : 1 : 2.8280$, $\beta = 67^\circ 6'$. Plane of the optic axis parallel to the plane of symmetry. The tetrathio-compound, $(\text{PhSO}_2)_2\text{S}_2$, crystallises in very thin, transparent, lustrous plates belonging to the monosymmetric system,

$$a : b : c = 2.2740 : 1 : 1.7425, \beta = 61^\circ 30'.$$

The pentathio-compound, $(\text{PhSO}_2)_2\text{S}_3$, crystallises in transparent, lustrous pyramids belonging to the tetragonal system, $a : b : c = 1 : 1 : 2.404$. They are hemihedral and are dextro-rotatory, $\omega = 1.7201$, $\epsilon = 1.7077$. Since this compound is isomorphous with the corresponding toluene derivative, the latter is also probably optically active, but the smallness of the crystals prevented the determination of the optical properties.

These thio-compounds dissolve easily in warm, aqueous potassium hydroxide, and also in aqueous potassium sulphide. The addition of hydrochloric acid to the solution precipitates sulphur, with formation of sulphinic acids. The pentathio-compound of toluene when heated with alcoholic ammonia in a sealed tube at 100° gives free sulphur and ammonium toluenethiosulphonate. Nascent hydrogen reduces the thioanhydrides to phenyl and tolyl mercaptans. The pentathio-compound when treated with metallic silver gives the disulphoxide, $\text{C}_7\text{H}_7\text{SO}_2\cdot\text{S}\cdot\text{C}_7\text{H}_7$, and the sulphonic anhydride, $(\text{C}_7\text{H}_7\text{SO}_2)_2\text{O}$. The latter is at once converted into the sulphonic acid.

Action of Iodine on a Mixture of Sodium Ethylsulphinic and Sodium Sulphide.—An aqueous solution of sodium sulphide and sodium ethylsulphinic in molecular proportion is carefully treated with an alcoholic solution of iodine in slight excess. A clear solution is obtained, from which ether extracts nothing. It contains sodium ethylthiosulphinic, which can be separated by evaporating to dryness and extracting with alcohol. When treated with zinc and hydrochloric acid, it yields ethyl mercaptan. Hydrochloric acid precipitates sulphur from the aqueous solution with production of sodium ethylsulphinic.

E. C. R.

Aromatic and Aliphatic Thiosulphonic Acids. By R. OTTO and A. RÖSSING (*Ber.*, 24, 1147—1156).—*The Action of Ethyl Chlorocarbonate on Alkali Salts of Aromatic Thiosulphonic Acids.*—The authors have shown that ethyl chlorocarbonate acts on an alkali aromatic sulph-

inate with production of the ethyl salt of an aromatic sulphinic acid. The action of ethyl chlorcarbonate on thiosulphonates was studied in order to determine if disulphoxides, $R \cdot SO_2 \cdot SC_nH_{2n+1}$, or the isomeric compounds $R \cdot SO \cdot SOC_nH_{2n+1}$ were produced. The reaction, however, takes place in quite a different way, and there are formed disulphoxides containing two similar aromatic residues, a sulphinic acid, ethereal salts of the sulphinic acid, and thioanhydrides of the thiosulphonic acid, with separation of carbonic anhydride and sulphur.

Potassium paratoluenethiosulphonate mixed with alcohol is gradually treated with a slight excess of ethyl chlorcarbonate: the mixture becomes acid. It is neutralised with potassium carbonate and the excess of ethyl chlorcarbonate neutralised with more thio-salt. The product is diluted with water and extracted with ether. The ethereal extract contains toluene disulphoxide, tolyl paratoluenethiosulphonate, ethyl toluenesulphinate, and a small quantity of the thioanhydride of toluenethiosulphonic acid. The residue, insoluble in water and ether, contains free sulphur, the thioanhydride of toluenedisulphothiosulphonic acid, $(C_7H_7SO_2)_2S_2$, and the trithio-compound. The aqueous liquors contain unaltered thiosulphonate and potassium toluenesulphinate. No gaseous products are evolved except carbonic anhydride. The authors put forward equations in explanation of this complicated reaction.

Potassium benzenethiosulphonate when treated with ethyl chlorcarbonate, behaves in an exactly similar way to the toluene salt.

Action of Phosphorus Pentachloride on Alkali Thiosulphonates.—Spring has stated that phosphorus pentachloride acts easily on sodium ethylthiosulphonate and yields a chloride which decomposes on heating, with separation of free sulphur, and when treated with caustic soda, yields the sodium thiosulphonate; so that its formula is probably EtS_2OCl . The authors, however, obtained a different result.

Potassium ethylthiosulphonate (2 mols.) is well mixed with phosphorus pentachloride (1 mol.) and the product poured into iced water. An oil is precipitated which is washed with very dilute potassium carbonate and dissolved in ether, and the product, after distilling off the ether, dried in a vacuum over sulphuric acid. The oily product contains only 3 per cent. of chlorine, which shows that very little chloride is present. When treated with aqueous potassium hydroxide, potassium ethylthiosulphonate is obtained. The explanation of this result is obtained on studying the products of the action of phosphorus pentachloride on potassium benzenethiosulphonate. The product of the action of phosphorus pentachloride on the latter salt is influenced by the proportions of the two compounds and also by the temperature. Phosphorus pentachloride first acts like free chlorine and phosphorus trichloride; potassium chloride and the thioanhydride of benzenethiosulphonic acid, $(PhSO_2)_2S_2$, are formed; the latter, as stated in the foregoing paper, easily splits up into the pentathio- and trithio-compounds. When the product is treated with potassium hydroxide, potassium benzenethiosulphonate is formed.

The authors conclude that the product obtained from potassium ethylthiosulphonate consists of compounds analogous to those obtained from salts of aromatic thiosulphonic acids.

E. C. R.

Synthesis of Indigo from Phenylglycocine. By L. LEDERER (*J. pr. Chem.* [2], 43, 303—304).—This constitutes the author's concluding remarks in the controversy between himself and Heumann as to priority.

Non-Formation of an Indigo Derivative by Fusing Paratolylglycocine with Alkalis. By K. HEUMANN (*Ber.*, 24, 1346).—Pure paratolylglycocine does not yield dimethylindigo on fusion with potassium hydroxide, as stated by Eckenroth (this vol., p. 722), and thus forms a remarkable exception to several other aromatic glycines which have been investigated by the author (this vol., p. 837).

A. R. L.

Isatin-blue. By C. SCHOTTEN (*Ber.*, 24, 1366—1373).—*Dipiperidylisatin*, $C_{16}H_{23}N_3O$, is prepared by heating an alcoholic solution of isatin (10 grams) with 2 molecular proportions of piperidine for an hour on the water-bath; the crystals formed are collected and washed with alcohol; a further quantity is obtained on adding water to the alcoholic filtrate; the yield is 15 grams. It crystallises from alcohol in colourless, flat prisms, does not decompose at 100° , and is sparingly soluble in cold alcohol, less so in ether, and almost insoluble in benzene and chloroform. It gives a blood-red solution with mineral acids, and, later, decomposes into isatin and piperidine, but is only resolved into the latter by alkalis, on heating; it dissolves in glacial acetic acid with decomposition, and production of a green colour. If it is heated to 100° and the temperature slowly raised to 150° , a blue colour is produced, piperidine in about 1 molecular proportion is eliminated, and ultimately a brown, crystalline compound is formed; whilst if it is quickly raised to a temperature between 125° and 160° , isatin-blue (see below) is produced.

Isatin-blue is prepared by shaking dipiperidylisatin with several times its weight of acetic anhydride in a closed flask, at the ordinary temperature or at 60° , pouring into water, collecting, and washing with water: it is also formed when dipiperidylisatin is heated with acetic anhydride and absolute ether in a sealed tube at 100° . It is a blue powder, which separates from glacial acetic acid in microscopic, dichroic prisms; a streak on a glass plate appears blue by transmitted and yellow in reflected light; it decomposes at 230° , a brown oil passing over; it is moderately soluble in glacial acetic acid, forming a deep-blue solution, less so in ether and alcohol, and insoluble in benzene and chloroform. Its solution in glacial acetic acid shows a very strong band between wave-lengths 655 and 628, and except beyond the red there is a weak continuous absorption; on standing, another band is observed between wave-lengths 589 and 580, which is, however, due to the decomposition of the compound. The band observed with a solution of indigo sulphate is between wave-lengths 643 and 616, but the latter shows a much stronger continuous absorption in the violet than isatin-blue. A compound dissolving in ether with a purple-red colour is formed when a solution of the new colouring matter in glacial acetic acid is allowed to remain, or more quickly when heated; also when dipiperidylisatin is treated with acid chlorides or anhydrous formic acid. Isatin-blue is readily decom-

posed by mineral acids, but may be boiled for some time with alcoholic potash before the colour of the solution changes to red; on distilling with the latter, however, piperidine passes over, and a brownish-red compound, sparingly soluble in alcohol, and not showing the indophenin reaction, remains behind. When dipiperidylisatin (2 mols.) is treated with acetic anhydride, piperidine (3 mols. about) is obtained, and this leads to the formula $C_{21}H_{17}N_3O_2$ for isatin-blue, whilst the values obtained by the elementary analysis of the latter agree with the formula $C_{26}H_{20}N_4O_4$; its formation and constitution are therefore obscure, but it may be related to or identical with the colouring matter obtained by V. Meyer (Abstr., 1884, 587), and by Ciamician and Silber (*ibid.*, 740), by the action of pyrroline on isatin; it also resembles indin and isatopurpurin. The author is investigating the action of piperidine on quinone and quinol.

A. R. L.

Benzidinedisulphonic Acid. By H. LIMPRICHT (*Annalen*, 261, 310—338).—The author has prepared a number of derivatives of benzidinedisulphonic acid, $\overset{2}{SO_3H} \cdot \overset{1}{C_6H_3}(\overset{4}{NH_2}) \cdot \overset{1}{C_6H_3}(\overset{4}{NH_2}) \cdot \overset{2}{SO_3H}$; the preparation of this acid, which was at first thought to be hydrazo-benzenedisulphonic acid, has been previously described (Abstr., 1889, 399; compare also Abstr., 1890, 987).

When benzidinedisulphonic acid (10 grams) is dissolved in soda, the solution mixed with sodium nitrite (2 grams), then gradually treated at 0° with dilute sulphuric acid and kept for several days in the cold, the *diazo*-compound, $SO_3H \cdot C_6H_3(NH_2) \cdot C_6H_3 \cdot \overset{SO_2}{\underset{N}{\text{>}}}$, is deposited in reddish-yellow crystals, together with benzidinedisulphonic acid and the tetrazo-derivative; if, however, the solution is allowed to get warm during the process, the tetrazo-compound alone is formed. As the *diazo*-compound was not obtained in a pure condition, and many of the substances described below were prepared from this impure *diazo*-compound, and as, moreover, no special precautions were taken to free them from benzidinedisulphonic acid, &c., they cannot be regarded as pure chemical compounds.

Hydroxyamidodiphenyldisulphonic acid,

is formed when the crude *diazo*-compound is boiled with water, and can be isolated by means of its barium salt; it is a soft, yellow substance, very readily soluble in water and alcohol. The *barium* salt, $C_{12}H_9NS_2O_7Ba + 7$ or $8H_2O$, crystallises in small, efflorescent, reddish needles or prisms, is readily soluble in water, and loses the whole of its water at 175 — 180° . The *potassium* salt and the *lead* salt crystallise in long, efflorescent, colourless prisms, and are readily soluble in water.

Bromamidodiphenyldisulphonic acid can be prepared by boiling the crude *diazo*-compound with copper bromide or with concentrated hydrobromic acid; the *barium* salt, $C_{12}H_9S_2O_6NBr$, crystallises in small, efflorescent needles, is moderately easily soluble in hot water, and loses its water at 160° .

Hydrazineamidodiphenyldisulphonic acid was obtained, but only in a very impure condition, by reducing the crude diazo-compound with stannous chloride and hydrochloric acid; it is a pale yellow, crystalline compound, only sparingly soluble in hot water. The barium salt, $C_{12}H_{11}N_3S_2O_6Ba + 4H_2O$, forms small, lustrous crystals. When the acid is boiled with copper sulphate, it is converted into *amido-diphenyldisulphonic acid*, the barium salt of which forms small, efflorescent crystals, having the composition $C_{12}H_9NS_2O_6Ba + 4H_2O$.

The tetrazo-compound, $C_{12}H_9N_4S_2O_6 + 2H_2O$?, is deposited in yellow crystals when benzhidinedisulphonic acid (25 grams) is treated with sodium nitrite (10.2 grams) and sulphuric acid, as described above, and the solution then kept for some days in a cool place (compare Balentine, Abstr., 1880, 809); it is very unstable, and therefore its composition could not be accurately determined. The *hydrobromide*, $C_{12}H_9N_4S_2O_6.HBr + 2H_2O$, prepared by treating dihydrazinediphenyldisulphonic acid with bromine in alcoholic solution, crystallises in reddish-yellow plates, is insoluble in alcohol, and is decomposed by water, yielding the tetrazo-derivative.

Dihydrazinediphenyldisulphonic acid is obtained when the tetrazo-compound is reduced with stannous chloride in the cold; it crystallises in yellowish prisms (with 2 mols. H_2O ?), and is only very sparingly soluble in hot water and insoluble in alcohol, ether, and chloroform. The barium salt, $C_{12}H_{11}N_4S_2O_6Ba$, seems to crystallise with 3 mols. H_2O , of which two are expelled at 110° .

Diphenyldisulphonic acid, $SO_3H.C_6H_4.C_6H_4.SO_3H$ is formed when the preceding compound is boiled with copper sulphate, and when the tetrazo-compound is boiled with finely-divided copper and 95 per cent. alcohol; it is a syrup. The barium salt (with 6.5 mols. H_2O) forms large, transparent, efflorescent prisms, and is readily soluble in water, but only sparingly in alcohol. The lead salt (with 5 mols. H_2O) crystallises in efflorescent needles, and is very readily soluble in water. The potassium salt crystallises in four-sided prisms, and is readily soluble. The *chloride*, $C_{12}H_8S_2O_4Cl_2$, crystallises from chloroform in small, colourless prisms, melts at 138° , and is readily soluble in ether, benzene, and chloroform. The *amide*, $C_{12}H_8S_2O_4(NH_2)_2$, crystallises from alcohol or water, in both of which it is readily soluble, in four-sided, colourless prisms, containing 2 mols. H_2O , and softens at about 300° . The *anilide*, $C_{12}H_8S_2O_4(NHPh)_2$, separates from alcohol in small, colourless crystals melting at 157° .

Dinitrodiphenyldisulphonic chloride, $C_{12}H_8S_2O_4Cl_2(NO_2)_2$, is obtained when the chloride just described is treated with a mixture of fuming nitric acid and concentrated sulphuric acid; it crystallises from chloroform in small rhombohedra and melts at 202° . The corresponding *amide* forms yellow, well-defined, rhombic plates, and does not melt below 260° .

Diphenol, $C_{12}H_8(OH)_2$ [$= 2:2'$], is formed when diphenyldisulphonic acid is fused with alkalis; it forms large, transparent prisms, melts at 99° , and is probably identical with the compound (m. p. 98°) obtained from fluorene by Hodgkinson and Matthews (Trans., 1883, 163).

Diphenoldisulphonic acid can be obtained by boiling the tetrazo-derivative of benzhidinedisulphonic acid with water (40 parts) for

pare Brunneman, Abstr., 1880, 807); it is a crystalline compound, readily soluble in water. The *barium* salt (with 2 mols. H_2O) and the lead salt (with 4 mols. H_2O) form well-defined crystals and are soluble in water. The *tetranitro*-derivative is formed when the acid is evaporated with nitric acid; its *sodium* salt (with 1 mol. H_2O) and *potassium* salt are yellow, crystalline compounds.

F. S. K.

Isobenzile. By H. KLINGER and O. STANDKE (*Ber.*, 24, 1264—1271).—Isobenzile may be prepared by the following method more readily than by the one previously given (Abstr., 1883, 920; 1886, 888):—900 grams of sodium amalgam (2·5 per cent.) is covered with 150 c.c. of dry ether, and 100 grams of benzoic chloride gradually added with constant cooling. After an hour, the product is placed in warm water and kept boiling for 36 hours, care being taken to exclude moisture. The yellow or yellowish-brown solution is then filtered, well shaken with sodium carbonate solution to remove benzoic acid and chloride, the ether distilled off, and the residue allowed to remain in a vacuum. The crystals which separate are collected and washed with a little ether; they consist of isobenzile mixed with a little of the compound melting at $242\text{--}244^\circ$, the formation of which was previously observed by Klinger (Abstr., 1883, 920). This is separated by recrystallising from hot alcohol and finally from cold ether, in which the high melting compound is sparingly soluble. Isobenzile crystallises well from acetic acid, forming lustrous, compact crystals, and melts 3° higher than formerly stated, namely, at 159° . It decomposes partially on boiling, forming benzoic anhydride.

It has already been shown that isobenzile is converted by bromine into benzile and benzoic bromide, and by nitric acid into benzile and benzoic acid, from which it would appear to be the benzoate of an alcohol containing the group $\text{PhC}\cdot\text{CPh}$, which is formed by the reduction of benzoic chloride, and then further acted on by the excess of the latter. This view was confirmed by the fact that the compound melting at $242\text{--}244^\circ$ is *hydrobenzoin dibenzoate*, which must be formed in the following manner:—

It is also readily obtained by the action of silver benzoate on stilbene dibromide.

By the action of alcoholic potash, isobenzile is resolved into benzoin and benzoic acid, and it must, therefore, be *diphenylacetylene dibenzoate*, $\text{PhC}\cdot\text{OBz}$, the corresponding diphenylacetylene glycol first formed by the hydrolysis passing at once into the tautomeric benzoin,

This formula is in agreement with the molecular weight found by Raoult's method, and readily explains the action of bromine and nitric acid on isobenzile, the benzoin first formed being oxidised to benzile.

By the action of hydrochloric acid on isobenzile the authors obtained benzoic acid and benzile, instead of benzoin as expected. This result is accounted for by Klingemann's observation, that benzoin itself is for the most part converted into benzile by the action of hydrochloric acid.

Attempts to synthesise isobenzile from toluene dibromide and silver benzoate have been made without success. H. G. C.

New Synthesis of Isobenzile. By H. KLINGER and L. SCHMITZ (*Ber.*, 24, 1276—1277).—By the action of sodium wire (3·3 grams) on a solution of benzoic chloride (20 grams) and benzaldehyde (15·1 grams) in anhydrous ether, a yellow solution is obtained, which on filtering leaves a residue of hydrobenzoin dibenzoate, sodium chloride, and sodium benzoate. The ethereal solution on evaporation leaves a residue which is distilled in a current of steam and treated with sodium carbonate solution to remove benzaldehyde, benzyl alcohol, and benzoic acid; the pasty residue is then recrystallised from acetic acid, and yields a mixture of hydrobenzoin benzoate and isobenzile; these are separated by means of alcohol and ether. The yield of isobenzile is not good; in its formation, it is possible that benzaldehyde and benzoic chloride unite directly, forming the compound $\text{CHPhCl} \cdot \text{OBz}$, 2 molecules of which then combine, with loss of hydrogen chloride and formation of isobenzile. H. G. C.

Naphthoic Acids. By Å. G. EKSTRAND (*J. pr. Chem.* [2], 43, 409—432; compare *Abstr.*, 1889, 52, 152, and this vol., p. 77).—**Nitro- β -naphthoic Acid.**—The *ethyl* salt of this acid is present in small quantity in the mother liquor from which the previously described nitronaphthoic acids (this vol., *loc. cit.*), are obtained, and crystallises from a solution of the mixed ethyl salts in acetic acid in the form of nodules, which, on repeated crystallisation from alcohol, give rhombic plates melting at 92° . The free acid crystallises in small, colourless needles, melts at 279° , and is readily soluble in alcohol; the *calcium* salt crystallises with 7 mols. H_2O , and is only slightly soluble in water. On reduction with ferrous sulphate in ammoniacal solution, the acid furnishes an *amido- β -naphthoic acid*, which crystallises from dilute alcohol in needles melting at 211° .

In addition to the four nitro- β -naphthoic acids specified, a fifth appears to be formed amongst the products of nitration. The author has not succeeded in isolating the free acid, but has obtained the *ethyl* salt in the form of long, hard, colourless needles; it melts at 131° .

Chloro- β -naphthonitrile, $\text{C}_{10}\text{H}_7\text{Cl} \cdot \text{CN}$, obtained on chlorination of a cold solution of β -naphthonitrile in acetic acid containing iodine, melts at 144° , and is converted into the crystalline *amide*, $\text{C}_{10}\text{H}_7\text{Cl} \cdot \text{CONH}_2$ (needles melting at 186 — 187°), on boiling with alcoholic potash, until ammonia commences to be evolved.

Chloro- β -naphthoic acid is conveniently prepared by digesting the above-mentioned nitrile (m. p. 144°) with alcoholic potash in a reflux apparatus; it crystallises from alcohol and acetic acid in colourless needles, and melts at 263° . The *ethyl* salt melts at 45° ; the sodium salt crystallises with 2 mols. H_2O , and the *barium* and *calcium* salts

with $4\frac{1}{2}$ mols. H_2O and $3\frac{1}{2}$ mols. H_2O respectively. The acid has most probably the constitution $[\text{COOH} : \text{Cl} = 2 : 1']$ or $[\text{COOH} : \text{Cl} = 2 : 4']$.

Chloronitro-β-naphthoic acid is obtained by heating chloro-β-naphthoic acid (m. p. 263°) with excess of nitric acid of sp. gr. 1.42. On cooling the clear solution, the acid separates in the form of slender needles, which, on recrystallisation from acetic acid, give a pure, colourless product; this melts at 271° . The *ethyl* salt melts at 118° ; the *calcium* salt crystallises with 5 mols. H_2O , and is only sparingly soluble in water.

Chlorodinitro-β-naphthoic acid is formed on warming the chloro-β-naphthoic acid (m. p. 263°) with red, fuming nitric acid in presence of a small quantity of concentrated sulphuric acid. It crystallises in long, flat needles, melts at 243° , and gives an *ethyl* salt forming brownish needles and melting at 132° .

Chlorotrinitro-β-naphthoic acid is obtained on warming in a water-bath a mixture of chloro-β-naphthoic acid (m. p. 263°) with a large excess of fuming nitric acid mixed with an equal volume of concentrated sulphuric acid. It crystallises from warm acetic acid in hard, yellow, apparently octahedral crystals, and melts with decomposition at 260 – 261° . The *ethyl* salt crystallises in needles which melt at 188° ; and the *calcium* salt in golden-yellow needles containing 2 mols. H_2O .

Chloro-β-naphthoic acid is obtained on diazotising the amido-β-naphthoic acid melting at 219° . It crystallises in slender, white needles, and melts at 260° . The *ethyl* salt is not well characterised; the *barium* salt crystallises in needles and contains 6 mols. H_2O ; and the *calcium* salt crystallises in nodular aggregates containing 7 mols. H_2O .

Dichloro-β-naphthonitrile is formed when a hot solution of β-naphthonitrile in acetic acid containing iodine is treated with excess of chlorine. It crystallises in needles, melts at 140° , is only sparingly soluble in alcohol; and, when cautiously heated with alcoholic potash, forms the *amide*, $\text{C}_{10}\text{H}_5\text{Cl}_2\text{CONH}_2$, which crystallises in slender, colourless needles, and melts at 218° . If the heating with potash be continued, dichloro-β-naphthoic acid (m. p. 291°) is produced, and this is identical with the acid obtained on direct chlorination of β-naphthoic acid in hot acetic acid solution containing iodine. The *ethyl* salt crystallises from alcohol in long needles, and melts at 66° ; the *potassium salt* (1 mol. H_2O) and the *barium salt* (4 mols. H_2O) both crystallise in colourless needles, and are well characterised; the *calcium salt* ($2\frac{1}{2}$ mols. H_2O) forms small prisms which are only slightly soluble in water (1 part in 3018). This acid is also the chief product of further chlorination of both the chloro-β-naphthoic acids m. p. 263° and m. p. 260° respectively, and must, therefore, have the constitution $[\text{Cl}_2 : \text{COOH} = 1 : 4' : 2]$. On oxidation with potassium permanganate, it appears to give a mixture of dichlorophthalic acid (75–80 per cent.) and trimellitic acid (20–25 per cent.).

Dichlorodinitro-β-naphthoic acid is obtained on heating dichloro-β-naphthoic acid (m. p. 291°) with a mixture of fuming nitric acid and concentrated sulphuric acid in a water-bath, until the solid is nearly all dissolved. On crystallisation from acetic acid, it forms rhombic

plates and melts at 283°. The *ethyl* salt melts at 128°; the *calcium* salt crystallises with 6 mols. H_2O .

On nitrating dichloro- β -naphthoic acid (m. p. 291°) with nitric acid of sp. gr. 1.42, at least two nitrodichloro-derivatives, both crystallising in needles, and melting at 247° and 261° respectively, are formed. In this respect dichloro- β -naphthoic acid resembles β -naphthoic acid.

Dichloro- β -naphthoic acid is obtained by first reducing and then diazotising the dinitro- β -naphthoic acid melting at 226°. It crystallises in needles, melts at 282°, gives an *ethyl* salt melting at 72°, and a sodium salt and a calcium salt, both crystallising in needles and containing 2 mols. H_2O and $3\frac{1}{2}$ mols. H_2O respectively.

Dichloro- β -naphthoic acid obtained from the dinitro-acid giving the diamido-acid melting at 248° crystallises in needles, melts at 254°, and gives an *ethyl* salt melting at 86—87°.

Bromo- β -naphthoic acid, obtained by the action of bromine on β -naphthoic acid suspended in water, crystallises in colourless needles, melts at 258°, and gives an *ethyl* salt crystallising in long, white needles melting at 53—54°. These characteristics differ from those ascribed to the compound by Hausemann (this Journal, 1876, i, 599).

G. T. M.

Alizarinsulphonic Acids; Conversion of Anthraquinone- α - and β -disulphonic Acids into Flavopurpurin and Anthrapurpurin. By R. E. SCHMIDT (*J. pr. Chem.* [2], 43, 232—237).—The author brings forward evidence to show that the intermediate products obtained during the conversion of anthraquinone- α - and - β -disulphonic acids into flavopurpurin and anthrapurpurin, respectively, by fusion with sodium hydroxide, are alizarinsulphonic acids (compare Graebe and Liebermann, *Annalen*, 160, 139; Perger, *J. pr. Chem.* [2], 8, 159). They both dye mordanted wool, and can be obtained directly from alizarin; the latter fact is of technical importance, because the best yield of these acids which can be obtained by melting the anthraquinonedisulphonic acids with sodium hydroxide is not more than 30 per cent., it being difficult to stop the fusion at the right moment. The process is patented by F. Bayer and Co.; it consists in acting on alizarin or the "usual alizarinsulphonic acids" with sulphuric anhydride (5—10 mols.) in the form of anhydrosulphuric acid of 25—30 per cent., until a portion of the mixture gives a not very intense, dirty colour on dissolving it in ice-cold water and adding sodium hydroxide. The alizarindisulphonic acids thus formed, unlike alizarinsulphonic acids, are not precipitated by sodium chloride, but are entirely thrown out by potassium chloride. To convert the disulphonic acids into the monosulphonic acids, they are heated with sulphuric acid (60° B.) in an open vessel at 180°. This mixture of alizarinsulphonic acids when melted with potassium hydroxide yields flavopurpurin and anthrapurpurin in almost equal proportions.

It is commonly stated in chemical literature that anthraflavic and isocanthraflavic acids are intermediate products in the preparation of flavopurpurin and anthrapurpurin; they are not so, but only by-products. Anthraflavic acid remains unaltered when fused with alkalis in presence of oxygen.

A. G. B.

New Dyes of the Anthraquinone Series. By R. E. SCHMIDT and L. GATTERMANN (*J. pr. Chem.* [2], 43, 237—252).—In this abstract, a paper by Schmidt and a succeeding one by Gattermann are embodied. The colouring matters here described have been patented by F. Bayer and Co.

“Alizarinbordeaux,” $C_{14}H_4O_2(OH)_4$, is prepared by acting on alizarin (1 part) with 70—80 per cent. anhydrosulphuric acid (10 or more parts) at 25—50° for four days, and then pouring the mixture into melting ice. An *acid sulphate*, $C_{14}H_4O_2(OH)_2 \cdot O_2 \cdot SO_3$, is thus obtained as an orange precipitate which crystallises from glacial acetic acid in lustrous leaflets; it is dissolved in an alkali, and the solution acidified and heated, whereby “alizarinbordeaux” is precipitated. “Alizarinbordeaux” can be distilled unchanged; it crystallises from nitrobenzene in brilliant, red needles having a green, metallic lustre; its *acetyl derivative*, $C_{14}H_4O_2(OAc)_4$, forms bright-yellow needles melting at 200°. The crystalline form and optical properties of “alizarinbordeaux” show that it is identical with Liebermann’s quinalizarin; its constitution is therefore $[(OH)_4 = 1 : 2 : 1' : 4']$ (compare this vol., p. 463).

The dyeing properties of the product are described; it is characteristic of it that it dissolves in strong sulphuric acid with a bluer colour than that of the original substance, a property not possessed by alizarin. In its behaviour to reagents it resembles alizarin. *Nitroquinalizarin*, $NO_2 \cdot C_{14}H_3O_2(OH)_4$, crystallises from nitrobenzene in brilliant, dark needles with a green, metallic lustre; by reduction, it yields an *amido-derivative*. By the action of stannous chloride on an alkaline solution of quinalizarin and subsequent acidification, a reduction product is formed which crystallises from glacial acetic acid in brilliant, brownish-red leaves.

Quinalizarin is also obtained when quinizarin is treated with sulphuric anhydride in the manner described above.

By oxidising quinalizarin with manganese dioxide in sulphuric acid, “alizarincyamin R.” $C_{14}H_3O_2(OH)_3$, is obtained; it crystallises from nitrobenzene in bronze-coloured leaves, and can be distilled unchanged; the *acetyl derivative* is described.

Hexahydroxyanthraquinone, $C_{14}H_2O_2(OH)_6$, is obtained when sulphuric acid acts on quinalizarin at 200°, or sulphuric anhydride on anthraquinone at 30°; it forms dark-green crystals.

A new *tetrahydroxyquinone*, crystallising in green needles, is obtained when anhydrosulphuric acid acts on purpurin. In all these reactions, the sulphuric anhydride acts as an oxidising agent, being reduced to sulphurous anhydride.

Reference is made to the production of several other new dyes, but they do not appear to have been chemically investigated.

A. G. B.

Massoyene. By O. WALLACH (*Arch. Pharm.*, 229, 116—120; compare Abstr., 1890, 638 and 1316).—The author still maintains that massoyene does not exist in massoya rind, but that the oil from this rind contains a relatively large quantity of pinene with limonene and perhaps dipentene.

J. T.

Oil of Polei. By E. BRÜNNMANN and M. PLEISSNER (*Annalen*, **262**, 1—37).—Spanish oil of Polei, from *Mentha pulegium*, is a light yellow or green, rather thick liquid with an odour recalling that of peppermint. On fractionating the oil (62 grams), under the ordinary atmospheric pressure, considerable decomposition takes place; a small portion (3 grams), consisting principally of water, passes over below 212°. the principal portion (50 grams) between 212° and 216°, and a small quantity of a dark-yellow liquid (4 grams) between 216° and 223°, leaving a brownish residue (5 grams).

A compound of the composition $C_{10}H_{16}O$, named by the author *pulegone*, can be isolated from the portion boiling at 212—216° by repeated fractional distillation under reduced pressure (60 mm.); it is a colourless liquid, of sp. gr. 0.9323 at 20°, boils at 130—131° (60 mm.), and has an odour recalling, but distinct from, that of oil of peppermint. Its specific rotatory power is $[\alpha]_D = 22.89$, but this value is slightly diminished when the oil is treated with sulphuric acid or distilled with steam, probably owing to resinification. Pulegone quickly turns yellow, even when kept in closed vessels, and it does not solidify when cooled in a mixture of ice and salt; it is gradually resinified by hot alcoholic potash, and it does not give an ethereal salt with benzoic or stearic anhydride; it gives some, but not all, the reactions of aldehydes, and with phenylhydrazine it yields only oily or resinous, very unstable compounds. Molecular weight determinations gave results in accordance with those required by the molecular formula $C_{10}H_{16}O$; its molecular refractive power was found to be $M_D = 45.55$, whereas the value calculated for the formula $C_{10}H_{16}O$ is $M_D = 45.82$.

Pulegoneoxime, $C_{10}H_{15}NO$, can be obtained by treating pulegone with hydroxylamine in boiling alcoholic ethereal solution; it crystallises from ether in long needles, melts at 157° with decomposition, and is only sparingly soluble in cold alcohol, benzene, and light petroleum; its specific rotatory power is $[\alpha]_D = -83.44$. Molecular weight determinations showed that the compound has the molecular formula given above. Pulegoneoxime is more readily soluble in dilute acids than menthoneoxime, and, unlike the latter, it is not acted on by cold sulphuric acid of sp. gr. 1.17; it dissolves freely in hydrochloric acid, yielding a solution which gradually turns brown, but it is only very sparingly soluble in alkalis. It reduces ammoniacal solutions of silver and copper on warming. The *hydrochloride*, $C_{10}H_{15}NO_2 \cdot HCl$, separates from alcoholic ether in well-defined rhombic crystals, $a:b:c = 0.6048:1:1.0477$, melts at 117—118° with decomposition, and is readily soluble in water; its specific rotatory power is $[\alpha]_D = -32.43$. The *benzoyl derivative*, $C_{10}H_{15}O \cdot N \cdot OBz$, prepared by treating the oxime with benzoic chloride in ethereal solution, crystallises from dilute alcohol in colourless needles melting at 137—138° with decomposition. The *acetyl derivative*, $C_{10}H_{15}O \cdot N \cdot OAc$, is formed when the oxime is warmed with acetic chloride; it crystallises in long needles, and melts at 149°.

Pulegoneamine, $C_{10}H_{15}ON$, is obtained when the oxime is treated with hydriodic acid, and the crystalline hydriodide obtained in this way warmed with excess of the concentrated acid. It is a ————

oil having a bitter taste and an amine-like odour, and it decomposes when heated; it is only sparingly soluble in water, but readily in ether and alcohol. The *hydrochloride*, $C_{10}H_{15}NO \cdot HCl$, was prepared, but only in an impure condition, by treating the base with hydrogen chloride in ethereal solution; it crystallises from alcohol in long needles, melts at 117° , and is readily soluble in water, alcohol, benzene, and glacial acetic acid, but only moderately easily in light petroleum, and sparingly in ether. *Pulegoneamine phenylthiocarbimide*, $C_{10}H_{15}O \cdot N \cdot CS \cdot NHPh$, is precipitated in colourless plates on warming a benzene solution of pulegoneamine with phenylthiocarbimide; it melts at 198° . The *benzoyl* derivative, $C_{10}H_{15}O \cdot NBz$, separates from warm, dilute alcohol in colourless, feathery crystals, melts at $100.5-101^{\circ}$, and is sparingly soluble in water, ether, and benzene, but readily in alcohol. The *methyl* derivative, $C_{10}H_{15}O \cdot NMe$, prepared by boiling the amine with methyl iodide, and decomposing the product with potash, is a light-yellow oil; its *platinochloride*, $(C_{10}H_{15}NO)_2 \cdot H_2PtCl_6$, crystallises in well-defined yellow needles, and is sparingly soluble in alcohol and ether. When pulegoneamine is boiled with concentrated potash, it is decomposed into pulegone and ammonia; methylpulegoneamine, under the same conditions, yields pulegone and methylamine.

An additive compound of the composition $C_{10}H_{17}BrO$ is deposited in colourless crystals when hydrogen bromide is passed into a well-cooled solution of pulegone in light petroleum; it separates from dilute alcohol in well-defined, colourless crystals, melts at 40.5° , and is readily soluble in alcohol and ether. It gradually decomposes on keeping, and it is converted into pulegone by freshly-precipitated silver oxide and lead hydroxide, but it is not acted on by cold dilute soda or by warm sodium carbonate: its specific rotatory power is $[\alpha]_D = -33.88^{\circ}$. When treated with hydroxylamine, as described in the preparation of pulegoneoxime, it is converted into a compound which crystallises in quadratic plates, melts at 38° , and has probably the composition $C_{10}H_{15}BrNO$; on keeping this substance for some time, it first changes into a mass of needles melting at 110° , which are free from bromine, but contain nitrogen, and then into pulegoneoxime. When the additive compound is reduced with zinc-dust in alcoholic solution, it yields very small quantities of pulegone and a considerable quantity of an oil, which has the same molecular formula as, and possesses all the properties of, the levomenthone described by Beckmann (Abstr., 1889, 721), except that its oxime melts at a higher temperature, namely, at $84-85^{\circ}$; when this isomeride of menthone is treated with sodium in ethereal solution, it is converted into a mixture of isomeric menthols, from which a considerable quantity of the benzoyl derivative of natural levomenthol can be isolated in a crystalline condition. Levomenthol is also obtained, together with resinous products, when pulegone is reduced with sodium under the same conditions.

The author gives three possible formulæ for pulegone.

F. S. K.

Saponin. By O. HESSE (*Annalen*, 261, 371—378).—A study of the literature of saponin and of senegin (Bolley, *Annalen*, 90, 211; Christophsohn, *Arch. Pharm.*, 206, 432, 481, 503) leads to the conclusion that the two compounds are identical, and that the supposed varieties of saponin obtained from various Caryophyllaceæ represent one and the same compound. According to Rochleder (*Wiener Acad. Ber.*, 56, 97), saponin, on hydrolysis, is converted into glucose (3 mols.) and a compound of the composition $C_{11}H_{23}O_2$, for which the author proposes the name *sapogenol*; assuming that sapogenol has the above composition, and that the hydrolysis takes its normal course, the composition of saponin is represented by the formula $C_{32}H_{52}O_{17}$ ($= C_{14}H_{22}O_2 + 3C_6H_{12}O_6 - 3H_2O$).

The analytical results obtained by Stütz (*Annalen*, 218, 231) in studying saponin and its derivatives are more in accordance with this view of the composition of the compound than with that of Stütz, who concluded that the glucoside had the composition $C_{19}H_{30}O_{10}$; assuming that the composition of saponin is expressed by the formula $C_{32}H_{52}O_{17}$, the tetracetyl, $C_{19}H_{28}Ac_4O_{10}$, tetrabutyl, $C_{19}H_{26}Bu_4O_{10}$, pentacetyl, $C_{19}H_{24}Ac_5O_{10}$, and heptacetyl, $C_{19}H_{22}Ac_6O_8(OAc)_2$, derivatives described by Stütz must be regarded as the heptacetyl, $C_{34}H_{46}Ac_7O_{17}$, heptabutyl, $C_{32}H_{44}Bu_7O_{17}$, octacetyl, $C_{32}H_{44}Ac_8O_{17}$, and dodecacetyl, $C_{32}H_{40}Ac_{12}O_{17}$, derivatives respectively, and the compound to which Stütz gave the formula $C_{19}H_{26}Ac_5O_8(OAc)_4$ as a compound of the composition $C_{32}H_{40}Ac_{12}O_{17}$, and a derivative of saponin trihydrate, $C_{32}H_{48}O_{20}$; the existence of a mono- and of a di-hydrate of saponin is also not improbable.

The formation of sapogenin, saponetin, and saporctin (senegenin), by the decomposition of saponin, can be easily expressed by simple equations, proceeding on the assumption that the formula $C_{32}H_{52}O_{17}$ is correct.

Poisonous Constituents of "Timbó." By F. PFAFF (*Arch. Pharm.* [2], 29, 31—48).—*Timbó* is the name given in Brazil to several plants such as *Serjania cuspidata*, St. H., *Serjania lathalis*, and *Paullinia pinnata* of the order Sapindacæ, and *Tephrosia toxicaria* and *Physallis heterophylla* of the order Leguminosæ, all of which are used for the purpose of stupefying fish. A decoction of the root is preferred as affording the more powerful poison. To isolate the active principle, an alcoholic extract of the plant was concentrated, washed with water, treated with ether, and the dark-coloured ethereal solution decolorised by means of sodium carbonate and dilute soda solution. After removing the ether and drying over sulphuric acid, solid crude timbóin was obtained, which softened when exposed to the air. A similar product was obtained by precipitating the alcoholic extract with lead acetate, and purifying the filtrate. Further treatment of the crude product with alcohol, light petroleum, and benzene or chloroform at length yielded a hard, yellowish-white, sandy substance, which, under the microscope, clearly indicates crystalline structure. *Timbóin*, $C_{27}H_{36}O_8$, melts at 83° , is very soluble in ether, alcohol, benzene, glacial acetic acid, toluene, and carbon bisulphide, exceedingly soluble in chloroform; very sparingly soluble in light

petroleum, and almost insoluble in water. Its alcoholic solution is not precipitated either by normal or basic lead acetate, iodine solution, or tannin. Its solution in acetic acid or in alcohol gives a white, flocculent precipitate with water; but these solutions give no coloration, either with ferric chloride or potassium chromate. The compound becomes first black and then reddish-brown with concentrated sulphuric acid. Sobieranski considers timboin to be a chemically neutral, indifferent substance, and a nerve poison of the toxine class. *Anhydrotimboin*, $C_{27}H_{24}O_7$, was obtained as slender, coloured, needle-shaped crystals during the refining of the crude timboin. It was also produced directly from timboin by heating the alcoholic solution with hydrochloric acid. This compound melts at $215-216^\circ$, and is not poisonous. Light petroleum, boiling at $38-40^\circ$, extracted from the crude timboin an oily compound, *timbol*, $C_{20}H_{16}O$, probably also a poisonous compound, occurring chiefly in the stem and branches of the plants. J. T.

Synthesis of Pyridine Derivatives from Derivatives of α -Pyrone. By M. GUTHZEIT and O. DRESSSEL (*Annalen*, 262, 89—132).—The authors discuss at some length the mechanism of the reactions which take place in the conversion of α -pyrone into pyridine derivatives, more especially as regards the formation of ethyl hydrogen ethoxyhydroxypyridinedicarboxylate from ethyl ethoxy- α -pyronedicarboxylate they arrive at the conclusion that the simplest and most probable explanation of such reactions is that the pyrone derivative first combines with the elements of ammonia to form an intermediate product, which is then converted into a pyridine derivative by the elimination of 1 mol. H_2O .

Ethyl hydrogen ethoxyhydroxypyridinedicarboxylate (ethyl ethoxy- α -pyridonedicarboxylate), $COOEt \cdot C \begin{smallmatrix} \text{C(OEt)} \text{---} \text{N} \\ \text{CH:C(COOH)} \end{smallmatrix} \text{---} C \cdot OH$, is obtained when ethyl ethoxy- α -pyronedicarboxylate, prepared as previously described (Abstr., 1889, 860), is shaken with 4—5 per cent. ammonia, and the filtered solution acidified with hydrochloric acid. It crystallises from a mixture of acetone and ether in colourless needles, melts at $159-160^\circ$, and is moderately easily soluble in acetone, alcohol, and glacial acetic acid, but more sparingly in ether and water, and almost insoluble in benzene, light petroleum, and carbon bisulphide. Molecular weight determinations by Raoult's method in glacial acetic acid solution gave results in accordance with those required by the molecular formula given above. The *silver* salt, $C_{11}H_{13}O_6N \cdot Ag$, is a crystalline, moderately stable compound, very sparingly soluble in water. The *acetyl* derivative, $C_{13}H_{15}O_7N$, is formed when the ethyl hydrogen salt is heated with acetic anhydride at 130° ; it melts at $99-100^\circ$, is freely soluble in cold benzene, and is readily decomposed by warm water.

Ethyl ethoxyhydroxypyridinedicarboxylate, $C_{13}H_{17}O_6N$, can be prepared by treating an alcoholic solution of the ethyl hydrogen salt with hydrogen chloride, but it is more easily obtained by decomposing the silver salt with ethyl iodide; it crystallises from alcohol and benzene in needles, melts at $80-81^\circ$, and is soluble in dilute am-

monia and dilute sodium carbonate. When the ethyl hydrogen salt is heated above its melting point, carbonic anhydride (1 mol.) is evolved and there remains a brown oil, which consists principally of ethyl ethoxyhydroxypyridinedicarboxylate, identical with the compound described above, and a basic substance which is probably α -ethoxy- α -hydroxypyridine, but which could not be isolated in a pure condition. Ethoxyhydroxypyridinedicarboxylic acid (compare Abstr., 1889, 860) separates from water in crystals containing 1 mol. H_2O , and melts at 181 – 182° with evolution of carbonic anhydride (2 mols.) yielding a brown oil which probably consists for the most part of ethoxyhydroxypyridine; when heated with concentrated hydriodic acid at 130° , it gives ethyl iodide, and when heated with fuming hydrochloric acid at 180° , it yields ethyl chloride, ammonia, and glutacnic acid (m. p. 133 – 134°).

Citrazinic acid undergoes a decomposition similar to that observed in the case of ethoxyhydroxypyridinedicarboxylic acid; when it is heated at 180° with hydrochloric acid, it yields ammonia and aconitic acid, together with carbonic anhydride, which is produced by the decomposition of some of the aconitic acid. The relationship between citrazinic acid and ethoxyhydroxypyridinedicarboxylic acid is also shown by their behaviour on reduction with tin and hydrochloric acid in the manner described by Behrmann and Hofmann in the case of citrazinic acid; the last-named compound yields tricarballylic acid under these conditions, ethoxyhydroxypyridinedicarboxylic acid giving glutaric acid.

aa-Dichlorodimicotinic acid, $\text{CH} \begin{array}{c} \text{C}(\text{COOH})\text{:CCl} \\ \text{C}(\text{COOH})\text{:CCl} \end{array} \text{N}$, is obtained when anhydrous ethoxyhydroxypyridinedicarboxylic acid is mixed with phosphorus pentachloride and phosphorus oxychloride, the mixture heated at 240 – 250° for 5–6 hours, and the product decomposed with ice-cold water; it separates from ether in colourless crystals, melts at 230° with evolution of carbonic anhydride, and is readily decomposed by warm water yielding dihydroxydimicotinic acid. It is moderately easily soluble in ether and alcohol, but more sparingly in cold water; it dissolves freely in dilute ammonia, the neutral solution giving with silver nitrate and with lead acetate a colourless, with ferric chloride a yellow, and with copper acetate a green, precipitate. The *ethyl* salt, $\text{C}_{11}\text{H}_{11}\text{Cl}_2\text{NO}_4$, is easily obtained by treating the chloride of the acid with alcohol; it crystallises in compact, monoclinic prisms, melts at 75 – 76° , and is readily soluble in ether, alcohol, chloroform, benzene, glacial acetic acid, and hot light petroleum, but more sparingly in cold light petroleum; it is quickly decomposed by sodium ethoxide in warm alcoholic solution with separation of sodium chloride. When the dichloro-acid is heated with concentrated hydriodic acid at 180° , it is converted into dimicotinic acid (m. p. 322°); the formation of this acid from ethyl hydrogen ethoxyhydroxypyridinedicarboxylate by the series of reactions described above is a conclusive proof that the ethyl hydrogen salt has the constitution assigned to it.

F. S. K.

Betaïnes of Pyridine Bases. By M. KRÜGER (*J. pr. Chem.* [2], 43, 271—303 and 364—377; compare Abstr., 1890, 1431).—There are four methods of obtaining betaïnes: (1) Hofmann's, by the action of ethyl chloracetate on the tertiary base, producing the chloride of the alkyl betaïne; (2) Liebrich's, by the action of chloracetic acid on the tertiary base at a raised temperature, producing the betaïne hydrochloride; (3) Griess', by the action of methyl iodide and an alkali on the amido-acid in methyl alcohol, producing the alkaline iodide of the betaïne; (4) Kraut's, by the action of an alkyl iodide on the silver amido-salt, producing the iodide of the alkyl betaïne.

Ethyl pyridinebetaïne chloride, $C_5H_5NCl \cdot CH_2 \cdot COOEt$, obtained by Hofmann's reaction and purified by extraction with ether, in which it is insoluble, forms a rose-coloured, crystalline powder; it melts at 100° to a yellowish-red liquid of peculiar odour, and decomposes with blackening at 110 — 115° ; it is very soluble in water, alcohol, and chloroform. The *platinochloride* forms lustrous, orange-red, rhombic leaflets and decomposes at 213° ; the *aurochloride* crystallises in thin, yellow leaflets and melts at 117° ; the *mercurochloride* forms microscopic, white, four-sided prisms which melt at 124 — 125° ; the *cadmiocchloride*, $C_5H_5NO_2Cl, CdCl_2$, crystallises in long, lustrous needles which aggregate to an opaque white mass at 141° ; the *cadmiocchloride*, $(C_5H_5NO_2Cl)_2, CdCl_2$, crystallises in vitreous, rhombic leaflets and melts at 107° . To convert ethyl pyridinebetaïne chloride into pyridinebetaïne, it is treated with silver oxide and water, silver chloride and alcohol being formed. Ethyl pyridinebetaïne does not exist; its *nitrate* was obtained by decomposing the chloride with silver nitrate.

Pyridinebetaïne hydrochloride has been described by v. Gerichten (Abstr., 1882, 1109); its *platinochloride* melts at 211° , its *aurochloride* at 165° ; the reactions of this base with the usual reagents for alkaloids are here given. The *hydrobromide* crystallises in rhombic leaflets and decomposes at 198 — 200° . The *nitrate*, obtained from the chloride by the action of silver nitrate, forms vitreous, colourless leaflets which melt at 145° with decomposition. The *sulphate* is similarly prepared; it crystallises in colourless leaflets and decomposes at 175° . The *chromate*, $C_7H_7NO_3, CrO_3$, forms a yellow, crystalline precipitate and explodes about 166° . The *picrate* crystallises in microscopic four-sided prisms with oblique ends, and melts at 142 — 143° . The *argentonitrate* and *bismuthiodide* are also described (compare Abstr., 1890, 1431).

The author finds that the product of the action of chloracetic acid (20 grams) on pyridine (10 grams) is a mixture of normal and basic pyridinebetaïne hydrochloride (compare Abstr., 1882, 1109), which is easily converted into the pure normal salt by adding a slight excess of hydrochloric acid. The crystallography of the normal hydrochloride is given. *Basic pyridinebetaïne hydrochloride*, $(C_7H_7NO_3)_2, HCl, H_2O$, separates from a hot alcoholic solution of the mixture before the normal salt in large, broad, vitreous, colourless crystals which are well developed on one side only and become opaque in air without change of composition; when quickly recrystallised it separates as long, slender

prisms; it melts at 159° with decomposition, and dissolves in water and hot alcohol, but not in ether; its aqueous solution is acid. The *mercurochloride*, $2\text{C}_5\text{H}_7\text{NO}_2, \text{HCl}, \text{H}_2\text{O}, 4\text{HgCl}_2$, crystallises in colourless, lustrous leaflets which melt at 134° .

Basic pyridinebetaine hydrobromide, is obtained from the normal hydrobromide by evaporating a solution of the latter with excess of pyridine on the water-bath; it crystallises in long, broad leaflets, or slender, needle-shaped prisms, and decomposes at 170° ; its aqueous solution is acid. Both the basic and normal hydrobromides are formed when pyridinebetaine (5 grams) is heated in a sealed tube with bromine (4 grams) and water (20 c.c.) at 100° ; when the bromine is in excess, only the normal salt is formed.

By heating pyridinebetaine hydrochloride at comparatively low temperatures, pyridine is produced; but at 230 – 240° , or when treated with strong organic bases, a more deep-seated reaction takes place. By oxidation with potassium permanganate, the betaine is entirely converted into pyridine.

When sodium amalgam acts on a warm solution of pyridinebetaine, a blue colour is developed; this changes to purple-violet on cooling, and to brown after some hours; heating restores the blue colour; when the amalgam acts on a cold, not alkaline solution of pyridinebetaine, an amorphous yellowish-white precipitate is obtained, and the filtrate from this becomes blue on the addition of more sodium amalgam. The same colour reaction is observed with ethyl pyridinebetaine chloride, but no precipitate is obtained. The amorphous substance is at first yellowish-green, but becomes black when dried at 100° ; analyses are given, but no formula is deduced. From the filtrate from this substance, a base was obtained which gave a platinumchloride melting at 224 – 225° and agreeing in properties with the platinumchloride of Coppola's pyridinecholine (Abstr., 1886, 76); that the new base is pyridinecholine was further proved by preparing the latter, when it was found to give the same colour reactions.

In Hasekiet's recipe for preparing β -picoline (Abstr., 1885, 812; 1886, 256), 24 hours digestion is unnecessary, 6–8 being sufficient; the author's product boiled at 141 – 143° .

β -Picolinebetaine hydrochloride, $\text{C}_6\text{H}_7\text{NOCl} \cdot \text{CH}_2\text{COOH}$, obtained by warming β -picoline with chloracetic acid (equal mols.), crystallises from alcohol in long, broad, four-sided, vitreous, colourless prisms; it melts at 189° with decomposition, and dissolves in hot alcohol and water but not in ether; when precipitated by ether from alcoholic solution, it is a white, crystalline, deliquescent powder. Its reactions with several alkaloidal reagents are given. The *platinochloride* crystallises in small, six-sided, orange-red tables and decomposes at 222° .

β -Picolinebetaine is obtained by decomposing the hydrochloride with moist silver oxide and evaporating; by adding ether to the solution of the residue in alcohol and stirring with a glass rod, the base is precipitated in microscopic, rhombic leaflets (with 1 mol. H_2O). The *basic hydrochloride*, $2\text{C}_6\text{H}_7\text{NO}_2, \text{HCl}, \text{H}_2\text{O}$, separates when a solution of the normal hydrochloride and the base (equal mols.) in hot alcohol is cooled, in small, thick crystals. When a hot alcoholic

solution of pyridinebetaine and β -picolinebetaine hydrochloride (equal mols.) is cooled, a double salt, $C_5H_5NO_2 \cdot HCl \cdot C_7H_7ON_2 \cdot H_2O$, crystallises in thin, rectangular leaflets.

Ethyl β -picolinebetaine chloride is obtained when β -picoline and ethyl chloracetate interact over potassium hydroxide; after several days, the crystallised mass is extracted with ether, which leaves the new compound as a rose-coloured, crystalline powder; it decomposes at 153° and is very hygroscopic. The *platinochloride* forms yellow, four-sided prisms and decomposes at 207° . When Kahlbaum's artificial picoline was acted on by ethyl chloracetate and the solution of the product precipitated by platinum tetrachloride, the above described salt was obtained; this method will serve to separate β -picoline from its isomerides in artificial picoline.

Ethyl ethylpiperidinebetaine chloride, $C_7H_{15}NCl \cdot CH_2 \cdot COOEt$, obtained by the action of ethyl chloracetate on ethylpiperidine, crystallises in very thin, lustrous leaflets. The *platinochloride* crystallises in thin, feebly lustrous, orange-yellow, rhombic leaflets and melts at 150° .

Ethylpiperidinebetaine is obtained by acting on the above chloride with moist silver oxide, alcohol being formed at the same time; it crystallises in small leaflets, soluble in water and alcohol, but insoluble in ether. The *hydrochloride* is obtained by the action of chloracetic acid on ethylpiperidine; the product is dissolved in alcohol and precipitated by ether, when microscopic, long, four-sided prisms separate; it is very hygroscopic and melts at 186 – 187° with decomposition; the *platinochloride* and some of the reactions with alkaloidal reagents are described.

A summary of the general reactions of these betaines concludes the paper. A. G. B.

Constitution of Rhodanic Acid. By A. MIOLATI (*Annalen*, 262, 82–88).—Rhodanic acid can be obtained (1) by heating thiohydantoin with excess of carbon bisulphide in alcoholic solution, (2) by warming ethyl chloracetate with an alcoholic solution of ammonium dithiocarbamate and hydrochloric acid, and (3) by treating ethyl thiocynoacetate with hydrogen sulphide in alcoholic solution; it crystallises in yellowish prisms and melts at 166 – 167° with decomposition.

These syntheses of the "acid" show that it is an α -keto- μ -thiothiazolidine of the constitution $CH_2 < \begin{matrix} S-SH \\ CO-NH \end{matrix}$ F. S. K.

Quinazolines. By C. PAAL and A. BODEWIG (*Ber.*, 24, 1157–1161).—Orthonitrobenzoylaniline and phenyl cyanate, when brought together, give a theoretical yield of orthonitrobenzoyldiphenylcarbamide. The authors attempted to obtain anilidophenyldihydroquinazoline by reduction of the latter compound. The reaction, however, takes place in a different way, and they obtained a feeble base of the composition $C_{14}H_{12}N_2O$, together with aniline. The production of this new base is due to the action of water on the unstable phenylamidophenyldihydroquinazoline, as expressed in the equation

Söderbaum and Widman (Abstr., 1889, 972), by treating ortho-hydroxytolylphenylcarbamide with hydrochloric acid, have obtained a compound to which they give the name benzophenyldihydroketo-metadiazine, and the formula $\text{C}_6\text{H}_5\text{<}\begin{array}{c} \text{NH}\cdot\text{CO} \\ \text{CH}_2\cdot\text{NPh} \end{array}$ It is entirely different from the former base.

Orthonitrobenzylidiphenylcarbamide, $\text{C}_{20}\text{H}_{17}\text{N}_3\text{O}_3$, is obtained by heating orthonitrobenzylaniline and phenyl cyanate in molecular proportion at 120° . It crystallises from alcohol in white leaflets or tablets, melts at $124\text{--}125^\circ$, and is easily soluble in most organic solvents, with the exception of petroleum. When cautiously warmed with alcoholic potash, it splits up into symmetrical diphenylcarbamide (m. p. 233°) and an amorphous compound, which the authors consider to be formed by the action of excess of alkali on the orthonitrobenzyl alcohol, which is first produced.

3'-Phenyl-2'-ketotetrahydroquinazoline, $\text{C}_6\text{H}_5\text{<}\begin{array}{c} \text{NH}\cdot\text{CO} \\ \text{CH}_2\cdot\text{NPh} \end{array}$, or 3'-phenyl-

2'-hydroxydihydroquinazoline, $\text{C}_6\text{H}_5\text{<}\begin{array}{c} \text{N}=\text{C}\cdot\text{OH} \\ \text{CH}_2\cdot\text{NPh} \end{array}$, is obtained by treating orthonitrobenzylidiphenylcarbamide in alcoholic solution with tin and hydrochloric acid. On adding excess of concentrated hydrochloric acid, the stannochloride, $\text{C}_{14}\text{H}_{12}\text{N}_2\text{O}\cdot\text{HCl}\cdot\text{SnCl}_2$, crystallises out, and aniline remains in solution. The salt is finely ground and decomposed with ammonium sulphide, and the base extracted with alcohol. It crystallises in white needles, melts at 170° , and is easily soluble in benzene, moderately in alcohol and ether, and almost insoluble in light petroleum. An attempt to reduce the base in alcoholic solution with sodium failed.

The isomeric base, benzophenyldihydroketo-metadiazine, $\text{C}_{14}\text{H}_{12}\text{N}_2\text{O}$, is obtained as described by Söderbaum and Widman. It crystallises in white, lustrous plates or flat needles, and melts at $144\text{--}145^\circ$.

The authors point out that the two bases $\text{C}_{14}\text{H}_{12}\text{N}_2\text{O}$, which from their method of formation ought to have the same constitution, are entirely different in properties. They are engaged in investigating the cause of this difference.

E. C. R.

Action of Dioxiquinones on Orthodiamines. By R. NIETZKI and G. HASTEBLIE (Ber., 24, 1337—1340).—Dioxiphenazine is prepared by the action of dioxiquinone on orthophenylenediamine hydrochloride; the acetyl derivative melts at 226° , not at 230° as stated by O. Fischer and Hepp. Corresponding compounds are obtained from orthotolylenediamine and 1:2-naphthylenediamine. Kehrman's imide formula for the eurhodoles and eurhodines, whilst facilitating the classification of the eurhodines, oxazines, and saffranines, is probably incorrect, since it is incompatible with the production of eurhodoles by fusion of azinesulphonic acids with alkalis, as observed by O. N. Witt; the formation of eurhodine diazo-compounds

also tells against the formula, as does the fact that the diacetyl derivatives are readily and completely hydrolysed by dilute alkalis, whereas if one acetyl group were linked to oxygen, and the other to nitrogen, the former would probably be readily eliminated, but the latter only with difficulty; hence a monacetyl derivative should be capable of being isolated, which is not the case. J. B. T.

Azonium Compounds. By F. KEHRMANN and J. MESSINGER (*Ber.*, 24, 1239—1241).—In a recent communication (this vol., p. 747), O. Fischer has shown that fluorescent colouring matters of the quin-oxaline series may be obtained by the action of alkylated ortho-diamines on α -ketonic alcohols or hydroxyquinones. The authors have found that the substituted orthodiamines also react readily with orthodiketones, forming the azonium compounds, from which the safranin dyes are derived. Thus, when alcoholic solutions of ortho-amidodiphenylamine and a slight excess of benzile are warmed with hydrogen chloride (1 mol.) on the water-bath, the product of the reaction saturated with ammonia and poured into water, a sulphur-yellow, crystalline precipitate is obtained, which, on recrystallisation from alcohol, forms well-developed sulphur-yellow prisms melting at 134—135°. It is readily soluble in alcohol, ether, and benzene, with a yellow colour and beautiful green fluorescence, has the composition $C_{26}H_{18}N_2 \cdot OH$, and is formed in the following manner:—

Its solution, on the addition of hydrochloric acid, becomes momentarily red and then pure yellow, without fluorescence. Its *ferrichloride*, $C_{26}H_{18}N_2FeCl_4$, forms lustrous, golden-yellow, prismatic crystals, moderately soluble in cold water, its *platinochloride*, $(C_{26}H_{18}N_2)_2PtCl_6$, brownish-yellow, lustrous scales, almost insoluble in water and alcohol, and the *mercuriochloride* canary-yellow scales. The *chloride*, *nitrate*, and *sulphate* are readily soluble in water, and have a yellow colour.

H. G. C.

Nicotine. By A. PINNER and R. WOLFFENSTEIN (*Ber.*, 24, 1373—1377).—It is stated by Will (*Annalen*, 118, 206) that nicotine reacts with benzoic chloride with the development of much heat, but when the latter is added to a solution of nicotine in anhydrous ether, a viscid substance separates, which after a time forms white, deliquescent crystals, resembling wavelite, of the composition $C_{10}H_{14}NOCl$; this he regarded as an additive compound, or as benzoyl-nicotine hydrochloride.

The authors have obtained a compound agreeing with the above description by dissolving nicotine (1 mol.) in ether rendered anhydrous by sodium, and adding benzoic chloride (2 mols.), but they find it to be *basic nicotine hydrochloride*, $C_{10}H_{14}N_2 \cdot HCl$; it is very soluble in water, and yields nicotine picrate (m. p. 218°; see *Ber.*, 24, 65) on adding picric acid to its aqueous solution. When pyridine, dimethylaniline, and piperidine are similarly treated with benzoic chloride, crystalline substances consisting of the hydrochlorides and benzoates

are formed. The production of these salts is due to the action of the moisture of the air on the benzoic chloride, whereby benzoic and hydrochloric acids are formed, the latter then reacting with the bases. When nicotine and benzoic chloride are dissolved in ether rendered anhydrous by phosphoric anhydride, and the mixture is kept in a closed flask over concentrated sulphuric acid, an oil separates which does not solidify if kept even for 14 days; it was not further examined. But little heat is developed on mixing nicotine with benzoic chloride (2 mols.), and if the mixture is heated on the water-bath for 20 minutes, a thick syrup is obtained; after washing this with water and dilute alkali, it is dissolved in dilute hydrochloric acid, and precipitated with ammonia; the precipitate is extracted with ether, and the residue, after distilling off the latter, dissolved in alcohol and water added, whereby a syrupy mass is obtained. It appears to be a compound of 1 mol. of nicotine with 1 mol. of benzoic chloride; it has basic properties; on adding picric acid to a solution of the compound in dilute hydrochloric acid, the *picrate*, $C_{23}H_{22}N_2O_8Cl$, separates as an oil, which solidifies after a time, and then melts at 139° .

A. R. L.

Cytisine and Ulexine. By J. v. D. MOER and P. C. PLUGGE (*Arch. Pharm.* [2], 29, 48—68).—The work done by Moer is communicated by Plugge. The finely-crushed seeds of *Cytisus laburnum* were extracted with cold water, and the solution was concentrated in winter by removing the ice which formed. The concentrated solution was treated with normal lead acetate and then with hydrogen sulphide; after excess of the latter had been removed by warming, sodium hydroxide was added to distinctly alkaline reaction, when the application of chloroform removed the cytisine and yielded it, when concentrated and treated with ether, as a colourless, crystalline mass. Repeated treatment with chloroform and ether gave the pure alkaloid. Cytisine, $C_{11}H_{16}N_2O$, forms colourless, odourless crystals melting at $150\text{--}151.5^\circ$ (uncorr.). It is a strong base, soluble in all proportions in water, alcohol, and chloroform, insoluble in ether, light petroleum, carbon bisulphide, readily soluble in ethyl acetate; benzene dissolves 1.26 per cent., and amyl alcohol dissolves 0.303 per cent. Cytisine dissolved in water has a rotatory power of $[\alpha]_D = -120^\circ$. The value for other solutions is also given. On adding a solution of a ferric salt to the free alkaloid, or one of its salts, a red coloration is produced; on adding to this some drops of hydrogen peroxide solution, the colour disappears, followed immediately on warming by a blue colour. This is a very characteristic reaction, and will indicate 0.00005 gram. Platinum chloride precipitates the alkaloid in not too dilute solutions. Precipitates are also produced by gold chloride, potassium mercuric iodide, iodised potassium iodide, phosphomolybdic acid, phosphotungstic acid (1 : 30000), tannic acid, and picric acid. Mercuric chloride precipitates the free base from its solutions, but not from solutions of its salts. The simple salts of cytisine are all soluble in water, and are easily soluble in absolute alcohol; the nitrate is the least soluble in the latter liquid, and can be obtained from its solution therein in the form of large crystals. The

composition of the following salts was found to be:—Cytisine nitrate, $C_{11}H_{16}N_2O, HNO_3 + H_2O$; platinumchloride, $(C_{11}H_{16}N_2O)_2, H_2PtCl_6$; anrochloride, $C_{11}H_{16}N_2O, HAnCl_4$.

For the detection of cytisine in poisoning cases, Dragendorff's method can be applied, advantage being taken of the solubility of the alkaloid in chloroform, and of the characteristic test given above. The vomit and urine should be first examined. Salts of the alkaloid pass away in the urine within 24 hours, but if leaves or seeds have been employed, the expulsion may take a longer time. Moer compares the composition and properties of cytisine and ulexine and their compounds, and concludes that these two alkaloids are identical (compare Partheil, this vol., p. 750). J. T.

Action of Alcohols and Aldehydes on Proteids. By T. L. BRUNTON and S. MARTIN (*J. Physiol.*, 12, 1—4).—Solutions of the following proteids were used:—(1) egg-albumin, (2) serum-albumin containing a little serum-globulin, and (3) a mixture of proto- and deutero-albumose prepared from Witte's "peptone." The solution was dropped into six times its bulk of an alcohol or aldehyde, and the following points noted:—*a.* Whether the reagent precipitated the proteid; *b.* Whether the precipitate was rendered insoluble in distilled water, by the prolonged action of the reagent; *c.* Whether any change of colour occurred in the precipitate. It was found that with egg-albumin, allyl alcohol was the most powerful precipitant and coagulant of the series. Methyl, ethyl, propyl, isobutyl, isopropyl, and tertiary butyl alcohols come next; they are all active coagulators; amyl alcohol is a partial coagulator; and heptyl and octyl alcohols do not precipitate or in any way change the solution. Acetaldehyde and propaldehyde are about equal in coagulating power to ethyl alcohol, and turn the precipitated proteid brown; isobutaldehyde has a slower action, and does not turn the precipitate brown.

With serum-albumin, the results were very similar; the alcohols may be arranged in the following order, the most active being placed first:—

1. Methyl, ethyl and propyl alcohols.
2. Isopropyl alcohol.
3. Tertiary butyl alcohol.
4. Isobutyl and amyl alcohols precipitate, but do not coagulate.
5. Heptyl alcohol does not precipitate.
6. The aldehydes previously mentioned neither precipitate nor coagulate albumin, but acetaldehyde and propaldehyde turn the solution brown.

With the albumose solution, allyl alcohol is the only one that precipitates and renders the precipitate insoluble. Methyl, ethyl, propyl, isopropyl, and tertiary butyl alcohols cause a precipitate; isobutyl alcohol causes a cloudiness; amyl, heptyl, and octyl alcohols have no effect whatever.

The general result obtained as to the effect of alcohols on proteids is that the higher alcohols have a less powerful action in precipitating and coagulating proteids than the lower ones. Allyl alcohol

stands apart from the others as the most powerful precipitating and coagulating agent employed. W. D. H.

A Product of the Putrefaction of Proteids. By S. GABRIEL and W. ASCHAN (*Ber.*, 24, 1364—1366).— α -Amidovaleric acid, prepared from benzoylpiperidine by C. Schotten (Abstr., 1888, 1104), and also by a synthetical method by S. Gabriel (Abstr., 1890, 1129), is identical with the compound obtained by the putrefaction of fibrin and flesh by E. and H. Salkowski (Abstr., 1883, 925). Neither of these compounds is poisonous; they dissolve copper oxide but not silver oxide, and give neither a precipitate nor a blue coloration with ammoniacal silver and copper acetate solutions respectively.

γ -Ethyl phthalimidopropylmalonate (Gabriel, *loc. cit.*) is prepared by dissolving sodium (3 grams) in alcohol (30 c.c.), adding ethyl malonate (21 grams) and γ -bromopropylphthalimide (30 grams), and heating the mixture in a reflux apparatus for 4 hours. The product is poured into water, the alcohol and unaltered ethyl malonate removed by a current of steam, and the oily residue extracted with ether; on evaporating the ethereal solution, a yellowish oil is left, which, after a time, solidifies to a crystalline cake; the yield is 80 per cent. of the theoretical.

β -Amidovaleric acid aurochloride, $C_5H_{11}NO_2.HAuCl_4 + H_2O$, is obtained by heating the above ethyl derivative with hydrochloric acid (5 parts) at 170° , filtering off the phthalic acid, evaporating the filtrate, and adding a 20 per cent. auric chloride solution to the resulting hydrochloride dissolved in a little warm water; it separates in glistening, red crystals which probably belong to the monoclinic system, melts at $86-87^\circ$, and seems in all respects to be identical with that obtained by E. and H. Salkowski (*loc. cit.*). A. R. L.

Physiological Chemistry.

Influence of Bile on the Fat-splitting Properties of Pancreatic Juice. By B. K. RACHFORD (*J. Physiol.*, 12, 72—94).—Some preliminary experiments on emulsions led to the following results:—No amount of stirring will give a permanent emulsion of neutral olive oil with either distilled water or 0.25 per cent. sodium carbonate solution; rancid olive oil, however, although it gives no emulsion with water, gives a good emulsion with the alkaline solution. In the formation of an emulsion, not only must the oil be broken into fine globules, but these must be prevented from running together, by a coating of soap or mucilaginous material. No mechanical emulsion, however, is as perfect as a physiological one. The influence of bile in emulsification is thus summarised:—Bile prevents the formation of an emulsion, probably by preventing the formation of soap membranes; if bile be added to an emulsion the moment after it is formed,

the emulsion clears; but if a few minutes elapse before the addition of bile, there is no such clearing, the emulsion having become more stable. Acids similarly destroy emulsions, probably by destroying soaps.

Rabbits' pancreatic juice is alkaline, and remains active for many hours after removal from the body; if it be shaken with neutral olive oil, fatty acids are formed and the oil becomes acid; if too much acid has not formed, admixture of sodium carbonate solution leads to the formation of an emulsion. By one to two hours action of the juice, all the oil is hydrolysed with formation of fatty acid and glycerol. Other fats, except castor oil, which is indigestible, are similarly acted on.

Bile alone does not hydrolyse fats, but it considerably hastens the hydrolytic power of pancreatic juice. The following conclusions state some further general results obtained:—

1. Pancreatic juice alone will do a certain piece of work in x minutes; namely, develop in neutral olive oil a sufficient quantity of fatty acid to give the best spontaneous emulsion.

2. The juice in the presence of five parts of 0.25 sodium carbonate solution will require $8x$ minutes to do the same work, and the presence of ten parts of the solution will destroy the action.

3. The juice in the presence of an equal amount of 0.25 per cent. hydrochloric acid will require $3x/2$ minutes to do the same work.

4. The juice in the presence of an equal amount of a mixture of bile and 0.25 per cent. hydrochloric acid will require only $x/4$ minutes to do the work.

The last-mentioned condition is considered analogous to the natural condition of things in the intestine, and thus it appears that the most favourable circumstances are present in the intestine for the carrying out of fat digestion.

W. D. H.

Digestion of Gelatin. By R. H. CHITTENDEN and F. P. SOLLEY (*J. Physiol.*, 12, 23—33).—The investigation of the products of digestion of gelatin were carried out on the same lines as the researches of Kühne, Chittenden, and their pupils on the digestion products of other proteid and albuminoid substances.

The following elementary analyses may be first given:—

	Gelatin.	Gastric digestion.		Pancreatic digestion.	
		Proto-gelatosc.	Deutero-gelatosc.	Proto-gelatosc.	Deutero-gelatosc.
C	49.38	49.98	49.23	49.45	49.07
H	6.81	6.78	6.84	6.61	6.66
N	17.97	17.86	17.40	17.81	17.52
S	0.71	0.52	0.51	0.57	0.65
O	25.13	24.86	26.02	25.56	26.10
Ash	1.26	1.98	1.08	1.75	1.08

There is thus no marked difference between gelatin and the gelatoses in composition.

Three distinct products are formed from gelatin during digestion; two of these are primary, and are formed both in gastric and pancreatic digestion; they are distinguished from the third product, gelatin peptone by being precipitated by saturation with ammonium sulphate. The proto-gelatoses are converted into deuto-gelatoses by further ferment action and ultimately into peptone. Proto-gelatoses differ from deuto-gelatoses by being partially precipitated by saturating its neutral solution with sodium chloride, and completely precipitated by the addition of a little acetic acid to the saturated fluid. Further, proto-gelatoses yields a heavy precipitate with hydrogen platinochloride; while deuto-gelatoses is not precipitated by these reagents. No trace of a hetero-gelatoses was found.

The gelatoses are readily soluble in cold water, and are slowly diffusible. They are undoubtedly formed by hydration, although their chemical composition affords no evidence of this view.

W. D. H.

Myosin-peptone. By R. H. CHITTENDEN and R. GOODWIN (*J. Physiol.*, 12, 34—40).—This research, carried out on the same lines as the preceding, was more particularly directed to ascertaining the composition and reactions of the final product in the digestion of myosin. The following are the averages of the elementary analyses of the substances in question obtained in this and previous communications:—

	C.	H.	N.	S.	O
Myosin	52·79	7·12	16·86	1·26	21·07
Proto-myosinose	52·43	7·17	16·92	1·32	22·16
Deuto-myosinose	50·79	7·42	17·00	1·22	23·39
Myosin-peptone	49·26	6·87	16·62	1·16	26·09

In myosin-peptone is seen another instance of the fact that peptones differ from the mother proteid in containing a lower percentage of carbon, which supports the view that the formation of peptones is the result of hydrolysis.

In reactions myosin-peptone does not differ materially from other peptones equally free from proteoses, and it is characterised, like these, mainly by lack of precipitation by ordinary reagents. Boiled with potassium hydroxide and lead acetate, an aqueous solution becomes darker in colour, but there is no pronounced separation of lead sulphide. Boiled with concentrated hydrochloric acid, there is a noticeable darkening of the fluid. Millon's reagent gives a heavy, white precipitate which, on boiling, becomes dirty yellow, then reddish, whilst the liquid has a dirty red appearance. W. D. H.

Influence of Alkalis on the Secretion and Composition of Bile. By W. NISSEN (*Chem. Centr.*, 1891, i, 335—336).—The bile

was collected from a dog with a biliary fistula; the pigment in it was estimated spectrophotometrically, and the bile salts were precipitated and estimated in portions of the bile collected at intervals of a few hours. The administration of 500 c.c. of water caused no difference in its composition. Various alkaline salts (sodium hydrogen carbonate, sodium chloride, potassium acetate, magnesium sulphate, sodium salicylate, &c.) dissolved in the same amount of water also produced no change if the solution was dilute, but lessened the amount of bile when the solution was strong. This appears to be due merely to a diminution of water, the pigment and salts being unchanged in amount; more water is passed from the body by the kidneys.

After the administration of bile or bile salts by the mouth, the amount of bile and of bile acids in the bile is increased, the pigment being unchanged in amount. The increase of water is due to the liver cells being stimulated by the bile acids; the increase in bile acids in the bile is proportional to the amount absorbed by the alimentary canal.

W. D. H.

Caseinogen. By S. RINGER (*J. Physiol.*, 12, 164—169).—By means of pure rennet and caseinogen with the addition of calcium chloride, casein is formed; thus phosphoric acid is not absolutely necessary for efficient rennet action. Sodium hydrogen carbonate antagonises the action of rennet and calcium chloride. This is not due to the conversion of caseinogen into alkali-albumin, for if the caseinogen be precipitated, and dissolved in a solution containing no sodium hydrogen carbonate, it once more is able to clot with rennet and calcium chloride. The clotting of milk by rennet consists of two processes; first, the conversion of caseinogen into casein by rennet; and, secondly, the union of the latter with a lime salt, leading to its precipitation. The calcium chloride used also favours the aggregation of minute particles into masses (curds). The two processes can be separated as follows:—Caseinogen solution with calcium chloride alone does not clot; with rennet alone it does not clot; but the caseinogen is nevertheless changed into casein, as, after heating to 40° to destroy the rennet, the addition of calcium chloride then causes curdling.

W. D. H.

Proteids of Milk. By J. SEDDLIEN (*J. Physiol.*, 12, 95—96).—The author reaffirms his statement that milk contains a globulin. This was questioned by Halliburton (this vol., p. 339).

W. D. H.

Chemistry of Sheep's Milk Cheese. By G. SARTORI (*Bied. Centr.*, 20, 194—196; from *Milchzeit.*, 19, 1001—1004).—Samples of milk from sheep of the district Agro Romano, on the Tiber, were analysed. The following table (next page) shows the percentage composition of milk collected:—(1) April 1, evening; (2) April 2, evening; (3) January 31, evening; and (4) January 30, morning. The first two were in 1887, the last two in 1890.

The difficulties of separating the cream of sheep's milk and the peculiar taste of the butter are the chief reasons against the manu-

	Amount in litres.	Sp. gr. at 15°.	Water.	Fat.	Proteids.	Ash.	Milk- sugar.

* 1·381 is given in Biedermann; the mean of 3 and 4 is given as 1·039.

Proteoses and Peptones. By R. H. CHITTENDEN and J. A. HARTWELL (*J. Physiol.*, 12, 12—22).—From quantitative experiments on artificial gastric digestion, it was found that the primary proteoses (proto- and hetero-) are only slowly converted into peptone, since they pass through the intermediate stage of deutero-proteose. Deutero-proteose, on the other hand, standing next to peptone, is far more quickly and readily changed, as is shown by the large percentage of peptone formed under the same circumstances as obtained in the digestion of the other proteoses.

The formation of peptone is thus a gradual process, as the greater part of the peptone formed by the action of pepsin-hydrochloric acid passes through the proteose stage, and at the end of the most vigorous gastric digestion a considerable part of the proteid digested will be in the form of proteose. To how great an extent it will be necessary to modify these conclusions in applying them to the proteolytic changes of natural digestion it is not at present possible to say.

W. D. H.

Peptonised Foods. By P. HORTON-SMITH (*J. Physiol.*, 12, 42—71).—"Benger's peptonised beef jelly," "Darby's fluid meat," and peptonised milk prepared by means of Benger's *liquor pancreaticus* in the usual clinical way were analysed as regards their proteid constituents, and some rough quantitative experiments made as to the relative amounts of proteoses and peptones in them. The results obtained with milk were as follows:—

Neutralisation precipitate.....	0.0636 per cent.
Proteose precipitate	1.3900 "
Peptone	0.3089 "
<hr/>	
Total	1.7625 "

These results, even allowing for loss due to the formation of amido-acids, are probably too low. They, however, show that the proteid in the so-called peptonised foods really consists for the most part of proteoses, though containing only a variable amount of true peptone. They cannot, therefore, entirely relieve the digestive organs from work.

The author, having noticed that an old man with liver cirrhosis passed abundance of uric acid when fed on peptonised foods, undertook on his own person to control this observation, but it was found that here the ingestion of large quantities of proteoses and peptones did not disarrange the metabolism of the normal body in the least; perfect health was maintained, the output of uric acid was normal, and its relation to urea unchanged.

W. D. H.

Intravascular Coagulation. By A. E. WRIGHT (*J. Physiol.*, 12, 184—191).—The injection of a solution of Wooldridge's tissue fibrinogen into the veins of a living dog leads to thrombosis of the portal area. During active digestion, clots are also found in the right heart and pulmonary artery. Wooldridge considered that the material

in the liver area absorbed from the alimentary tract that favoured coagulation would, during digestion, overflow into the cardiac blood. This, however, cannot be, because coagulation in the portal area can be made to occur after six days inanition, and the injection of tissue fibrinogen leads to universal thrombosis if the animal be made dyspnoic. In the present research, increased venosity of the blood was produced by various methods, asphyxia, muscle tetanus, and retinal stimulation, and, wherever and however caused, subsequent injection of Wooldridge's fluid always led to thrombosis in the area affected. This must be due either to excess of carbonic anhydride or to diminution of oxygen. Animals allowed to breathe air containing a normal amount of oxygen, but excess of carbonic anhydride, suffered from universal thrombosis when the fluid was injected. Thus, increase of carbonic anhydride will alone explain the phenomena. The influence of food, especially of fatty food, as observed by Wooldridge, is probably due to an increased formation of this gas.

W. D. H.

Action of Salts on Heat Coagulation. By S. RINGEE and H. SAINSBURY (*J. Physiol.*, 12, 170—183).—Calcium salts favour the heat coagulation of the proteids of serum. Magnesium sulphate acts similarly. Zinc salts do not act so. It is of interest to note that, in heat coagulation, as in blood-clotting and rennet action, lime plays an important part. One is led to infer a possible likeness in nature between the heat coagulation and the ferment coagulation of proteids. One difference, however, is that in heat coagulation the solution becomes more alkaline, whereas in many ferment actions, as in *rigor mortis*, there is development of acid.

Potassium and sodium salts antagonise, to some extent, the favouring action of calcium salts on heat coagulation, as in processes of clotting brought about by ferments, with this difference, however, that sodium and potassium chloride, when used singly, have a slight favouring action in the separation of proteids by heat.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

The Sugars present in Fungi. By R. FERRY (*Chem. Centr.*, 1891, i, 220).—An examination of 82 varieties of fungi (*Ascomycetes* and *Basidiomycetes*) showed the very wide distribution of mannitol in these plants; trehalose was found much less frequently. In only a few was there any substance present capable of reducing alkaline copper solution. Several species contained considerable quantities of potassium chloride.

J. W. L.

Composition of the Leaves of *Maclura Aurantiaca*. By A. PIZZI (*Staz. Sper. Agrar.*, 18, 589—596).—The leaves of *Maclura aurantiaca*, an American plant, are recommended as a substitute for mul-

berry leaves for feeding silk-worms. The following analytical results were obtained with leaves of plants grown in Italy, and collected at the end of July. The numbers show the percentage in the fresh leaves :—

Water.	Fat.	Proteids.	Non-proteid nitrogenous matter.	Crude cellulose.	Carbo- hydrates.	Ash.
65.71	0.64	4.78	3.23	9.52	12.68	3.42

The ash has the following percentage composition :—

K ₂ O.	Na ₂ O.	MgO.	CaO.	Fe ₂ O ₃ .	SiO ₂ .	P ₂ O ₅ .	SO ₃ .	Cl.	Not deter- mined and lost.
9.24	6.16	6.73	25.73	3.81	26.25	17.54	2.41	1.33	1.81

The results are compared with those obtained by others with mulberry leaves grown in Italy and elsewhere, and the composition of the leaves of both plants shows them to be analogous.

With regard to the digestibility of the leaves, the results of experiments with gastric juice show that in 100 parts of dry leaves there is 1.10 parts of nitrogen digested and 1.14 parts not digested, corresponding with 6.85 and 7.03 parts of proteids respectively. The rest of the nitrogen (1.51 per cent.) is present as amides.

N. H. M.

Chemical Composition and Anatomical Structure of the Fruit of Tomatoes (*Lycopersicum esculent.*). By G. BRISSI and T. GIGLI (*Stuz. Sper. Agrar.*, 18, 5—34).—The ripe fruit of tomatoes was separated into skin, seeds, and pulp. The pulp was further separated, by filtration through calico, into a red, insoluble substance and a yellow liquid, both of which were examined qualitatively, and then the various constituents determined quantitatively. The results given below are the averages of several analyses.

The pulp itself forms 85.4 per cent. of the whole fruit; it contains: total dry matter, 4.725; soluble substance, 3.735; and insoluble matter, 1.093 per cent.

The following numbers show the percentage composition (I) of the dry matter of the red insoluble substance, and (II) of the dry matter of the yellow filtrate :—

	I.	II.
Total nitrogen	4.002	2.254
Proteids	25.012	2.43
Colouring matters	21.128	—
Cellulose	34.390	—
Ash	7.959	10.96
Levulose	—	46.68
Citric acid	—	14.03
Amide-nitrogen	—	0.641
Amido-acid nitrogen	—	1.224

The percentage composition of the ash of the two products is as follows :—

	K ₂ O.	Na ₂ O.	CaO.	MgO.	Cl.	SO ₃ .	P ₂ O ₅ .
I.	—	—	18.127	1.423	—	—	15.866
II.	58.554	1.425	1.315	0.169	8.842	0.781	7.182
		CO ₂ .		SiO ₂ .	Not determined.		
	I.	—		—	64.584		
	II.	18.832		0.451	2.449		

N. H. M.

Composition of the Fruit of Tomatoes (*Solanum lycopersicum*). By N. PASSERINI (*Staz. Sper. Agrar.*, 18, 545—572; compare preceding abstract).—The fresh fruit of tomatoes consists of skin (1.3), pulp and juice (96.2), and seeds (2.5 per cent.). The pulp contains two colouring matters, a yellow, amorphous substance and a red, crystalline substance. They are both insoluble in water, soluble in amyl alcohol, and very soluble in ether, and both are decolorised by chlorine- and bromine-water. The red crystals are almost insoluble in cold alcohol, whilst the yellow compound is very soluble. Hydrochloric acid has no action on either compound.

The sap of the fruit has a sp. gr. = 0.01833 at 15°, and is lævoro-rotatory. It contains a yellow colouring matter, which differs from that of the pulp in being soluble in water, insoluble in alcohol, ether, chloroform, and light petroleum, and in not being decolorised by chlorine-water or bromine-water. The acidity of the sap is due chiefly to citric acid; it contains also a small amount of an alkaloïd, which, like the acid, decreases as the fruit ripens.

The following table shows the percentage of dry matter (1) in the skins, (2) in the pulp, (3) in the sap, and (4) in the seeds, as well as the percentage composition of the dry matter in each case.

	Dry matter.	Organic matter.	Ash.	Proteïds.	Carbohydrates and fat.
Skins	40.50	99.20	0.80	1.85	97.05
Pulp	6.35	89.56	10.44	15.15	71.41
Sap	2.44	74.52	25.48	21.80	52.72
Seeds	53.70	95.56	4.40	25.40	70.16

The carbohydrates of the skins are chiefly in the form of cellulose.

The numbers in the last column for sap refer to carbohydrates and acids.

The following analyses are given of the entire fruit collected (1) in September, 1888, and (2) August, 1889; (1) was unripe, and (2) ripe. The percentage of dry matter was 93.50 and 91.01 respectively. The numbers show the percentage in the fruit dried at 105°.

	Glucose.	Citric acid.	Proteïds.	Fat and colouring matter.	Cellulose.	Ash.
1.	2.68	48.53*	11.25	11.73	7.83	8.05
2.	41.54	9.07	11.48	7.02	18.14	12.73

* Citric acid and substances not determined.

The ash of the fruit has the following percentage composition :—

K ₂ O.	Na ₂ O.	CaO.	MgO.	Fe ₂ O ₃ .	P ₂ O ₅ .	SO ₃ .	SiO ₂ .	Cl.
59.46	5.99	1.34	3.09	0.22	12.93	3.49	0.27	19.14

Having regard to the large amount of potash in the fruit, and the large amount of lime in the stems and leaves (the crude ash of the stems contains 28.32 per cent. of lime) the following manuring is recommended for tomatoes :—Farmyard manure, 5000 kilos., calcium superphosphate (18 per cent.), 30 kilos.; potassium chloride (50 per cent.), 60 kilos. per hectare.

N. H. M.

The Non-nitrogenous Extract-substance from Barley, Malt, and Beer. By C. J. LINTNER (*Bied. Centr.*, 20, 198—200; from *Allgem. Brauer- u. Hopfenzeit*, 1890, No. 128).—When beer is shaken violently with ether, an emulsion is obtained which, only after a long time, separates into two layers. The ethereal layer contains a slimy mass in suspension, like frog's spawn. This substance, which is occasioned by the presence of gummy substance, can be obtained from barley, malt, or beer, in the following manner:—Barley or malt (1 part) is digested with water (5 parts) for a day at the ordinary temperature, filtered, washed, and concentrated by evaporation. It is again filtered and treated with absolute alcohol, as long as a precipitate is formed. This precipitate is filtered by suction, washed with ether, dried, and dissolved in water, with addition of potash. It is filtered, and the filtrate treated with aqueous copper sulphate, being stirred at the same time; a precipitate, the copper oxide compound of the gum, is formed and quickly settles. It is of importance that the liquid should remain strongly alkaline. The precipitate is washed by decantation, until no longer alkaline, filtered, dissolved in strong hydrochloric acid, and precipitated by alcohol: as the first precipitate still contains some copper, this is repeated twice. It is filtered, washed with alcohol, and finally with ether, dried in a vacuum over sulphuric acid, and then at 110°. It is thus obtained as a pure white, very loose powder. When dried in air, it is vitreous and transparent. Both modifications are non-hygroscopic, and dissolve slowly in cold water, but without giving a quite clear solution. It is lævoptatory; after treatment with dilute acids, it is dextrorotatory. It contains carbon (40.00 per cent.) and hydrogen (6.66 per cent.) corresponding with the formula of arabinose, C₅H₁₀O₅; some reactions indicate that it is a substance with 5 (or a multiple of 5) carbon atoms.

It is obtained from beer as described above; Munich beer yielded 0.25 per cent.

N. H. M.

Constituents of the Fruit and Seed of *Illicium anisatum*. By F. ONWALD (*Arch. Pharm.* [2], 29, 84—115).—The fruit of the Star-anise extracted with light petroleum yields a mixture of ethereal and fatty oils. The former oil consists essentially of anethoil. It contains, also, small quantities of terpenes, safrole, quinol ethyl ether, anisic acid, and probably other aromatic compounds which, by oxidation,

give rise, amongst other compounds, to veratric acid and piperonal. The fatty oil contains considerable amounts of fatty and oleic glycerides, with detectable amounts of cholesterol and phosphates. The aqueous extract contains protocatechuic acid, and shikimic acid, discovered by Eijkman. Sugar is not present in the fruit of this plant in any considerable quantity; its sweet taste is to be ascribed essentially to the presence of the ethereal oil. No nitrogenous bases could be detected in the aqueous extract. J. T.

Soil containing Iron and Chromium from the Andaman Islands, East Indies. By C. J. H. WARDEN (*Chem. News*, 63, 85).—These islands are remarkable for the great diversity of soil found on them. The one in question, a rich loamy soil, came from a coffee plantation, and has been submitted to mechanical analysis and various physical tests by the author, the results of which are detailed in the paper; the numbers from chemical analysis in percentages of air-dry soil are as follows:—

Loss at 100°	11.3410
Loss on { water	2.2773
{ organic matter ..	10.4459
ignition { nitric nitrogen	0.00129
{ organic and ammoniacal nitrogen	0.24080

Soluble in water and concentrated hydrochloric acid:—CaO, 0.294; Fe₂O₃, 35.433; Al₂O₃, 10.491; MgO, 0.109; Cr₂O₃, trace; Mn₂O₃, 0.417; Na₂O, 0.455; K₂O, 0.863; Cl, 0.006; P₂O₅, 0.401; SO₃, 0.139; CO₂, trace; SiO₂, 0.046. Insoluble portions:—soluble in alkalis, 14.4819 per cent.; not dissolved by alkalis, but decomposed by sulphuric acid, 2.6569 per cent., containing Fe₂O₃, Al₂O₃, Cr₂O₃ = 2.425; not decomposed by sulphuric acid, 9.256 per cent. The total amount of Cr₂O₃ present was 1.6139 per cent. D. A. L.

Soil Analyses. By A. MAYER (*Bied. Centr.*, 20, 149—151; from *J. f. Landw.*, 38, 157—163).—In connection with the project for reclaiming land between Friesland and Ameland, a large number of mud samples were examined. When the samples are arranged according to the percentage of sand they contain, they show a certain regularity of composition as regards some important constituents (besides clay). The same inverse proportion is shown between sand and humus and between sand and hygroscopic moisture of the air-dried soils. The following numerical results are given:—

Soil sample.	Clay.	Humus.	Moisture.
90—100 p. c. of sand..	0.0—4.8	0.2—2.4	0.0—0.5
60—80 „ ..	5.6—24.1	1.1—6.6	0.3—2.9
20—40 „ ..	34.2—55.8	5.6—14.4	2.6—10.6

The variation in the amount of chalk showed no regularity, but this was of no great practical importance, as all the samples contained more than sufficient chalk. The amount of phosphoric acid was always in exact relation to the clay. Thus, samples with 90 per cent.

of sand contained 0.04 per cent., with 30 per cent. of sand 0.15 per cent. of phosphoric acid soluble in nitric acid. The amount of sand was always an excellent measure of the fertility of the soil.

The method employed was that already described by the author (*Lehrb. d. Agr. Chem.*, 2, 53). The soil (10 grams) is treated with dilute hydrochloric acid to remove chalk, and the separation of sand and clay conducted in a Schöne's apparatus so arranged that, at a water pressure of 5 cm., 1 litre flows out in 10 minutes. The sand is ignited and weighed. The amount of clay is ascertained by difference, when, from the original amount, the sand humus and moisture are subtracted.

Analytical Chemistry.

Dry Reactions in Qualitative Analysis. By W. TATE (*Chem. News*, 63, 86—87).—The author advocates the systematic application of dry reactions in qualitative analysis employing the moist group precipitates, obtained in the ordinary manner, for the purpose; groups II and III being subdivided respectively into the copper and arsenic and the zinc and iron sub-groups. As an example of the proposed method:—Group I precipitate is examined, α , for mercury, by heating a minute quantity on a thread of asbestos in the upper reducing flame of a Bunsen and beneath a cooled porcelain surface, the sublimate being converted into iodide for confirmation; β , for lead, by heating on charcoal until the mercury is dissipated, and heating any residue strongly with potassium iodide and sulphur; γ , for silver, by obtaining bead on charcoal. The method of examining the other groups in a similar manner is described.

D. A. L.

Standardising Acidimetric and Alkalimetric Solutions. By E. HART and S. GROSDALE (*Chem. News*, 63, 93—94; from *J. anal. Chem.*, 4, part 4).—Advantage is taken of the well-known accuracy of the electrolytic method of estimating copper, and therefore pure copper sulphate is electrolysed, and the copper carefully weighed. The exact amount of sulphuric acid in solution is then readily ascertained, and is employed for standardising any desired alkaline solution, which, in its turn, serves for controlling the standard acids. By this means, various disadvantages attached to the use of sodium carbonate, oxalic acid, or potassium oxalate are obviated.

D. A. L.

The Liguoscope: an Instrument for Comparing the Refractive Indices of Liquids. By K. SONDÉN (*Zeit. anal. Chem.*, 30, 196—199).—The apparatus consists of two similar hollow prisms, which are immersed, side by side, in a glycerol-bath formed of a cylindrical vessel with glass ends. When both prisms are filled with liquids having the same refractive index, a horizontal black line

observed through them appears continuous; but if the indices are different, one part of the line is displaced with respect to the other. The instrument is very serviceable for indicating adulteration of butter, oils, glycerol, &c. M. J. S.

Estimation of Nitric Acid by Reduction to Ammonia. By K. ULICH (*Zeit. anal. Chem.*, 30, 175—195).—The reduction of nitric acid to ammonia by iron and sulphuric acid takes place with quantitative completeness (this vol., p. 617).—The estimation can be very conveniently made by means of the deficit in the hydrogen evolved. The iron for this purpose, which should be in the form of the most finely-powdered wrought-iron filings, as free as possible from oxide, should be coated with copper by warming 3 grams of it with 20 c.c. of a 10 per cent. solution of copper sulphate, and washing. This quantity suffices for 25 estimations, when working on about 10 milligrams of nitrate. On warming a known quantity of sulphuric (or hydrochloric) acid with an excess of this couple, a constant volume of hydrogen is evolved, and the reaction is rapidly and sharply completed. The presence of 1 mol. of a nitrate (MNO_3) causes a deficit of 10 atoms of hydrogen, or 1.106 c.c. of hydrogen (dry, and at 0° and 760 mm.) per milligram of potassium nitrate. The apparatus used is here figured.

The decomposition flask holds about 20 c.c., the azotometer 50 c.c., of gas. The tube B has a diameter of 3 mm., and is used for removing the spent liquids. The narrow tube of C should be drawn to a fine point, and bent towards the wall of the neck of the flask.

Before commencing a series of estimations, the air in the apparatus must be displaced by hydrogen, by adding 10 c.c. of normal sulphuric acid to the iron-copper couple in the flask, and warming to 75° with vigorous shaking, whilst the cock A remains open, and the azotometer is filled to the top with water. This treatment removes traces of iron oxide at the same time. The flask is then cooled in a water-bath to the temperature of the air, the water is adjusted to zero, and the apparatus is ready for use. It is necessary to ascertain the exact volume of hydrogen yielded by 20 c.c. of the N/10 sulphuric

acid in use, as this is slightly below theory. By warming to 75° , the reaction is complete in about three minutes. The same volume of acid with the nitrate dissolved in it is then used for the estimation. The temperature of 75° must not be exceeded, since, even at 80° , the couple decomposes water, and an excess of hydrogen would be evolved. (Should this have occurred in any one case, the following experiment, if conducted at a temperature not exceeding 75° , would show an exactly equal deficiency of hydrogen.) The volume of the liquid introduced has to be deducted from the observed volume of gas; the acid in C cannot therefore be rinsed into the flask, but C must be wetted with acid of the same strength as that to be measured into it. A certain excess of acid seems to be necessary, but 20 c.c. of N/10 acid suffices for 15 milligrams of potassium nitrate. The test estimations reported are highly satisfactory, and the method seems to be one of the most rapid known. In the absence of nitrates it may also be used as an acidimetric method. Hydrochloric acid, although it yields precisely the same volume of hydrogen as sulphuric acid, cannot be used in the estimation of nitrates, since low results are always obtained. The presence of much chloride is therefore inadmissible.

M. J. S.

Nitrates in Wine. By M. ZECCHINI (*Staz. Sper. Agrar.*, 18, 35—40).—In testing for nitrates in wine by diphenylamine, it is not sufficient to decolorise the wine with animal charcoal or to precipitate with basic lead acetate, as there still remain substances which give a brown colour with sulphuric acid, and so mask the reaction, if any, with diphenylamine. The following method is recommended as being easy to carry out, and not liable to the danger of introducing nitrates:—50 or 100 c.c. of wine, contained in a porcelain capsule, is treated with a slight excess of lime (prepared from marble) and evaporated to dryness. The residue is detached from the sides of the capsule, well stirred with 20 or 30 c.c. of 92—95 per cent. alcohol, left for about 10 minutes, and filtered. The filtrate is evaporated down on a water-bath, and the residue dissolved in a little pure, distilled water (about 1 c.c.). Half of the solution is tested with diphenylamine; if the coloration is very intense, the experiment is repeated two or three times with more dilute solutions. In this manner it is possible to ascertain whether a larger or smaller amount of nitrate is present.

When wine contains much sugar, it may be necessary to repeat the treatment with lime and alcohol; but this is unnecessary in most cases.

N. H. M.

Densimetric Estimation of the Phosphorus in Iron. By E. E. METZ (*Zeit. anal. Chem.*, 30, 200—206).—The principle introduced by Popper (*Abstr.*, 1877, 638, and 1879, 480) of ascertaining the weight of a precipitate without washing or drying it, by transferring it to a specific gravity bottle, which is filled up with a liquid of known density, and weighing the whole, appeared to be suitable for ammonium phosphomolybdate, owing to the high specific gravity of the precipitate. This was found, as an average of four determinations, to be 3.252. The precipitation took place in a stoppered cylinder of about 250 c.c. capacity, the lower end of which was pro-

longed into an almost capillary tube of 2 c.c. capacity, with a stop-cock at the bottom. The oxidised solution of the iron (0.5 gram in 50 c.c.) after removal of silica, was introduced into this vessel and mixed, first with 20 c.c. of strong ammonia and subsequently with just enough nitric acid to redissolve the precipitate; then (without allowing to cool) 100 c.c. of molybdate solution at about 60° was added, the whole well shaken, and the precipitate allowed to subside until it had wholly entered the narrow tube. After part of the clear liquid had been poured out and its specific gravity ascertained, then, without rinsing the pycnometer, the precipitate was delivered into it by opening the stop-cock. In six test analyses, of which details are given, the results agree closely enough with those of gravimetric estimations to be employed for technical purposes. M. J. S.

Assaying Lead Ores by Fusion with Potassium Cyanide. By W. J. COOPER (*Chem. News*, 63, 73).—The author's experiments show that with an ore of the following percentage composition:— SiO_2 , 83.05; Fe_2S_3 , Cu_2S , 10.639; FeS_2 , 2.967; PbS , 3.001; An , trace; Fe_2O_3 , 0.343; the dry cyanide method for the assay of lead ores offers no advantage over the ordinary wet methods. D. A. L.

Assaying Lead Ores by Fusion with Potassium Cyanide. By A. W. WARWICK (*Chem. News*, 63, 145—146).—A continuation of a previous communication (this vol., p. 863). Anglesite and pyromorphite have now been successfully treated, the latter requiring a very high finishing temperature. It is obvious that minerals or ores containing large quantities of other reducible minerals, which will come down with the lead, such as the ore tried by W. J. Cooper (preceding abstract), are not suitable for assaying by the cyanide method. D. A. L.

Estimation of Mercury in Animal Tissues. By F. HOPMEISTER (*Zeit. anal. Chem.*, 30, 258—259).—The tissue is minced and heated with its own weight of 20 per cent. hydrochloric acid, in a flask with reflux condenser, until completely dissolved. After cooling to 60°, a few grams of potassium chlorate is added in small portions, and the cooled and filtered liquid is shaken with about 5 grams of zinc-dust, to precipitate the mercury. The precipitate is washed successively with water, with soda, and again with water, collected on glass wool, washed with alcohol, and air-dried. It is then introduced into a combustion tube containing columns of granulated lime and copper oxide between asbestos plugs. One end of the tube is drawn out to a U-shape. The mercury is distilled from the zinc in a stream of dry air, over the red-hot lime and copper oxide into the U-tube, where it condenses.

In examining urine, the destruction of the organic matter should not be attempted. It suffices to gently warm the urine with hydrochloric acid before adding the zinc-dust. M. J. S.

Volumetric Estimation of Manganese. By T. MOORE (*Chem. News*, 63, 56—57).—The following method of estimating manganese is recommended as yielding excellent results:—The material, dissolved in syrupy phosphoric acid (sp. gr. 1.75) or in solution to which

that acid has been added, is oxidised by warming gently with potassium chlorate; when all the chlorine has been expelled, the solution is diluted and titrated with ferrous sulphate until the violet colour disappears, or the ferrous sulphate is added in excess and titrated back with permanganate. The equation $\text{Mn}_2\text{O}_3 + 2\text{FeO} = 2\text{MnO} + \text{Fe}_2\text{O}_3$, represents the change, and therefore 1 part of iron is equivalent to 1.4108 of manganic oxide. The only metal which is found to interfere with the method is chromium; however, when cobalt is present it is well to add excess of ferrous sulphate, annul the cobalt colour with nickel sulphate, and then titrate back with permanganate. Nitrites are obviously undesirable; therefore potassium chlorate is preferable to the nitrate for the oxidation. D. A. L.

Quantitative Separation of Manganese and Zinc. By P. JANNASCH and J. F. MACGREGORY (*J. pr. Chem.* [2], 43, 402—406).—To the hydrochloric acid solution (75—100 c.c.) containing the manganese and zinc in a porcelain dish, are added a 15—20 per cent. solution of ammonium chloride, and then ammonia until the liquid is strongly alkaline; the mixture is stirred and hydrogen peroxide added until oxygen begins to be rapidly evolved; the dish is then heated on the water-bath for 10—15 minutes, the precipitated manganese dioxide filtered, washed, first with hot ammonia water, then with hot pure water, and ignited whilst still moist in a platinum or porcelain crucible, being finally heated over the blowpipe until constant in weight. The zinc may be precipitated from the mixed filtrate and washings with ammonium sulphide, but is more rapidly determined by evaporating to dryness in a platinum dish, heating the residue first at 125—150° for one hour and then over a flame, with an intervening asbestos millboard to prevent too high a temperature and consequent loss of zinc; the residue is dissolved in hot water with a drop or two of hydrochloric acid, and the solution precipitated with hot sodium carbonate solution. A. G. B.

Estimation of Manganese in Iron and Steel. By L. BLUM (*Zeit. anal. Chem.*, 30, 210—211).—The modification of Volhard's process proposed by Rürup contains several sources of error. The method consists in dissolving and oxidising 6 grams of substance, neutralising, and adding sodium sulphate, making up to a litre, and filtering. Of the filtrate, 500 c.c. is mixed with zinc oxide, heated, and titrated with potassium permanganate. According to Meineke, however, the presence of free zinc oxide and the absence of soluble zinc salts are both conditions leading to low results. On the other hand, the neglect of the bulk of the basic ferric sulphate has an opposite influence. The advantage of the method would in any case be small, since an estimation by Volhard's process can be completed within an hour. M. J. S.

Glaser's Method for the Estimation of Ferric Oxide and Alumina in Phosphates. By v. GRUBER (*Zeit. anal. Chem.*, 30, 206—207; see this vol., p. 501).—The modifications introduced into

this process by Jones are acknowledged to be improvements. Jones dissolves 5 grams of substance to 500 c.c.; takes 100 c.c. and evaporates it to about half, adds 10 c.c. of dilute sulphuric acid (1 : 5), and then 150 c.c. of alcohol. After a repose of three hours, the precipitate is filtered off and washed with alcohol until neutral. In precipitating the earthy phosphates, the complete expulsion of the excess of ammonia is essential; the precipitate would otherwise contain magnesia.

M. J. S.

Tannin in Urine. By S. KATHEIM (*Chem. Centr.*, 1891, i, 272—273; *Pharm. Zeit.*, 35, 785).—The author recommends the following test:—4—5 c.c. of urine, either after remaining a short time or warmed, is mixed with 5—10 drops of iodine solution (1 : 10); the urine is shaken after the addition of each drop of iodine. In the presence of tannin, a beautiful and characteristic green coloration is produced; with excess of iodine, the coloration becomes brownish-red. In the absence of tannin, the iodine is at first absorbed, and then a red coloration is produced, which changes to reddish-brown on the addition of more iodine.

J. W. L.

Fractional Crystallisation of Quinine Sulphate. By L. PRUNIER (*J. Pharm.* [5], 23, 265—270 and 387—390).—A quinine sulphate containing 6 per cent. of foreign sulphate, when saturated at 100°, gives scarcely any deposit on cooling to 90°; from 90° to 50°, the crystals have nearly a constant composition and contain not more than 1 to 2 per cent. of impurity. Below 50° (and principally about 40°), more than the average amount of cinchonidine appears in the deposit. Between 35° and 25° usually, an abundant crystallisation takes place, dependent on the proportion of cinchonidine and cinchonine present with the quinine; this arises from the separation in a solid form of molecular compounds, and sufficient time is required before filtering off the liquid which is to be employed for the ammonia assay of the quinine sulphate. The results with various samples of sulphate show that the amount of aqueous ammonia required in the ammonia test diminishes with the temperature of filtration. An inspection of the curves plotted from these results shows that the temperature 15°, selected for filtration in the ammonia assay, has been well chosen.

J. T.

Estimation of Theine in Tea. By G. L. SPENCER (*Chem. Centr.*, 1891, i, 373; from *J. Anal. Chem.*, 4, pt. 4).—3 grams of the tea is boiled for half an hour in a 300 c.c. flask, cooled, and a slight excess of lead acetate added (about 0.3 c.c. of concentrated solution per 1 gram of tea). The flask is filled to the mark, shaken, and filtered. 100 c.c. of the filtrate is precipitated with hydrogen sulphide in a flask graduated at 100 c.c. and 110 c.c. The conducting tube is washed with 10 c.c. of water, filtered, and 55 c.c. of the filtrate is extracted seven times with chloroform. The chloroform is evaporated, and the residue, dried at a temperature not exceeding 79°, represents the theine from 0.5 gram of tea.

J. W. L.

General and Physical Chemistry.

Spectra of the Elements of the Second Periodic Group. By H. KAISER and C. RUNGE (*Ann. Phys. Chem.* [2], 43, 385—409).—In a former paper (this vol., p. 137), the authors studied the relations of the line spectra of the alkali metals. They now extend their investigation, using the same methods, to the metals of the alkaline earths and the zinc group. The spectrum of beryllium, on account of its poverty in lines, is left out of consideration.

The values of the constants in the formula $A - B_{\lambda}^{-3} - C_{\lambda}^{-4}$ for the first lines in each series of triplets are contained in the following table:—

	First series.			Second series.		
	A.	B.	C.	A.	B.	C.
Mg	39796	130398	1432090	39837	125471	518781
Ca	33919	123547	961696	34011	120398	346097
Sr	31080	122328	837473	—	—	—
Zn	42945	131641	1236123	42955	126919	532850
Cd	40735	128635	1280619	40797	126146	555137
Hg	40159	127484	1252695	40218	126361	613268

Barium gives no series of triplets. It will be seen from the table that the bivalent elements fall into two groups, namely, the alkaline earths and the zinc-mercury group. In each the values of the constants decrease in general with increasing atomic weight.

J. W.

Chemical Effects of Light: Measurement of Physical Absorption. By G. LEMOINE (*Compt. rend.*, 112, 936—938).—The experiments were made with a solution of ferric chloride and oxalic acid, the quantity of ferrous salt formed being estimated. One cell containing this solution was exposed directly to light, whilst a similar cell was exposed behind the medium the absorption of which was under investigation. In the case of ferric chloride, the absorption varies somewhat with the state of the atmosphere, but under favourable conditions the variations are not great, and the results may be represented by the following expression, which is calculated for semi-normal ferric chloride, i being the intensity of the transmitted light, and l the thickness of the absorbing layer, $i = 0.01(0.986)^l + 0.07(0.40)^l + 0.13(0.10)^l + 0.79(10^{-10})^l$.

C. H. B.

Determination of the Maximum Conductivity of Very Dilute Copper Sulphate Solutions. By P. SACK (*Ann. Phys.*

Chem. [2], 43, 212—224).—As a deduction from the dissociation hypothesis, Arrhenius has shown that the conductivity of electrolytes must reach a maximum as the temperature increases, and then begin to fall (*Abstr.*, 1889, 1044). Experimental confirmation of the theoretical conclusions was obtained for the cases of hypophosphorous and phosphoric acids, but owing to the difficulty of determining the conductivity at high temperatures, no further confirmation has, up to the present, been obtained. The author has, however, succeeded in determining the conductivity of dilute copper sulphate solutions at temperatures up to 120°, the solutions being contained in a sealed apparatus to prevent change of concentration by evaporation. Measurements were thus successfully obtained for three solutions of 0.327 per cent., 0.5 per cent., and 0.64 per cent. concentration, and in each case the conductivity was observed to reach a maximum: for the first solution at 94°, for the second at 95°, and for the third at 96°. A calculation of the temperature of maximum conductivity for the third solution by means of the formula given by Arrhenius (*loc. cit.*) gave 99°. H. C.

Thermochemistry of Platinic Chloride and its Compounds.

By L. PIGEON (*Compt. rend.*, 112, 791—793).—The heat of dissolution of anhydrous platinic chloride, PtCl_4 , is +19.58 Cal.; hence $\text{Pt} + \text{Cl}_4 + \text{Aq} = \text{PtCl}_4$ diss. develops +79.40 Cal. (compare *Abstr.*, 1890, 439). The last value has been verified by reducing a solution of platinic chloride with cobalt, the number obtained being +79.66 Cal. The heat of dissolution of the hydrate $\text{PtCl}_4 + 4\text{H}_2\text{O}$ is -1.74 Cal., and hence PtCl_4 sol. + $4\text{H}_2\text{O}$ liq. = $\text{PtCl}_4 \cdot 4\text{H}_2\text{O}$ sol. develops +21.32 Cal. The reduction of solutions of the alkaline platinichlorides by metallic cobalt shows that

hence,

In the preparation of hydrated platinic chloride by Norton's method, the liquid is at first colourless, and is free from both silver and platinum, but contains a yellow precipitate which must be regarded as silver platinochloride. After some time, especially if heated, the precipitate gradually becomes white, whilst the colour of the liquid becomes deeper. Direct experiment shows that the union of platinic chloride with silver chloride would develop +7.42 Cal., a number considerably lower than the heat of combination of platinic chloride with water, so that

C. H. B.

Calorimetric Data. By BERTHELOT (*Compt. rend.*, 112, 829—834).—*Aspartic Acid*.—Heat of dissolution at 16° —7.25 Cal., heat of neutralisation by sodium hydroxide, first equivalent +3.0 Cal., second equivalent +3.5 Cal., third equivalent 0.0 Cal. In concentrated solution the second equivalent of alkali develops +3.9 Cal. The second acidic function of aspartic acid, as in the case of many allied acids, is not equivalent to the first.

Malonic Chloride, $\text{CH}_2(\text{COCl})_2$.—Decomposition by excess of water develops +44.5 Cal.; decomposition by excess of sodium hydroxide develops +99.7 Cal. The heat developed by the action of water on a molecule of malonic chloride is practically double that developed by the similar decomposition of a molecule of acetic chloride (+23.3 Cal.). The corresponding value for butyric chloride is +21.7 Cal. (Lougouine).

$\text{CH}_2(\text{COCl})_2$, liq. + $2\text{H}_2\text{O}$ liq. = $\text{C}_2\text{H}_4\text{O}_4$
 cryst. + 2HCl gas develops +14.2 Cal.

Tartrates.—When normal sodium dextrotartrate is mixed with calcium chloride, there is development of heat but no precipitation. After a few minutes, a precipitate separates with a further and greater development of heat, the values being for 1 mol. of the salt +0.98 Cal. and +2.68 Cal. respectively.

Sodium lævotartrate behaves in a similar manner, the values being respectively +0.92 Cal. and +2.60 Cal.

Sodium paratartrate is formed without thermal disturbance by mixing equal quantities of the dextro- and lævo-tartrates. When an equivalent quantity of calcium chloride is added, precipitation begins at once, and the thermal disturbance, which at first is equal to +2.20 Cal., rises after a few minutes to +6.3 Cal., the development of heat being perfectly continuous from the moment of mixing up to the maximum.

The heats of neutralisation of the four tartaric acids by sodium hydroxide are practically identical under similar conditions of temperature and concentration, the heat developed being +12.7 Cal. per equivalent.

A solution of sodium paratartrate made by neutralisation of paratartric acid, and mixed immediately with calcium chloride, gives precisely the same thermal disturbance as the solution obtained by mixing the lævo- and dextro-tartrates. The sodium salt of the true inactive tartaric acid under the same conditions yields a precipitate of an insoluble calcium salt with the development of only +3.0 Cal.

Sodium lævo- and dextro-tartrates, when precipitated with an equivalent quantity of silver nitrate, give a continuous development of heat rising from +1.5 Cal. to a total of +4.6 Cal. in the first case, and from +1.1 Cal. to a total of +4.5 Cal. in the second case. Sodium paratartrate, or a mixture of the lævo- and dextro-tartrates, gives an immediate precipitate with a total development of +5.7 Cal.

The greater heat of formation of the insoluble paratartrates corresponds with the greater heat of formation of paratartric acid as established by the author and Jungfleisch.

C. H. B.

Thermochemistry of Bibasic Organic Acids. By G. MASSOT (*Compt. rend.*, 112, 1062—1065).—The author has applied Berthelot's method of calculating the heats of formation of solid salts to the consideration of the relative energy of combination of the first equivalent and the second equivalent respectively of a base with bibasic acids of the oxalic acid type. The heat of neutralisation per equivalent of base of these acids in dilute solution varies from +13 to +14 Cal. In the cases of oxalic and malonic acids, and also with sulphuric, arsenious, and selenic acids, the second equivalent of base disengages rather more heat than the first; whereas succinic, tartaric, sulphurous, selenious, and arsenic acids set free more heat with the first equivalent. The differences vary between 0.5 Cal. and 1 Cal. For the solid salts, the heats of formation are as follows:—

Acids—	Oxalic.	Malonic.	Succinic.	Sulphuric.
1st KOH..	+34.28	+27.87	+25.26	+47.8 Cal.
2nd KOH...	+24.69	+20.70	+21.15	+33.6 "
Total ..	+58.97	+48.57	+46.40	+81.4 "
1st NaOH ..	+28.3	+25.8	—	+42.7 Cal.
2nd NaOH..	+24.7	+15.6	—	+26.6 "
Total ...	+53.0	+41.4	+40.0	+69.3 "

Hence it is evident that in reality the addition of the first equivalent of a base to a bibasic acid with formation of the acid salt sets free more heat than the addition of the second equivalent to form the normal salt. The author thinks that these data give no grounds for assuming an unsymmetrical constitution for the acids, but attributes the thermal differences to a reciprocal action between the two acid groups. This point he illustrates from the data given above. Oxalic acid may be viewed as a substituted formic acid; the two COOH groups appear when near together to cause a mutual strengthening of the acid function, and the bibasic oxalic acid has more than double the heat of neutralisation of formic acid, but when one of these groups is neutralised, the acid salt acts just like formic acid, and has almost the same heat of neutralisation. Malonic and succinic acids behave similarly, the COOH groups having less reciprocal action as they become farther apart in the molecule.

Berthelot observes, with respect to the above paper, that it contains new facts relative to the salts of malonic and succinic acids, but that the conclusion as to the greater heat liberated by the first equivalent of the base is a necessary consequence of the known fact (*Ann. Chim. Phys.* [5], 4, 130) that the union of a bibasic acid with its own normal salt to form an acid salt, in the solid state, disengages heat. It is by the difference between the heats of formation of the acid and normal salts that he has explained the reciprocal actions and the equilibrium between a monobasic and a bibasic acid, for instance, the decomposition of normal sulphates by nitric and hydrochloric acids (*Essai de Méc. Chim.* [2], 586).

W. T.

Thermochemistry of Dextro- and Lævo-tartaric Acids. By H. JAHN (*Ann. Phys. Chem.*, 43, 306—309).—A solution containing dextrotartaric acid was mixed in a Bunsen's ice-calorimeter with an equally strong solution of levotartaric acid. No thermal effect was observed. It was also found that the heat of neutralisation of these acids by an optically active base (morphine, nicotine) was the same in both cases. J. W.

Vapour Pressures of Homologous Compounds. By G. C. SCHMIDT (*Zeit. physikal. Chem.*, 7, 433—468).—Dalton's law that the vapour pressures of all compounds are the same at equal distances from their boiling points has been shown by Regnault and others to be incorrect when applied generally. But it still remains doubtful whether this law does not hold among organic compounds belonging to the same homologous series, although according to the researches of Kahlbaum this is not the case. Examining the evidence for and against, the author found so much discrepancy between the data of different observers, that he decided to submit this point to a very thorough experimental examination. The present paper contains his results with acids of the acetic series, from formic to valeric acid. The substances were heated in a bulb attached to an air-pump and manometer, and the boiling points under different pressures were measured. Great care was taken to ensure the purity of all material used. From the results it is evident that for the compounds examined, and for all pressures below 760 mm., Dalton's law holds with remarkable accuracy. For instance, taking the two extreme cases, the decrease in the boiling point of formic acid with a decrease of pressure from 760 to 10 mm. is 102.8° , and that of valeric acid 103.8° , two numbers which in view of the numerous sources of error may be regarded as identical. The author intends to investigate other homologous series in like manner. H. C.

Data for the Critical State of Liquids. By E. HEILHORN (*Zeit. physikal. Chem.*, 7, 601—613).—The author has brought together in a series of tables the critical data (temperature, pressure, and volume) of the substances which have been investigated in this direction.

Copious references and annotations are given.

J. W.

Adhesion at the Freezing Point. By F. WALD (*Zeit. physikal. Chem.*, 7, 514—517).—If a liquid wets a solid substance, it follows from thermodynamical considerations that the vapour tension of the liquid will be reduced, and that it will exercise a pressure on the solid. Applying this view to the case of melting ice, if the water first formed remains in contact with and wets the ice, its vapour pressure will be less than that of water at 0° . But since the vapour pressure of the water in contact with the ice is equal to that of the ice itself, the vapour pressure of dry ice should be less than that of water at 0° , and not equal to it, as has been hitherto assumed.

H. C.

Dissociation of Amylene Hydrobromide under Low Pressures. By G. LÉMOINE (*Compt. rend.*, 112, 855—858).—The following data were obtained with carefully purified amylene bromide:—

Pressure	764	452	238	121	43	21 mm.
Boiling point ..	105°	90°	71°	55°	34°	28°
Temperature	0.1°	7.2°	18.6°	38°	61°	90° 97°
Sp. gr.	1.224	1.215	1.200	1.176	1.146	1.106 1.100

$$D_t = D_0 (1 - 0.00102t - 0.0000004t^2).$$

	52—15°.	58—16°.	87—17°.
Sp. heat	0.324	0.325	0.335

The determinations of the vapour pressures under ordinary atmospheric pressure indicate more decomposition than was observed by Wurtz, a result probably due to the fact that by means of a thermo-regulator they were prolonged for several hours, in order to attain the limit of decomposition.

The most striking phenomenon is the great variation in the sp. gr. between 175° and 190°.

	Temperature....	100	150°	175°	185°	200°	225°	300°
1 atmos.	Sp. gr. of vapour	„	5.2	5.0	4.1	3.5	3.0	2.6
	Proportion decomposed	„	0	0.05	0.28	0.50	0.75	1
$\frac{1}{10}$ atmos.	Sp. gr. of vapour	5.0	4.6	4.1	3.4	3.1	2.8?	2.6
	Proportion decomposed	0.05	0.14	0.28	0.54	0.69	0.87?	1

It is clear that reduction of pressure facilitates decomposition.

C. H. B.

Diffusion of Fresh Water into Sea Water. By J. THOULET (*Compt. rend.*, 112, 1068—1070).—A cylindrical vessel of 600 c.c. capacity, divided into parts of equal height and equal capacity, was filled up to the 300 c.c. mark with sea water, concentrated to a density of 1.0646; six small spheres of wax, so weighted with quartz that their densities ranged between the density of the salt water and that of fresh water, were placed on the surface, and 300 c.c. of distilled water added without causing any admixture. The vessel was placed in a cellar, with coverings to protect it from changes of temperature. The positions of the spheres were noted from time to time, and the curve belonging to each traced out. The diffusion was very slow, requiring, according to the indications given in 5 months, about 18 months to become complete. From the consideration of the curves of density the following deductions have been drawn:—The fresh water seems to pass into the saline solution as if its molecules interposed themselves between the molecules of the salt; they travel in such a manner that, at any moment, the quantity of fresh water is the same in each horizontal plane of the liquid; it follows that the elementary speed of diffusion is the same, whatever may be the percentage of salt in the solution.

The velocity of diffusion decreases with the time. The decrease cannot be infinite, for then two different salt solutions would never completely mix.

W. T.

Cryoscopy of Dilute Solutions. By S. U. PICKERING (*Ber.*, 24, 1469).—A preliminary notice of results obtained on the freezing points of aqueous and benzene solutions of non-electrolytes containing 1·6 to 0·02 mols. of the dissolved substance to 100 mols. of the solvent. In one or two cases only, is the depression proportional within the limits of experimental error to the strength of the solution, and in most cases it increases with the dilution, becoming notably greater than the value given by Van't Hoff's equation, just as in the case of solutions of electrolytes, although the excess is smaller than with the latter. It is only with a particular strength of solution, and with a strength which is different with different substances, that Van't Hoff's equation expresses the true results. Marked irregularities also were noticed in some cases in the rate at which the depression increases with the strength.

S. U. P.

Freezing Points of Dilute Aqueous Solutions of Non-electrolytes and Electrolytes. By J. TRAUBE (*Ber.*, 24, 1853—1859).—The author has determined the molecular reduction of the freezing point of water, caused by different typical electrolytes and non-electrolytes in solutions of varying concentration. The solutions contained from 2 to $\frac{1}{125}$ gram-mols. of dissolved substance per litre, and in every case the molecular reduction, which for non-electrolytes, at least, should remain constant, was found to increase with rising dilution. This increase is proportionately as great, or even greater, in the case of the non-electrolytes as in that of the electrolytes. From this the author concludes that the cryoscopic behaviour of solutions cannot be accepted as supporting the hypothesis of electrolytic dissociation in aqueous solution, since in this respect there is no essential difference between the behaviour of electrolytes and that of non-electrolytes.

H. C.

Electrical Conductivity and Freezing Point. By J. TRAUBE (*Ber.*, 24, 1859—1864).—In a former paper (this vol., p. 255), the author endeavoured to show that the simple relation said by Arrhenius to exist between the electrical conductivity and the reduction of the freezing point had no experimental foundation. This he now further supports by showing that non-electrolytes, such as cane-sugar, urea, and phenol, have a definite molecular conductivity, which increases with the dilution, and, therefore, the value of $i = 1$, which Arrhenius assumes for these substances, must be incorrect. It is also shown that in the case of electrolytes the values obtained for i vary enormously with the concentration, and in no cases in which the values calculated from the conductivity and those from the freezing point of solutions of the same concentration were compared, was an agreement between the two sets of numbers observed.

H. C.

The Cryoscopic Behaviour of Aqueous Cane-sugar Solutions. By J. F. EYKMAN (*Ber.*, 24, 1783—1785).—The author has repeated the experiments of Traube (this vol., p. 824) with regard to the freezing point of cane-sugar solutions, and finds, contrary to Traube's results, that the depressions with different concentrations are perfectly normal. H. G. C.

The Theory of Dissociation into Ions, and its Consequences. By S. U. PICKERING (*Phil. Mag.* [5], 32, 20—27).—The dissociationists, in opposition to Arrhenius' original view, now hold that the dissociation of compounds evolves heat, the evolution being due to the combination of electric charges with the atoms. The author raises the question as to the origin of such charges in the absence of the expenditure of external energy and the absence of friction, induction, and contact difference of potential: also how an affection of matter (a charge) can combine with matter to produce heat, and itself remain *in statu quo*; how the opposite electrification of the different atoms can, contrary to the older electro-chemical theory, dissolve the union between them. He characterises both this view, and that of the ions being allotropic atoms with less internal energy than ordinary atoms, as an hypothecation of a new form of matter to satisfy a theory which is inconsistent with known matter, or a verbal alteration designed to conjure away a stock of energy, so that the theory may not be said to be contradicted by the principle of the conservation of energy.

Dilution is held to increase dissociation, and, since in the case of calcium nitrate heat is thus absorbed, gaseous calcium nitrate should, on dissolving, absorb heat, for it thereby becomes dissociated; but this can not be true, for it can be shown that gaseous calcium nitrate would evolve heat on dissolution.

The author contrasts the present dissociation hypothesis with that of Clausius, which requires only the presence of a few atoms freed by accidental superheating, or else the continual interchange of atoms between contiguous molecules. The presence of any free atoms however, he considers as opposed to the fact that molecules of the elements are not formed in solutions, and suggests that polarisation currents may be explained by a coating of oriented molecules, not atoms. S. U. P.

Association versus Dissociation in Solutions. By S. U. PICKERING (*Ber.*, 24, 1579).—When $x\text{H}_2\text{NO}_4$ is dissolved in $y\text{H}_2\text{O}$, the dissociation theory represents the acid as becoming partially dissociated into ions, so that the solution consists of more than $x + y$ units, whereas, on the association theory, the acid and water combine together to a certain extent, so that there are less than $x + y$ units present: by its effect on the freezing point of acetic acid the number of acting units can, according to the physical theory, be determined, and is found to be less than $x + y$, and less even than y alone; this was found to hold good for the weakest as well as the strongest solutions. Aqueous solutions of hydrochloric acid and of calcium chloride gave similar results; whilst with aqueous solutions of phosphoric acid and of nitric acid, as well as

with alcoholic solutions of calcium chloride and nitrate, the acting units present, although less than $x + y$, were not less than y alone. According to the author's views, the actual composition of the compounds present cannot be ascertained by this method, and if the second solvent (the one which is frozen) has a much greater affinity for the dissolved substance than the first solvent has, the depression observed will be practically equal to that which would be produced by the substance and first solvent if they acted independently: this was found to be the case when the freezing point of sulphuric acid was depressed by aqueous acetic acid, and that of acetic acid by aqueous alcohol. S. U. P.

Reduction of the Results of Experiments with Special Reference to the Hydrate Theory of Solution. By S. LUPTON (*Phil. Mag.* [5], 31, 418—429).—A criticism of part of Pickering's work on sulphuric acid solutions (*Trans.*, 1890, 64 and 331).

Reduction of the Results of Experiments. By S. U. PICKERING (*Phil. Mag.* [5], 32, 90—98), and by E. H. HAYEN (*Phil. Mag.* [5], 32, 99—104).—Replies to Lupton's criticisms. (See also *Proc.*, 1891, 105—109.)

Objections to the Work on Sulphuric Acid Solutions. By S. U. PICKERING (*Chem. News*, 64, 1, 2).—A further reply to objections raised in the discussion (*Proc.*, 1891, 105—109) on the author's work on this subject.

Solutions of Double Salts. By J. E. TREVOR (*Zeit. physikal. Chem.*, 7, 468—476).—This paper deals with the question of the relative solubilities of two salts which are capable of forming a double salt with one another, when mixed in varying proportions and brought into contact with water. The salts taken were potassium and copper sulphates, and the temperature at which the experiments were conducted was 25°. The solubility of copper sulphate alone in parts per 100 of water is 22.29, that of potassium sulphate 12.04, and that of the double salt 11.14. If excess of both salts is treated with water, or if a saturated solution of the two at a higher temperature is cooled down to 25°, it will be found in each case that the maximum solubility is obtained in 30 minutes, when the solution contains 15.6 grams of solid salt to 100 of water. After this, the solubility decreases, but in no case was it observed to fall to that of the double salt. At the point of maximum solubility, the solid salt is found to contain 5.2K₂SO₄ and 10.4CuSO₄. The proportions calculated on the assumption that each salt is present in the solution in the same proportion as in their saturated solutions would be 5.41K₂SO₄ and 10.13CuSO₄. Hence the solubility of the more soluble salt is greater and that of the less soluble salt is less in the solution of the two than in pure water, a result which, as Noyes has shown (this vol., p. 142), may be predicted from Nernst's theory of solubility. If the saturated solution of one of the salts is added to the saturated solution of the other, the double salt, being less soluble than either of the others, separates out, and this continues until equilibrium is

established, when no further separation takes place. This result is in keeping with Nernst's experiments on salts which contain a common ion (Abstr., 1890, 3), but contradicts Rüdorff's assertion that potassium and copper sulphates displace one another in their concentrated solutions. Rüdorff (Abstr., 1888, 899) also found that if potassium and copper sulphates are allowed to diffuse from a solution in contact with the solid salts, the diffusate will be found to contain the two salts in the proportions in which they are present in the double salt. From this he concludes that the double salt diffuses without decomposition. This view the author shows is incorrect, for, on analysing the solution which is left behind in the dialyser, it is found to contain a greater proportion of copper sulphate than that originally present, and this result explains the above apparent diffusion of the double salt. For the potassium sulphate in the first instance diffuses more rapidly than the copper sulphate, and the latter is therefore left behind in the dialyser. The copper sulphate in the dialyser becomes more and more concentrated, until at length, owing to its concentration, it diffuses as rapidly as the potassium sulphate. The two will then be found in the diffusate in equivalent proportions, but each salt diffuses separately, and not as the double salt, and it remains very doubtful whether the double salt can exist at all in solution. H. C.

Influence of Inorganic Potassium Salts on the Solubility of Potassium Hydrogen Tartrate. By C. BLAREZ (*Compt. rend.*, 112, 808—811).—The author has previously shown (this vol., p. 676) that the solubility of potassium hydrogen tartrate, in moderately strong solutions of potassium chloride at different temperatures, can be represented by the formula $Q_t = 0.05 + 0.000005t^2/\sqrt{K}$, where K is the quantity of potassium existing in the form of chloride. He now finds that this formula holds good for the bromide, iodide, chlorate, and nitrate. In other words, the effect depends solely on the weight of potassium present, and is independent of the nature of the acid with which it is combined; the effect of the various salts is proportional to their respective molecular weights. C. H. B.

Influence of Potassium Halides on the Solubility of Normal Potassium Sulphate. By C. BLAREZ (*Compt. rend.*, 112, 939—942).—The solubility of potassium sulphate between 0° and 30° is represented by the equation

$$S_t = 8.5 + 0.12t.$$

If a saturated solution is mixed with successive small quantities of a potassium halide, a certain quantity of potassium sulphate is precipitated, but the sum of the salts in solution continually increases until a reverse action begins and the potassium sulphate affects the solubility of the halide. There is no simple relation between the quantity of potassium sulphate remaining in solution and the mass of the halide added; at a given temperature, however, the sum of the potassium sulphate in solution and the potassium in the salt added remains constant, so that $K_2SO_4 \text{ diss.} = \text{const.} - K \text{ in the halide.}$

The constant varies with the temperature, but between 0° and 30° the solubility of the potassium sulphate is represented by the equation

$$S_t = 7.5 + 0.1417t - K,$$

where K is the weight of potassium in the halide added. It is noteworthy that in this case, as with the hydrogen tartrate, the influence of the different potassium halides is proportional to their molecular weights.
C. H. B.

Influence of Temperature on the Limits of the Explosion of Gaseous Mixtures. By J. ROZKOWSKI (*Zeit. physikal. Chem.*, 7, 485—499).—The author has investigated the conditions of the explosion of hydrogen, carbonic oxide, methane, and coal gas when mixed with oxygen or air, in different proportions, in the presence of an indifferent gas, such as carbonic anhydride, and at different temperatures. Dilution with an indifferent gas decreases the tendency to explode in gaseous mixtures; but this decrease is less the higher the temperature. This is probably due to the fact that the heat generated by combination of the two gases is largely used up in heating the indifferent gas present, instead of being employed in propagating the explosion. At low temperatures, methane will bear the greatest dilution without losing its power of exploding with oxygen, then come coal gas and hydrogen, and, lastly, carbonic oxide. At high temperatures (300°), the order is reversed.
H. C.

The Dead-space in the Chloral-Soda Reaction. By E. BUDDI (*Zeit. physikal. Chem.*, 7, 586—600).—The figures drawn by Liebreich (*Zeit. physikal. Chem.*, 5, 529—558; see also Abstr., 1890, 1207) to show the form of the dead-space in the chloral-soda reaction are compared by the author, who finds that the inferior surface makes in all cases an angle of about 150° with the glass walls. This signifies, in the author's opinion, that emulsions have a special coefficient of capillarity, and therefore a special mean surface-tension. The chloroform produced in the reaction he supposes to evaporate from the free surface of the liquid, and the lower boundary of the dead-space is that surface where the loss of chloroform by diffusion and evaporation exactly balances the production of chloroform by the interaction of the chloral and sodium carbonate. Various arguments are adduced to support the evaporation theory, the author considering unnecessary the assumption, made by Liebreich, that the mobility of the liquid molecules is diminished at measurable distances from the free surface.
J. W.

The Factors of Energy. By W. MEYERHOFFER (*Zeit. physikal. Chem.*, 7, 544—585).—Any form of energy can be decomposed into two factors: for example, electrical energy = quantity \times potential, energy of gases = volume \times pressure.

The author gives the general equation:—Energy = content (*Inhalt*) \times potential, and enunciates the following principle:—"The energy-contents of the ultimate particles of matter are equal." He proceeds to show that nearly all known stoichiometric regularities are parti-

cular cases of this rule, and that all known methods of determining molecular weights are based on one and the same principle, that, namely, of finding what masses possess the same energy-content.

The second law of thermodynamics is next discussed, and the author concludes that, in its ordinary form, it is untenable, there being no fundamental difference between heat and any other form of energy, the apparent distinction resting merely on the fact that we cannot attain zero-potential (the absolute zero of temperature) in the case of heat-energy, whilst this is possible for other forms. Some considerations on the general conditions of equilibrium follow, and the author concludes by identifying his "heat-content" with the "calorique" of Carnot, and by contesting the existence of energy as substance.

J. W.

Inorganic Chemistry.

Volumetric Composition of Water. By E. W. MORLEY (*Amer. J. Sci.* [3], 41, 220—231 and 276—288).—By the electrolysis of dilute sulphuric acid and most careful purification, hydrogen was obtained containing no impurity other than nitrogen in amount large enough to be detected. The amount of nitrogen present was never more than one-hundredth of a cubic centimetre in 2 litres of hydrogen, and was always determined in the gas used. An apparatus for the measurement of the gases was constructed, and is described in the paper, in which the mean error of measurement of the volume of hydrogen and oxygen used in the experiments was less than 1 part in 50000. With this 20 experiments were made, which gave a maximum value of 2.00047, a minimum value of 2.00005, and a mean value of 2.00023 volumes of hydrogen to unit volume of oxygen for the composition of water.

H. C.

Preparation of Hydrobromic Acid. By M. FIERI and F. CROSA (*Gazzetta*, 21, 64—65).—The authors have found the following process convenient and economical for the preparation of considerable quantities of hydrobromic acid:—A mixture of 1 part of red phosphorus, 2 parts of water, and sufficient sand to form a paste, is introduced into a flask, 10 parts of bromine then gradually added by means of a funnel provided with a stopcock, the flask gradually warmed, and the mixture of hydrogen bromide and bromine vapour passed through a deep glass jar filled with a mixture of red phosphorus and asbestos, impregnated with concentrated hydrobromic acid. Every trace of bromine vapour is thus effectually retained, and the process is continuous, and requires no supervision beyond an occasional shaking of the flask.

S. B. A. A.

Two New Modifications of Sulphur. By ENGEL (*Compt. rend.*, 112, 866—868).—One volume of sodium thiosulphate solution, saturated at the ordinary temperature, is poured, with continual

agitation, into 2 vols. of a solution of hydrochloric acid, saturated at 25—30°, and cooled to about 10°. Sodium chloride is precipitated, and the thiosulphuric acid is so far stable that the liquid can be filtered. The filtrate is at first colourless, but soon becomes yellow, the intensity of the colour gradually increasing, as if a soluble sulphur establishes equilibrium in the decomposition of the thiosulphuric acid; sulphurous anhydride is evolved at the same time. When the liquid has acquired a deep-yellow colour, but while it is still quite transparent, it is agitated with its own volume of chloroform, which becomes yellow, whilst the colour of the aqueous solution becomes less intense. If the chloroform is allowed to evaporate, orange-yellow crystals of sulphur are obtained, quite different from octahedral sulphur; they have been examined by Friedel (next abstract). They are denser than octahedral sulphur (sp. gr. = 2.135), and at first are transparent, but in three or four hours they increase in volume, and pass gradually into the state of amorphous insoluble sulphur. They melt below 100°, and pass into the condition of the pasty sulphur from the thiosulphates and become partially soluble in carbon bisulphide.

If the solution of thiosulphuric acid in hydrochloric acid is allowed to remain, sulphur separates as a yellow, flocculent precipitate, completely soluble in water. The solution is yellow, and decomposes very rapidly, giving the ordinary pasty sulphur of the thiosulphates. The original precipitate gradually agglomerates, and passes into the same insoluble form without any evolution of hydrogen sulphide.

These phenomena are probably due to the gradual condensation of sulphur from an atomic to a polyatomic form. C. H. B.

Crystalline Form and Optical Properties of Engel's Crystalline Modification of Sulphur. By C. FRIEDEL (*Compt. rend.*, 112, 831—835).—The crystals are rhombohedral, and belong to the hexagonal system; with converging polarised light, they show the cross and rings of birefractive uniaxial substances. The rhombohedron is very obtuse; $2p$ (normal) = 40° 50'. It is noteworthy that tellurium crystallises in rhombohedral forms. C. H. B.

Volatility of Sulphuric Acid at Ordinary Temperatures. By A. GOLDBLAX (*Chem. News*, 63, 179).—G. A. Koenigs has noticed that skeleton crystals of metallic iron, placed on a watch glass, supported on an iron triangle, in an ordinary desiccator containing sulphuric acid, had, after nine months, become coated with a white crust of anhydrous ferrous sulphate, and regards this as an indication of the volatility of sulphuric acid at the ordinary temperature of the air. This view finds support in the behaviour of the neutral compound obtained by the author of the present note from phenylic acid (*Trans.*, 1891, 190); this white, crystalline substance, when supported in a watch glass on a glass triangle over sulphuric acid in a perfectly clean ordinary desiccator, becomes rapidly brown and moist, a behaviour which it does not exhibit when exposed either over phosphoric anhydride or calcium chloride, or in an atmosphere containing sulphurous anhydride or nitrous fumes. D. A. L.

Formation of Dithionic Acid from Sodium Sulphite. By A. HOLST and R. OTTO (*Arch. Pharm.*, 229, 171—177).—Malschevski and Sokoloff (*J. Russ. Chem. Soc.*, 1881, i, 169) showed that by the gradual addition of a dilute solution of iodine in potassium iodide to a dilute solution of hydrogen sodium sulphite, dithionic acid was produced to the extent of 20 per cent. of that theoretically possible. Doubt has been thrown on the above statement; but the authors' results confirm it. In their last experiment, 20·4 per cent. of the theoretically possible amount of dithionic acid was obtained. To estimate the amount of dithionic acid in its salts, it is only necessary to heat an aqueous solution with hydrochloric acid until all sulphurous anhydride is expelled, and then to precipitate the sulphuric acid in the residue with barium chloride. J. T.

Sulphuryl Peroxide (Holoxide). By M. TRAUBE (*Ber.*, 24, 1764—1770; compare *Abstr.*, 1889, 940).—It is not possible to isolate sulphuryl peroxide (holoxide) from its solution in 40 per cent. sulphuric acid by precipitating the sulphuric acid with barium carbonate, as the peroxide, not being capable of existence in pure water, then undergoes decomposition with the evolution of oxygen and the formation of hydrogen peroxide. When, however, the solution is diluted with 2—4 times its volume of water, and freshly-prepared barium phosphate added, the filtrate contains sulphuryl peroxide (holoxide) and barium phosphate dissolved in phosphoric acid; the amount of active oxygen is then determined by adding ferrous sulphate and titrating the excess with potassium permanganate, and that of sulphuric anhydride by boiling the solution with barium chloride and weighing the barium sulphate precipitated; the ratio of the weights of active oxygen and sulphuric anhydride is thus found to be 1 : 5, which agrees with the empirical formula SO_4 . When the electrolysed 40 per cent. sulphuric acid, containing the sulphuryl peroxide (holoxide), is diluted with 1—2 vols. of water, and saturated with alkali at -10° , the peroxide remains practically undecomposed, so that alkali sulphates appear to exercise a protective influence on it; when, however, the solution is boiled for about half an hour, it ceases to give a blue colour with zinc iodide-starch, and becomes acid. It follows, therefore, that the compound is not the anhydride of an acid, or it would have formed the salt K_2SO_4 when saturated with potassium hydroxide, and this would then have decomposed into normal potassium sulphate and oxygen on boiling. Quantitative determinations of the amount of active oxygen in the neutralised solution, by adding potassium iodide and titrating with potassium thio-sulphate, and also of the sulphuric acid produced on boiling it, by titrating with alkali, employing rosolic acid as indicator, gave, as a mean result, the ratio 1 : 4·85. When the active oxygen is determined by the ferrous sulphate method (see above), a higher value is obtained, which, when compared with the alkalimetric determination of the sulphuric acid, gives another ratio; this is explained as follows:—A large quantity of alkali, which always contains carbonates, being necessary to saturate the sulphuric acid solution of the peroxide, a certain amount of the hydrogen carbonate (which, owing to its neutral

reaction, escapes detection) is invariably produced; when, however, the solution is boiled, a portion of the resulting sulphuric acid is neutralised by the hydrogen carbonate, and thus a low result is obtained by the alkalimetric method; the hydrogen carbonate exerts an influence in the opposite direction on the iodometric determination of the active oxygen, and the two errors compensating each other the correct ratio is preserved. It is, therefore, obvious that when the alkalimetric determination of sulphuric acid is compared with the accurate determination of the active oxygen by the ferrous sulphate method, a different ratio will be obtained. When the solution of the peroxide in 40 per cent. sulphuric acid (6—10 c.c.) is saturated by the very gradual addition of 33·3 per cent. sodium hydroxide solution at -15° , a slight excess of sulphuric acid and water, free from carbonic anhydride (100 c.c.), added to the crystalline mass, and after evaporation of the solution in the desiccator, and renewed dilution with water (100 c.c.), the active oxygen is determined by the ferrous sulphate method, and the acidity before and after boiling by titrating with standard alkali (the difference between the two giving the acid produced by the decomposition of the anhydride), the ratio 1 : 4·4 is obtained.

Sulphuryl peroxide (holoxide) is the analogue of the peroxides of organic acids discovered by Brodie. Berthelot's compound S_2O_7 is, perhaps, formed by the union of sulphuryl peroxide (holoxide) and sulphuric anhydride. According to Berthelot, his compound is decomposed by water with the evolution of oxygen, but it dissolves in not too dilute sulphuric acid without the evolution of oxygen. The author suggests that in the latter case it may react with the water present, forming sulphuric acid and sulphuryl peroxide (holoxide), $S_2O_7 + H_2O = H_2SO_4 + SO_2$, and this explains his observation that such a solution is identical with the solution of sulphuryl peroxide (holoxide) in not too dilute sulphuric acid prepared by electrolysis.

A. R. L.

Boron Hydride. By P. SARATIER (*Compt. rend.*, 112, 865).—Magnesium boride is prepared by heating boric anhydride with magnesium powder in iron dishes in an atmosphere of hydrogen. The product is a brown mass, which is rapidly attacked by hydrochloric acid, leaving a slight residue of amorphous boron. The gas liberated by the action of the acid has an intensely disagreeable odour, burns with a beautiful green flame, and with silver nitrate solution, yields a brown precipitate soluble in nitric acid. When passed through a glass tube heated to dull redness, a ring of boron is deposited, and the issuing gas is ordinary hydrogen. In contact with potash there is a slight increase of volume, and the residual gas consists of pure hydrogen; water acts on the gas very slowly; mercury is attacked by it, and becomes covered with a brown layer. Electric sparks decompose it, leaving pure hydrogen.

This product (the boron hydride of Jones) is clearly hydrogen mixed with a very small proportion of boron hydride. C. H. B.

Boron Triiodide. By H. MOISSAN (*Compt. rend.*, 112, 717—720).—Boron triiodide is obtained (1) by passing a mixture of hydrogen

iodide and boron chloride vapour through a porcelain tube heated to redness; (2) by the action of iodine on boron at 700–800°, and (3) by the action of hydrogen iodide on amorphous boron. The last method gives the best results. Amorphous boron, dried in hydrogen at 200°, is heated in a current of dry hydrogen iodide in a Bohemian glass tube at a temperature approaching the softening point of the glass. Boron triiodide sublimes in large lamellae, which have a purple-red colour, owing to the presence of a small quantity of iodine. When the crystals are dissolved in carbon bisulphide, and the solution is agitated with mercury, it becomes colourless, and on evaporation deposits colourless crystals, which, however, rapidly become coloured when exposed to light.

Boron triiodide is extremely hygroscopic, and is decomposed by the water which it attracts. It melts at 43°, and when it cools contracts and crystallises very readily; at 210°, it boils without decomposition, and if the vapour is heated to redness in a glass tube it burns when brought into contact with the air, iodine being liberated. It is very soluble in carbon bisulphide, benzene, and carbon tetrachloride, and is slightly soluble in phosphorus chloride, arsenic chloride, and many organic liquids.

Boron triiodide is decomposed immediately by water, yielding boric and hydriodic acids; it is not affected by hydrogen at a cherry-red heat, but burns when heated in oxygen, and is rapidly attacked by melted sulphur. Phosphorus interacts with it in the cold, with vivid incandescence, but silicon has no action at a dull-red heat. Sodium has no action at 50°, nor even at 210°, but at a red heat interaction takes place with incandescence.

Magnesium is attacked at 500°, with incandescence, but aluminium is not affected. Silver has no action at 500°, but silver fluoride interacts at the ordinary temperature, with incandescence and formation of silver iodide and boron fluoride. Phosphorus oxychloride, chloroform, and many organic liquids also produce an energetic reaction. Alcohol decomposes at once, and yields ethyl iodide and boric acid, $3\text{EtOH} + \text{BI}_3 = \text{H}_3\text{BO}_3 + 3\text{EtI}$. Ether yields ethyl iodide, boric acid, and alcohol. C. H. B.

Action of Hydriodic Acid on Boron Bromide. By A. BLISSON (*Compt. rend.*, 112, 1001–1003).—At the ordinary temperature no action takes place, but, by passing a current of hydrogen iodide containing boron bromide vapours through a glass tube heated to 300–400°, the substitution products BBr_2I , BBri_2 , and BI_3 are obtained. The yield is very small; the triiodide is easily separated from the other products, which can only be isolated with difficulty. The iodide and bromides are rapidly decomposed by air and light; light alone appears to be unable to effect the decomposition, the mechanism of which appears to be as follows:—The atmospheric moisture sets free hydriodic acid, which, in presence of light and the oxygen of the air, is decomposed with liberation of iodine. They are decomposed by water with violence. The bromide, BBr_2I , is a colourless liquid, distilling at about 125°. The second product, BBri_2 , is a similar substance, distilling at about 180°. W T

Boron Sulphide. By P. SABATIER (*Compt. rend.*, 112, 862—864).—Boron sulphide was prepared by the action of hydrogen sulphide on amorphous boron at a red heat. The product is carried forward by the excess of gas, and condenses in different forms in different parts of the apparatus. Near the hottest part of the tube it is fused, and becomes opalescent when cold; further away it forms an opaque porcelain-like mass, with a slight nacreous lustre and a conchoidal fracture; in the coolest part of the tube it forms brilliant, very light needles. These needles are pure boron sulphide, B_2S_3 ; the vitreous product always contains an excess of sulphur, varying from 11 to 17 per cent. All the forms of boron sulphide are attacked by water with very great violence, with formation of boric acid and hydrogen sulphide, the heat developed ($B_2S_3 = 118$ grams) being 58 Cal. with the acicular sulphide, and 56 Cal. with the vitreous sulphide. Solution of the sulphide in iodine solution develops +124.6 Cal., and from this the decomposition by water would develop +58.6 Cal. The mean value is +57.8 Cal.

From these results, it follows that B_2 amorphous + S_2 solid = B_2S_3 solid, develops +82.6 Cal., a number lower than the heat of formation of a corresponding quantity of oxide or chloride; lower even than the heat of formation of the iodide. As a matter of fact, iodine has no action on boron sulphide in the cold, but decomposes it at a dull-red heat, with formation of brown lamellæ, which seem to be identical with the iodide described by Moissan. C. H. B.

Boron Selenide. By P. SABATIER (*Compt. rend.*, 112, 1000).—Boron selenide is prepared by passing a slow regular current of dry hydrogen selenide over boron, maintained at a bright-red heat, in a hard glass tube. The brownish-black boron is entirely transformed into the yellowish-grey boron selenide without fusion, a little of the compound only being deposited in a pulverulent state on the tube beyond the boat. The selenide is much less fusible and volatile than the corresponding sulphide. Water acts violently on the grey boron selenide, disengaging hydrogen selenide, and at the same time liberating some red, pulverulent selenium; hence, doubtless, the disgusting odour of the substance is due to the action of atmospheric moisture.

The yellow, pulverulent selenide deposited beyond the boat is decomposed by water without deposition of selenium; hence its composition is doubtless comparable with that of the sulphide, and would be represented by B_2Se_3 ; this conclusion is borne out by the results of a rapid analysis of the compound. The author will determine the heat of combination of this selenide as well as that of boron telluride.

W. T.

Action of Hydrogen Bromide on Silicon Chloride. By A. BISSON (*Compt. rend.*, 112, 788—791).—Hydrogen bromide, mixed with vapour of silicon chloride, was passed repeatedly through a red-hot tube, and the product was digested with mercury and fractionated. Silicon bromotrichloride, $SiBrCl_3$, was easily purified by fractionation; it boils at +80°, and does not solidify at -60°. With ammonia, it yields a white, amorphous compound, $2SiClBr_2 \cdot 11NH_3$, and with

hydrogen phosphide at 0° under 25 atmos., or at -22° under 17 atmos., it also forms a solid compound.

The chlorotribromide and the dichlorodibromide could not be separated by fractionation; but the former solidifies at -39° , whilst the latter does not solidify even at -60° .

Silicon chlorotribromide, SiClBr_3 , melts at -39° , and boils at $136-128^{\circ}$. It shows a great tendency to remain in superfusion, even at -50° . With ammonia it yields a white, amorphous compound, $2\text{SiClBr}_3 \cdot 11\text{NH}_3$, readily decomposed by water.

Silicon dichlorodibromide yields with ammonia a white, amorphous compound, $\text{SiCl}_2\text{Br}_2 \cdot 5\text{NH}_3$, which is decomposed by water.

The products of the interaction of the haloid acids and boron halides are under investigation.

C. H. B.

Potassium Persulphate. By H. MARSHALL (*Proc. Roy. Soc. Edin.*, 18, 63—64).—A mixture of cobaltous sulphate, potassium sulphate, and sulphuric acid, when submitted to electrolysis in a divided cell, yields crystals of potassium persulphate. Also the same compound is obtained when potassium hydrogen sulphate is electrolysed under the same conditions. The salt dissolves readily in hot water, but, if boiled, oxygen is evolved; it appears to be isomorphous with potassium permanganate; experiments on the electrical conductivity of the solution show that the formula is $\text{K}_2\text{S}_2\text{O}_8$; it forms no precipitate with barium salts; with silver nitrate, silver peroxide is produced; hydrochloric acid gives chlorine, and strong nitric or sulphuric acid yields oxygen highly charged with ozone.

E. W. P.

Sodium. By M. ROSENFELD (*Ber.*, 24, 1658—1660).—Sodium, which when kept under mineral oil has become covered with a crust, is easily purified by immersing in a mixture of amyl alcohol (1 part) and petroleum (3 parts) and rubbing with a rag soaked in the same mixture until it acquires a silvery lustre. It is then laid in petroleum containing 5 per cent. of amyl alcohol, washed with pure petroleum, and kept in petroleum containing 0.5 to 1 per cent. of amyl alcohol. The bright metal becomes slowly covered with a film of sodium amyloxide, which is, however, easily rubbed off with filter paper. Potassium and lithium can be purified in the same way and then keep their metallic lustre for a long time.

Sodium cleaned as above combines at once with mercury with evolution of light. The liquid alloy of sodium and potassium is easily prepared by pressing together the two clean metals under a mixture of amyl alcohol (1 part) and petroleum (3 parts). Sodium sulphide is also easily prepared by rubbing the clean metal (1 gram) and salt (3 grams) to a fine powder, and then mixing with sulphur (0.7 gram), care being taken to avoid any pressure. When the two substances are intimately mixed, combination suddenly takes place with evolution of light. If the mixture of sodium powder and salt be mixed with sulphur in the proportions required to form di- or trisulphide, the reaction takes place more quickly and violently.

Selenium and tellurium behave in the same way as sulphur when mixed with sodium powder.

E. C. R.

Argentous Compounds. By GÜNTZ (*Compt. rend.*, 112, 861—862).—When dry hydrogen chloride is passed over silver subfluoride (Abstr., 1890, 1055), the latter becomes violet, and when the action has reached its limit, the product has the composition Ag 83.35 to 84.08; Cl 15.07 to 14.19 (calc. for Ag_2Cl , Ag = 85.88; Cl = 15.12). Carbon tetrachloride, silicon tetrachloride, phosphorus chloride, &c., behave in a similar manner and yield silver subchloride, Ag_2Cl , and the corresponding fluoride. The author has prepared the subiodide by the action of hydrogen iodide; the subfluoride by the action of hydrogen sulphide; and the suboxide by the action of water vapour at 160° .
C. H. B.

The Cause of the Slight Solubility of Chemically Pure Zinc in Acids. By J. M. WERREN (*Ber.*, 24, 1785—1798).—The slight solubility of pure zinc in dilute acids is usually explained by supposing that the solution of impure zinc is in reality due to the electric currents set up by the contact of the zinc with the impurities, and that as in pure zinc no such currents can occur, it remains undissolved. This theory does not, however, account for the solubility of the pure metal in nitric acid, or even in dilute sulphuric or hydrochloric acid at their boiling points, and the author has, therefore, again investigated the subject. As the result of his experiments he finds that the insolubility of the pure zinc is due simply to the formation of a condensed layer of hydrogen on the surface, which then prevents the further action of the acid. In the case of nitric acid, this layer is oxidised by the acid as it forms, and cannot protect the surface of the metal, whilst in the case of impure zinc, the hydrogen is evolved from the surface of the more electro-negative impurities according to the usual law, thus leaving the surface of the zinc exposed to the action of the acid.

The experiments were made with chemically pure zinc and sulphuric acid, the latter being diluted with 20 parts of pure water. It was proved that even such simple means as brushing the surface of the zinc caused a considerable increase in the quantity dissolved. This became much more striking when the reaction was allowed to take place in a vacuum, the relation of the mean quantity dissolved under atmospheric pressure and in a vacuum being 1:6.6. The quantity of impure zinc dissolved under similar conditions was found to undergo very little change.

In the next series of experiments, the quantity of pure zinc dissolved by the acid at different temperatures was determined. The quantity dissolved in 30 minutes increased regularly from 2.1 milligrams at 0° to 9.3 milligrams at 98° , but as soon as 100° was reached and ebullition commenced the quantity rose to 122.1 milligrams. This is in full agreement with the author's theory, as the evolution of bubbles, which start for the most part from the zinc plate, would naturally affect the hydrogen film and expose fresh surfaces of the zinc to the action of the acid. If the temperature be raised above 100° by increasing the pressure, the quantity of zinc dissolved is not appreciably more than at 98° so long as ebullition does not take place. The quantity of impure zinc dissolved is not appreciably affected by the ebullition of the liquid.

The addition of chromic acid and of hydrogen peroxide to the acid also causes a great increase in the solubility of the pure zinc, the former causing an increase in the ratio 175:1, and the latter in the ratio 306:1, a result which is again strongly in favour of the author's theory. These oxidising agents do indeed also increase the solubility of impure zinc, but to a much smaller extent, the ratio for chromic acid being 6.5:1, for hydrogen peroxide 3.5:1.

Similar results have been obtained with cadmium, cobalt, iron, and aluminium. The latter, which is as a rule almost insoluble in dilute acids, dissolves readily in a vacuum, and also dissolves under similar conditions in neutral ferric chloride solution, the latter being reduced to ferrous chloride by the hydrogen evolved. H. (i. C.

Determination of the Molecular Weights of some Metals. By G. MEYER (*Zeit. physikal. Chem.*, 7, 477—484).—The author has determined the molecular weights of a number of metals by measuring the E.M.F. of cells containing two amalgams of the metal in question of different concentration as electrodes and a salt of the metal as electrolyte (comp. Turin, Abstr., 1890, 1046). If E is the E.M.F. measured, the molecular weight may then be obtained by means of the equation $M = 1.1908 \frac{qT}{E} \times \log_{10} \frac{c_1}{c_2}$, where c_1 and c_2 are the concentrations of the two amalgams, q is the electrochemical equivalent of the metal, and T is the absolute temperature. In this way the molecular weights of zinc, cadmium, lead, tin, copper, and sodium were determined at ordinary temperatures. All these metals were found to have monatomic molecules. H. C.

Magnesium Lead Iodide. By R. OTTO and D. DREWES (*Arch. Pharm.*, 229, 179—181).—Magnesium carbonate was dissolved in aqueous hydriodic acid and the solution evaporated until a skin formed on the surface; then as much dry lead iodide was added as the liquid would take up. On filtering hot and allowing to remain until cold, a copious deposit of crystals of magnesium lead iodide, $PbMg_2I_6 + 16H_2O$, was obtained. The honey-yellow salt loses its water of crystallisation at 140° and becomes citron-yellow. Above 150° , it decomposes with separation of iodine. Like the corresponding chloride, it is exceedingly hygroscopic. In the air it quickly becomes a magnesium iodide lye, containing lead iodide in suspension. Water decomposes it into soluble magnesium iodide and insoluble lead iodide. Exposed to hydrogen sulphide, it immediately gives rise to lead sulphide, which afterwards passes into lead sulphate. The crystals belong to the rhombohedral system. J. T.

Earths of the Cerium and Yttrium Groups. By A. BETTENDORFF (*Annalen*, 263, 164—174).—The brown oxide ($RO = 113.2$ — 114) obtained from orthite as already described (Abstr., 1890, 851) contains didymium, samarium, gadolinium, and terbium; when it is submitted to a further systematic partial decomposition of the nitrates, the didymium accumulates in the last fractions, as its nitrate is relatively the most stable, and, after a number of operations, didymium oxide ($RO = 110.76$) can be isolated from the mixture. The

first fractions yield a yellow, or reddish-yellow oxide ($RO = 118-119.5$) the concentrated solution of which does not give the absorption lines of didymium at all, but shows those of samarium in a very marked manner; when a concentrated neutral solution of the nitrate of this oxide ($RO = 118-119.5$) is mixed with a warm saturated solution of potassium sulphate, no separation takes place for some hours, and then a yellowish, crystalline powder, consisting principally of potassium samarium sulphate, is deposited. From this salt, an almost colourless earth, having the equivalent 116.49, can be isolated, whilst there remains in solution the double salt of a yellowish-red earth ($RO = 119.96$) containing terbium and gadolinium but only very small quantities of samarium.

By fractionally precipitating with very dilute ammonia the nitrate of the crude samarium oxide, prepared from the potassium samarium sulphate, the oxide can be obtained in a colourless condition. The atomic weight of samarium was determined by submitting the nitrate of this colourless oxide to fractional decomposition and converting the first, fifth, and ninth fractions into the sulphate; the first fraction gave $RO = 115.97$, but the fifth and ninth gave concordant results, namely, $RO = 116.05$ and $RO = 116.06$ respectively, from which the atomic weight of samarium is calculated to be 100.06 ($O = 15.96$, $S = 31.98$), or $R''' = 150.09$.

The pure samarium earth is colourless, and has in a high degree the property of emitting light when it is heated to a high temperature on platinum wire, giving a luminous spectrum in which are observed bright lines, corresponding exactly with the dark bands in the absorption spectrum of its solution; the wave-length measurements of five of these bright lines and a diagram of the spectrum are given.

On comparing the spectrum of glowing samarium earth with the absorption spectrum of a solution of a samarium salt, it is seen that in the former there are present bright lines with which there are no corresponding dark lines in the absorption spectrum; the same phenomenon was observed by Bahr and Bunsen in the case of erbium earth.

The absorption spectrum, obtained by passing the light emitted from zirconium oxide heated in the oxyhydrogen flame through a plate (1.5 mm. in diameter) of a crystal of samarium sulphate, is unusually sharp, the six bands of the absorption spectrum of a solution of the salt being separated into twelve well-defined lines; the measurements of the wave-lengths of these lines and a diagram of the spectrum are given, as are also those of the spark spectrum of samarium chloride.

All the observations made in the course of the author's investigation of samarium earth tend to show that it is a definite chemical compound; if, as is held by some chemists, it is really a mixture of several earths having almost identical properties, it is improbable that the methods at present employed for the separation of the rare earths will be successful in the case of samarium earth.

Samarium earth has not the property of phosphorescence (luminescence), but pure lanthanum earth, which has been strongly ignited,

shows a bright-green phosphorescence, the spectrum of which exceeds, in beauty and intensity, the flame spectrum of calcium chloride; a diagram of, and measurements of the wave-lengths of the various lines in the phosphorescent lanthanum earth spectrum are given.

F. S. K.

Amalgams. By J. SCHUMANN (*Ann. Phys. Chem.* [2], 43, 101—125).—The author has prepared a large number of amalgams of different metals. The original object was to determine the thermal changes attending the formation of these amalgams, but, owing to the fact that their dissolution in acids only takes place very slowly, this had to be abandoned. On the other hand, it was noticed that after a time a change took place in many of the amalgams, in some cases leading to the formation of crystals, whilst with others, even those containing difficultly oxidisable metals, a separation into metallic oxide and mercury took place. Several of the amalgams were examined dilatometrically, in order to ascertain the changes in volume which take place with change of temperature, and particularly with the change from the solid to the liquid condition. It was noticed that on cooling, and also on again heating, the amalgams occupied a greater volume than when first heated. A definite melting or solidifying point was not observed, but the melting was in all cases a gradual one and the solidification still more gradual. An amalgam on being heated, cooled, and then again heated, will be found to melt at a lower temperature than at first, but if a considerable time is allowed to elapse between the first and second heating, the second melting point will then be found higher than the first. A great increase in volume takes place on melting. From the results, the author concludes that solid amalgams consist of different crystalline modifications, some of which are stable at a given temperature and others unstable, and that, under certain circumstances, the latter will be transformed into the former. An interesting instance of this is furnished by sodium amalgam. On being melted and allowed to cool in a vertical tube, the amalgam, on solidification, separated into four different layers, one of which consisted of long, thick, prismatic needles, and the others of fine needles or were without definite crystalline form. The composition of the first layer was found to be $\text{Na}_4\text{Hg}_{10}$, and in course of time, this layer was found to increase in volume, so that in half a year the whole contents of the tube were found to have changed into this compound, with the separation of a small quantity of a liquid amalgam.

H. C.

Ammoniacal Mercuric Chlorides. By G. ANDRÉ (*Compt. rend.*, 112, 859—861).—When 1 part of yellow mercuric oxide is boiled with 5 parts of ammonium chloride dissolved in 17.5 parts of water, a small quantity of a crystalline precipitate forms on cooling; its composition varies, but approaches to $\text{HgCl}_2 \cdot 2\text{NH}_3$. If the mother liquor is mixed with excess of ammonia, a white, curdy precipitate separates, and this, when washed rapidly by decantation and dried at 100° , has the composition $\text{N}_2\text{H}_4\text{HgCl}_2 + \text{NH}_4\text{HgCl}$. The same compound is obtained in sealed tubes at 100° with only a small quantity of ammonia. If the curdy precipitate is subjected to pro-

longed washing, it is converted into a compound of the chloramide and the chloride, $\text{NH}_2\cdot\text{Hg}\cdot\text{O}\cdot\text{HgCl}$, the latter being the ultimate product of the action of water.

If the curdy precipitate is heated with excess of ammonia in sealed tubes at 200° , it yields a crystalline product which, when washed with a very small quantity of water, has the composition $\text{N}_2\text{H}_2\text{HgCl}_2$. The mother liquor, when mixed with a large quantity of water, yields a white precipitate of the compound $\text{NH}_2\cdot\text{Hg}\cdot\text{O}\cdot\text{HgCl}$.

If a cold solution of ammonium chloride containing free ammonia is mixed with mercuric chloride, the precipitate at first redissolves, but on continued addition of mercuric chloride to the cold liquid, a white, curdy precipitate separates, and this, when dried at 100° , has the composition $\text{HgCl}_2\cdot\text{NH}_3$. The same product is obtained with a hot solution, provided that mercuric chloride is added in excess; it is decomposed by water with formation of the chloramide.

Basic Magnesium and Zinc Chromites and Normal Cadmium Chromite. By G. VIARD (*Compt. rend.*, 112, 1003—1006).—These compounds have been prepared in the dry way (I) by calcination of the chromate, (II) by the action of potassium dichromate on the oxide, or (III) by the action of potassium dichromate or chromate on the chloride. The residue is in each case treated with boiling hydrochloric acid and washed by decantation.

Magnesium Chromites.—(a) A clear brown powder of the formula $2\text{MgO}\cdot\text{Cr}_2\text{O}_3$ formed at a red heat by method I; (b) a grey-yellow substance of the composition $5\text{MgO}\cdot 4\text{Cr}_2\text{O}_3$, formed at the melting point of silver by method I; (c) at a very high temperature the same substance is obtained as (b), but its colour is greyish-green; (d) a brown powder, $3\text{MgO}\cdot 2\text{Cr}_2\text{O}_3$, formed at a dull-red heat by method II.

The third method is believed by the author to be incapable of yielding pure products, as the oxygen liberated readily attacks magnesium chloride, setting free chlorine, which, as shown by Fremy, acts on alkaline chromates at a red heat yielding chromic oxide. The vapour of magnesium chloride passed over strongly heated potassium chromate gives a crystalline product which, under the microscope, is seen to consist of lamellæ of chromium oxide and octahedra of magnesium chromite.

Zinc Chromites.—I. Zinc chromate slowly decomposes at 440° yielding a violet-black powder, $3\text{ZnO}\cdot 2\text{Cr}_2\text{O}_3$ (a). As the temperature is raised, zinc oxide separates out, and, at a very high temperature, the product obtained approaches the normal chromite in composition; the colour changes just as in the case of the magnesium compounds.

By method II, a reddish-brown powder is obtained represented by $6\text{ZnO}\cdot 5\text{Cr}_2\text{O}_3$ (b), whatever the proportions of oxide and dichromate taken. By method III, mixtures of the two products (a) and (b) are usually obtained. The author has previously shown (*Abstr.*, 1889, 1111) that the normal chromite is obtained in regular octahedra by passing the vapour of zinc chloride over potassium chromate maintained at a white heat.

Cadmium Chromite.—The normal chromite is obtained as a green

powder at any temperature above a red heat. The crystalline substance may be obtained by passing the vapour of cadmium chloride over strongly heated chromate. W. T.

New Oxygen Compound of Molybdenum. By E. PÉCHARD (*Compt. rend.*, 112, 720—722).—It is well known that hydrogen peroxide produces an orange coloration when added to a solution of an alkaline molybdate, but the nature of the product has not been investigated.

Molybdic acid, which is insoluble in water and in acids, dissolves readily when gently heated with hydrogen peroxide, forming a yellow liquid, and the product of the action of hydrogen peroxide on molybdic acid or alkaline molybdates gives no precipitate with phosphoric acid. Ammonium paratungstate behaves like molybdic acid, and readily dissolves in hydrogen peroxide, whilst solutions of alkaline tungstates that have been mixed with hydrogen peroxide no longer give precipitates with acids.

Potassium trimolybdate dissolves in hydrogen peroxide, forming an orange-yellow solution which, when concentrated at a gentle heat, deposits beautiful, yellow crystals (seemingly triclinic) of the composition $K_2O, Mo_3O_7, 4H_2O$. When heated gently in a vacuum, they lose water and oxygen, and leave a white residue of acid potassium molybdate. The yellow compound is soluble in hot water, but is only slightly soluble in alcohol.

Ammonium molybdate, when evaporated with hydrogen peroxide at 100° , yields yellow crystals (seemingly monoclinic) of the analogous compound $(NH_4)_2O, Mo_3O_7, 4H_2O$, very soluble in water, but insoluble in alcohol. When carefully heated in a vacuum, ammonia, water, and nitrogen are evolved and molybdic acid is left.

Molybdic acid, when evaporated in a vacuum with hydrogen peroxide, yields only a reddish-yellow, amorphous residue insoluble in water.

The potassium and ammonium salts are decomposed by alkalis with evolution of oxygen; hydrochloric acid, when heated with them, evolves chlorine; potassium iodide rapidly turns brown, owing to the liberation of iodine. The two salts are derived from a new higher acid of molybdenum, permolybdic acid, Mo_3O_7, H_2O . C. H. B.

New Oxygen Compound of Tungsten. By E. PÉCHARD (*Compt. rend.*, 112, 1060—1062).—A solution of sodium paratungstate, when boiled for a few minutes with hydrogen peroxide, assumes a yellowish tint and no longer gives any precipitate with nitric acid. When evaporated in a vacuum, a syrupy liquid remains which deposits small, white, radiating crystals of the formula $Na_2O, W_2O_7, 2H_2O$. The crystals are more soluble in water than sodium paratungstate, and give off water when heated in a vacuum, finally decomposing with evolution of oxygen if the heating be continued.

Ammonium paratungstate yields a similar salt. Alkalis destroy these salts with liberation of oxygen. Solutions of the new salts liberate iodine from potassium iodide and chlorine from hydrochloric acid.

These oxygenated compounds are hypertungstates analogous to the hypermolybdates (preceding abstract). W. T.

Thiovanadates. By G. KRÜSS and K. OHNHAIS (*Annalen*, 263, 39—72).—In this paper the authors give a rather more complete account of the methods of preparation and properties of various thiovanadates, all of which have been previously described (compare *Abstr.*, 1890, 1381). F. S. K.

Mineralogical Chemistry.

Formation of Graphite by Contact Metamorphosis. By R. BECK and W. LUZI (*Ber.*, 24, 1884—1886).—Graphite occurs in many different associations in nature. Quite recently the authors have discovered some beautifully crystallised graphite in rocks which have been metamorphosed by contact with ancient volcanic rocks; the graphite crystals are easily discernible from the amorphous carbonaceous substances of the original clay slates and siliceous slates. Mention is made in the literature of the apparent occurrence of graphite in certain slates metamorphosed by granite, but analytical and crystallographic data are wanting. The authors have now proved that graphite has been formed from carbonaceous substances by contact metamorphosis in the case of certain rocks in Saxony. In Pirna and Kreischa, upper Silurian clay slates and siliceous slates occur, which are very rich in carbonaceous substances, and lie partially within the region of contact of the granite and hornblende-granite; those within this region of contact have become converted into graphitic rocks. A chistolite slate and a graphitic quartzite were examined. The former occurred imbedded in the much metamorphosed grey trap of Burkhardt Forest; whilst the latter turned out to be a true contact rock from the immediate vicinity of the granite in Röhrsdorfer Valley, Kreischa; both have been formed from original siliceous slates, and their composition and structure show that they are true contact products. The graphite from the chistolite slate formed completely opaque, jagged lumps having a metallic lustre by reflected light, and measuring between 0.003 and 0.02 mm.; whilst the carbonaceous particles in the unaltered upper Silurian clay-slates and siliceous slates were almost too small to measure (below 0.001 mm.). There were also some isolated perfect hexagonal crystals. The quartzite was still richer in graphite, which, moreover, occurred in more beautiful crystals; viewed under a lens, the quartzite appeared to consist of a crystalline mixture of quartz and graphite. The graphite frequently existed as hexagonal crystals, some having plain faces and some rounded. Single well formed crystals measured 0.03 mm. It occurred most frequently, however, in jagged, ramified, irregular, crystalline aggregates of 0.3 mm. from which sometimes crystallographically perfect individual crystals

grew out. The graphite had a greasy feeling, and produced a metallic streak; it had also a metallic lustre. Analysis showed that the graphite from the chialstolite slates had the composition C = 98.84 per cent., H = 0.21 per cent.; whilst that from the graphitic quartzite had the composition C = 99.94 per cent., H = 0.05 per cent. The graphitic quartzite itself contained over 2 per cent. of graphite, and its specific gravity was 2.62—2.637.

Proof is therefore afforded by this discovery that graphite is formed in nature from amorphous carbon in much the same manner as it is produced artificially. A. R. L.

Action of Dry Hydrogen Sulphide on Metals; Synthesis of Minerals. By R. LORENZ (*Ber.*, 24, 1501—1510).—The author has previously observed that when zinc sulphide containing ammonium chloride is strongly heated, the zinc sulphide volatilises and is obtained from the sublimate in a crystalline condition. Corresponding experiments made with ferrous sulphide containing ammonium chloride gave similar results (see also Weinschenk, *Zeit für Kryst.*, 17, 486). This volatilisation is due to the fact that when the mixture is heated, ammonia, zinc chloride, and hydrogen sulphide are formed, and the two last-named compounds then react together on cooling with formation of crystallised zinc sulphide. This is proved by the fact that the vapours given off when ammonium chloride is heated and driven over zinc sulphide, if quickly cooled, deposit considerable quantities of zinc chloride. The method is, therefore, in principle identical with that of Durocher (*Compt. rend.*, 32, 823), the presence of ammonia gas being of no importance.

Led by these experiments, the author has also examined the action of dry hydrogen sulphide on different metals; the reaction with silver has, however, been previously studied by Deville and Troost (*Compt. rend.*, 52, 920), who succeeded in thus obtaining silver-glance. When the dry gas is passed over a bundle of iron wire heated to a temperature rather below the melting point of the sulphide, the wire became covered with a layer of crystallised iron sulphide, which, on crystallographic investigation, proved to be troilite; the quantity of sulphur in the different parts is, however, not quite constant. If dilute hydrogen sulphide be employed, the crystals are more sharply developed, and appear to be hexagonal and hemimorphic.

Nickel, under similar circumstances, does not yield crystals of millerite, but forms a crystalline crust of nickel sulphide. The vapour of zinc on the other hand, readily reacts with dry hydrogen sulphide forming a conglomerate of wurtzite crystals, which are also hemimorphic. Cadmium vapour acts still more readily, so that the reaction may be carried out in an ordinary combustion tube. The product is a mixture of hexagonal greenockite crystals with a hitherto unknown modification of cadmium sulphide which forms monosymmetric twin crystals. H. G. C.

Artificial Formation of Daubreelite. By S. MEUNIER (*Compt. rend.*, 112, 818—820).—Hydrogen sulphide is passed at a red heat, over (1) a mixture of ferrous chloride and chromic chloride: (2)

finely powdered native chrome iron ore; or (3) an alloy of iron and chromium. The alloy of iron and chromium (Abstr., 1890, 568) gives the best results. Pyrrhotine is formed in distinct hexagonal crystals, and when this is removed by treatment with hydrochloric acid, a black, crystalline powder is left, which has the composition and all the properties of natural daubreelite, FeCr_2S_4 . The powder consists of irregular angular grains with distinct and brilliant cleavage faces, but very little indication of any specific forms; sp. gr. = 5. It dissolves in nitric acid and had the composition, in one case, S 45.01; Fe 19.99; Cr 35.0 = 100.00.

The simultaneous formation of pyrrhotine is of great interest since the two minerals are constantly found associated in meteoric iron. The results afford further evidence in support of the view that holo-siderites are formed by the interaction of gases. C. H. B.

Artificial Production of Hyalite at the Ordinary Temperature. By S. MEUNIER (*Compt. rend.*, 112, 953—954).—A porous cell containing Nordhausen sulphuric acid is placed in a syrupy solution of sodium silicate; in less than 48 hours all the alkaline silicate is replaced by a granular, hyaline, colourless, and fragile substance. Prolonged boiling with successive quantities of ordinary sulphuric acid removes all the sodium, and washing with boiling water removes the sulphuric acid without otherwise affecting the product.

The product contains 5.69 per cent. of water, but it is evident that all the grains are not hydrated to the same extent; when strongly heated, some become opaline and opaque, whilst others remain hyaline and transparent. The latter, although soluble in concentrated alkaline solutions, act strongly on polarised light; they have no crystalline form, but the planes of fracture recall cleavage planes and give elongated forms, the optical extinction following the direction of the elongation. Many of the fractures are conchoidal, and the general properties of these hyaline granules agree with those of the opal of Pont-du-Château.

Amongst the portions that are not affected by a bright-red heat are thin plates with parallel surfaces often more than 10 mm. broad, resembling lamellæ of glass. Between crossed Nicols they show a crowd of black crosses similar to those shown by spherulitic opal.

C. H. B.

Artificial Periclase; A Product of the Magnesium Chloride Industry. By R. OTTO and J. H. KLOOS (*Ber.*, 24, 1480—1482).—Artificial periclase is formed under certain conditions in the furnaces in which magnesium oxychloride is heated for the preparation of hydrochloric acid and chlorine. In the course of repairing one of the muffle furnaces used for this purpose, large blocks of magnesia were removed, which, on examination, were found to contain druses filled with crystals of periclase. These varied in size from almost microscopic crystals to octahedra having an edge 4 mm. in length, and showed a strong diamond lustre. In the larger crystals, the edges were frequently rounded off by a combination with a forty-eight sided figure, these having usually a yellowish-grey colour, but the

smaller crystals were for the most part sharply developed and colourless.

Two specimens were analysed with the following result:—

	I.	II.
MgO	98.21	97.94
Fe ₂ O ₃	1.57	1.70

The specific gravity was found to be 3.555 and 3.571, which is considerably less than that of the natural periclase (3.75), and also of Rose's artificial preparation (3.644), this being probably due to the fact that they contain less iron. The crystals show a very distinct cubical cleavage and have a hardness between that of felspar and quartz.

H. G. C.

Chromite. By H. PEMBERTON, JUN. (*Chem. News*, 63, 241—242).—On the Pacific Coast of the United States there are several deposits of chromite, and it is found throughout the Santa Lucia mountains and the coast hills of San Luis, Obispo Co., California, in serpentine rocks in greater or less masses, existing as loose and fragmentary rocks in the ravines and as pockets and veins on the mountains; a sample obtained from the Pick and Shovel mine, located on the South Fork of Chlorro Creek, at an elevation of 1800 feet, gave the following numbers on analysis:—

Cr ₂ O ₃ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	MgO.	FeO.	MnO.	SiO ₂ .	H ₂ O.	Total.
52.68	11.40	3.52	16.23	11.77	0.15	3.40	0.94	100.09

Deducting the water and the magnesia and silica due to gangue, the numbers for the pure mineral became—

Cr ₂ O ₃ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	MgO.	FeO.	MnO.
56.96	12.32	3.81	14.02	12.73	0.16

from which is deduced the relationship

$$R_2O_3 : RO = 1.00 : 1.02.$$

To decompose the mineral, it is mixed with sodium carbonate, heated over night by a Bunsen burner in a loosely-covered crucible, and the next morning it is heated for an hour over a blast lamp, stirring frequently. The ferrous oxide was determined by dissolving in sulphuric acid, sp. gr. 1.34, in a closed tube, under pressure.

D. A. L.

Crystallised Azurite from Arizona. By O. C. FARRINGTON (*Amer. J. Sci.*, 41, 300—307).—The author has made a detailed crystallographic study of the crystals of azurite from Arizona. Altogether 21 forms were observed on these crystals, four of which are new. The axial ratio deduced from the measurements made is $a : b : c = 0.85676 : 1 : 0.88603$; $\beta = 87^\circ 36'$. This result differs but little from that deduced by Schrauf from his measurements of crystals from European localities.

B. H. B.

Ferro-goslarite, a New Variety of Zinc Sulphate. By H. A. WHEELER (*Amer. J. Sci.*, 41, 212).—In a zinc mine at Webb City,

Jasper Co., Missouri, there occurs a new variety of goslarite, containing about 5 per cent. of ferrous sulphate. It appears as incrustations on the wall of a large body of zinc blende. Analysis shows that the mineral is a double sulphate of zinc and iron, in the ratio of 4.9 per cent. FeSO_4 , to 55.2 ZnSO_4 , or nearly 1 to 11. As the properties of the mineral correspond closely to those of goslarite, the author has given it the name of ferro-goslarite.

B. H. B.

Halotrichite from Colorado. By E. H. S. BAILEY (*Amer. J. Sci.*, 41, 296—297).—This mineral was found in the Elk mountain range, Pitkin Co., Colorado, and, as no record could be found of the description of this mineral from an American locality, the author has submitted it to analysis. The results were as follows:—

SiO_2 .	SO_3 .	Al_2O_3 .	Fe_2O_3 .	FeO .	MgO .	H_2O .	Total.
0.42	33.46	12.98	1.60	5.19	0.17	46.04	99.86

It is, therefore, essentially a sulphate of aluminium and iron, with part of the alumina replaced by ferric oxide, and part of the ferrous oxide replaced by magnesia.

B. H. B.

Occurrence of Pollucite at Hebron, Maine. By H. L. WELLS (*Amer. J. Sci.*, 41, 213—220).—The author announces the discovery of pollucite, the mineral originally termed pollux by Breithaupt, in a new locality. Hitherto this rare mineral has been found only on the island of Elba. Its composition adds greatly to its interest, as it is the only known mineral of which caesium is an essential constituent. Analysis of pollucite from the new locality at Hebron, Maine, gave the following results:—

H_2O .	SiO_2 .	Al_2O_3 .	CaO .	Cs_2O .	K_2O .	Na_2O .	Li_2O .	Total.
1.53	43.48	16.41	0.21	36.77	0.47	1.72	0.03	100.62

From this the formula $\text{H}_2\text{R}_1\text{Al}_4(\text{SiO}_3)_8$ is calculated. A comparison of all the ratios calculated from the published analyses of pollucite, makes it probable that the new formula can be assigned also to the Elba mineral.

B. H. B.

Pink Grossularite from Mexico. By C. F. DE LANLERO (*Amer. J. Sci.*, 41, 321—323).—The occurrence of pink garnets at Xalostoc, in Mexico, has been known for some years, but the locality had not been properly explored, the specimens obtained being merely from the surface. Analysis of very pure crystals, obtained in January of this year, gave the following results:—

SiO_2 .	Al_2O_3 .	Fe_2O_3 .	CaO .	MgO .
40.64	21.48	1.57	35.38	0.75

The formula is $(\text{CaMg})_3(\text{Al}_2\text{Fe}_2)\text{Si}_3\text{O}_{12}$. The crystals are rhombic dodecahedra, with a sp. gr. of 3.516, and a hardness of 7.5.

B. H. B.

Occurrence of Xenotime as an Accessory Constituent of Rocks. By O. A. DERRBY (*Amer. J. Sci.*, 41, 308—311).—In the

examination of the heavy residues obtained by concentration in the gold-washer's pan of crushed samples of a large number of Brazilian crystalline rocks, the rare mineral xenotime has been found to be a fairly constant accessory of the muscovite granites. The xenotime occurs in the well-known octahedral form, with the prismatic faces barely noticeable. Samples of muscovite granite from 21 different localities were tested, and of these 14 gave xenotime, always accompanied by zircon, and in all but three cases by monazite. The almost constant occurrence of these cerium and yttrium phosphates in the Brazilian rocks suggests the hypothesis that they will be found in similar rocks all over the world. B. H. B.

Magnetite Ore Districts in Brazil. By O. A. DERBY (*Amer. J. Sci.*, 41, 311—321).—The districts of Jacupiranga and Ipanema afford instances of what appears to be a hitherto unnoticed mode of occurrence and association of magnetic iron ores. In specimens of nearly pure ore from the former district, the magnetite forms a continuous network enclosing detached grains of pyroxene in part altered to mica. This peculiar rock is distinguished as *jacupirangite*. The rocks included under this title present the various types of pure magnetite, magnetite with accessory pyroxene, pyroxene with accessory magnetite, and pyroxene and nepheline with biotite and olivine as accessory or essential constituents. The gradual passage from one type to another has been satisfactorily proved. At Ipanema, a rock of similar composition cuts the carboniferous strata. B. H. B.

Occurrence of Sulphur in Marine Muds and Nodules, and its bearing on their Mode of Formation. By J. Y. BUCHANAN (*Proc. Roy. Soc. Edin.*, 18, 17—39).—The examination of muds obtained from the bottoms of various seas showed that they are, as a rule, nearly black, owing to the presence of ferrous sulphide: this blackness is, however, not found on the immediate surface layer, because the sulphide in presence of water and oxygen is oxidised, sulphur being set free, and the dark blue changed to a reddish colour. The presence of ferrous sulphide is ascribed to annelids who, in search of food, pass the mud through their bodies, and thus the sulphates present are converted into sulphides; at the same time the coarser particles are rendered finer. All the deep-sea muds and manganese concretions, when fresh, yield ammonia when heated, demonstrating the presence of organic matter; when such "blue mud" is dried, no sulphide is to be found, but the mass is permeated with fine particles of ferric oxide. The free sulphur was estimated by digestion with chloroform, and weighing the residue after evaporation. By far the largest percentage of sulphur was found in clay from the Sound of Jura, the quantity amounting to 0.4 per cent.; a radiolarian ooze from the North Pacific, at a depth of 2900 fathoms, contained 0.0031 per cent.; the percentages of sulphur in other muds is given in a table.

The method employed to estimate the ferrous sulphide was based on the reaction of ferric chloride in excess on the sulphide, whereby ferrous chloride is formed, the amount produced being estimated by

potassium permanganate; other ferrous compounds present were estimated by treatment of the mud with hydrochloric acid and titrating with permanganate.

E. W. P.

Action of Metallic (and other) Salts on Calcium Carbonate. By R. IRVINE and W. S. ANDERSON (*Proc. Roy. Soc. Edin.*, 18, 52—54).—Corals were exposed to the action of solutions of manganese, zinc, chromium, mercury, and tin chlorides, iron sulphate, nickel, cobalt, copper, lead, and silver nitrates, and ammonium phosphate. The action of salts of nickel and cobalt was very slow, whilst that of copper and manganese was rapid. In most cases there is a direct interchange, the oxide of the metal taking the place of the lime. With ammonium phosphate, the interchange was between the carbonic anhydride of the coral and the phosphoric anhydride of the phosphate; it is probable that this reaction accounts for the formation of calcium phosphate deposits through the excreta of birds deposited on coral or calcium carbonate, but only in rainy climates, for without water the change does not occur. Silver and mercury salts are deposited as oxides.

E. W. P.

Manganese Deposits in Marine Muds. By R. IRVINE and J. GILSON (*Proc. Roy. Soc. Edin.*, 18, 54—59).—The authors do not consider the present theories of Buchanan and Murray as sufficiently or correctly accounting for manganese nodules found in sea mud. They base their new theory on the following experiment:—When ferrous and manganous carbonates were mixed with decomposing mussel flesh, the mass became black and evolved hydrogen sulphide: air was then blown through the mixture for 12 hours, after which no manganese was found in the solid residue, whilst all the iron had been converted into sulphide; they therefore conclude that the formation of manganese sulphide cannot be a result of the animal life, or the decomposition of animal matter, at the sea-bottom, for carbonic anhydride must always be present in excess. Buchanan does not give proofs of presence of manganese sulphide, but relies on the analogy of manganese to iron.

E. W. P.

Composition of some Deep-Sea Deposits from the Mediterranean. By J. Y. BUCHANAN (*Proc. Roy. Soc. Edin.*, 18, 131—138).—The muds of which analyses are given were collected on the line of the telegraph cable between Marseilles and Algiers; the depths at which they were collected vary from 265 to 1536 fathoms. The methods of analyses are stated; the SiO_2 was found to vary from 14.79 to 44.37 per cent.; Fe_2O_3 , 3.45 to 6.64; Al_2O_3 , 1.30 to 12.30; CaCO_3 , 18.3 to 47.1; loss on ignition, 2.90 to 10.89; further analytical details are given.

E. W. P.

Silica and the Siliceous Remains of Organisms in Modern Seas. By J. MURRAY and R. IRVINE (*Proc. Roy. Soc. Edin.*, 18, 229—258).—Analyses of sea-water show that only 1 part of silica is contained in 200,000 to 500,000 parts of sea-water, so that it is inconceivable that diatoms and other forms of life obtain the silica necessary for their

growth from the water. It appeared probable, however, that the silica was derived from the suspended clay, and this idea received considerable support from the fact that waters of high salinity contain less suspended mud than those of low salinity; moreover, higher temperatures prevent suspension of matter, it being also known that siliceous organisms are more abundant in shore waters, or in waters of low salinity and in cold waters, as for instance diatoms in brackish waters, and in those of the cold southern and Polar seas, and radiolaria in Polar waters, and in the West Pacific and East Indian oceans, where there is a relatively low salinity. There are other theories propounded to explain the source of soluble silica, but the authors are still experimenting, with the view of definitely settling the question.

Organic Chemistry.

Formation of Ethers in the Preparation of Isoallylene and its Homologues from the corresponding Halogen Derivatives and Alcoholic Potash. By W. VAUBEL (*Ber.*, 24, 1685—1695).—Isoallylene, $\text{CH}_2\text{:C:CH}_3$, can be prepared by three methods, namely, by the electrolysis of potassium itaconate, by the action of sodium on β -chloroallyl chloride, and by the action of zinc-dust and alcohol on dibromopropylene, $\text{CH}_2\text{CBr-CH}_2\text{Br}$. By the action of alcoholic potash on allyl bromide, allyl ethyl ether is formed, together with a small quantity of isoallylene. The present paper deals with the behaviour of allyl halogen compounds with alcoholic potash.

Allyl Bromide.—If allyl bromide is added to concentrated alcoholic potash, at first only a small quantity of potassium bromide is precipitated; after five minutes, however, a violent reaction sets in, bubbles of isoallylene are given off, and heat is liberated in quantity sufficient to cause the boiling of the mixture. The semi-solid mixture which remains consists of potassium bromide, alcoholic potash, and allyl ethyl ether. Several experiments are described, with the object of determining the conditions under which the greatest yield of isoallylene is obtained. The results show that the best yield is obtained by using equivalent quantities of allyl bromide and alcoholic potash at 13° ; 10 grams of allyl bromide then yield 66.5 c.c. of isoallylene. Raising the temperature, or the use of excess of potash or alcohol, reduces the yield considerably.

Allyl Chloride.—Equivalent proportions were used as with the bromide. The reaction takes place very slowly at the ordinary temperature (16°); on heating on the water-bath, 56 c.c. of isoallylene were obtained, whilst 6.1 grams of allyl chloride remained unaltered.

Allyl Iodide.—The reaction takes place slowly at the ordinary temperature. 10 grams of allyl iodide at 18° in one hour yielded 19 c.c. of isoallylene; at 100° , however, 115 c.c. was obtained.

The above reaction is not a convenient method for the preparation of isoallylene, since only 1 per cent. of the allyl bromide and 9 per cent. of the iodide is converted into it. The reaction probably takes place according to the equations $C_3H_5Br + KOH = C_3H_4 + KBr + H_2O$ and $C_3H_5I + EtOH = C_3H_5OEt$. It is not probable that the ether is formed first, and that this breaks up into alcohol and isoallylene. Experiments to settle this point gave the following results:—Allyl ethyl ether usually decomposes so as to yield allyl alcohol and ethyl alcohol, but even when boiled with alcoholic potash no reaction takes place.

If alcohol cooled below 0° be saturated with isoallylene, and the solution heated in sealed tubes with solid potash, first at 100° , and then at 150 — 170° , allyl ethyl ether is formed. The ether is not formed when isoallylene and ethyl alcohol are heated alone, but in this case a liquid is obtained which the author considers is a polymeride of isoallylene. It quickly resinifies on exposure to air, or by the action of dilute sulphuric acid, and gives a white precipitate with mercuric chloride. Allyl ethyl ether also gives a white compound when shaken with mercuric chloride.

Tetramethylisoallylene, $CM_2:C:CM_2$, is obtained by the action of alcoholic potash on the chloride $CHM_2\cdot CCl_2\cdot CHM_2$. It forms a white precipitate with mercuric chloride; and it is probable that this reaction is characteristic of isoallylene and its homologues. Isoallylene and its homologues cannot be obtained in any quantity from the corresponding alkyl halogen compounds and alcoholic potash; instead of the hydrocarbons, ethers are formed. There are, however, two exceptions, the hexine, $CM_2\cdot CH\cdot CH\cdot CH_2$, which is obtained from dimethylallylcarbonyl chloride, and tetramethylisoallylene obtained as above.

The author sums up the results already obtained as follows:—(1.) When alkyl halogen compounds are decomposed with alcoholic potash, a hydrocarbon is always formed, but under certain conditions it is converted into an ether. (2.) Alkyl halogen compounds which already contain a double bond always yield a hydrocarbon containing a treble bond, even if the formation of a hydrocarbon with two double bonds is possible, thus, $CH_2\cdot CBr\cdot CH_2 + KOH = CH:C\cdot CH_2 + KBr + H_2O$. (3.) Those halogen compounds which already contain a double bond, and ought to yield hydrocarbons with two double bonds, yield these hydrocarbons, but the greater part combines with the alcoholic potash to form an ether. If, however, the ether would be a tertiary ether, then the hydrocarbon remains unchanged, as is the case in the formation of tetramethylisoallylene. (4.) The ethers are not formed from an alcohol and the unsaturated hydrocarbon alone. It is necessary that alcoholic potash should be present. (5.) Isoallylene and its homologues, and the ethers obtained from them, yield white precipitates with mercuric chloride. This is proved for isoallylene, tetramethylisoallylene, and ethyl allyl ether.

E. C. R.

Purification of Crude Alcohol. By E. MOHLER (*Compt. rend.*, 112, 815—818).—The author has applied his methods of analysis (this vol., p. 503) to follow the rectification of crude alcohol from treacle. 80 per cent. of the total alcohol can be obtained free from higher alcohols or other poisonous compounds, the chief impurities being

minute quantities of ethereal salts. The head products consist chiefly of aldehydes and ethereal salts, and are much purer than the tailings, which contain a large proportion of the higher alcohols, chiefly amyl alcohol, with a small quantity of aldehydes and ethereal salts of high boiling point. C. H. B.

The Fourth Primary Amyl Alcohol. By L. TRIGNIER (*Compt. rend.*, 112, 1065—1068).—*Trimethylethyl alcohol* (*trimethylcarbinol*), $\text{CMe}_3\text{CH}_2\text{OH}$, has not been previously prepared. The author some time ago obtained trimethylethylamine from tertiary butyl cyanide, and characterised it by its platinochloride (*Bull. Soc. Chim.* [3], 3, 497). Freund and Senze, without acknowledging the priority of the author's work, obtained an alcohol boiling at $102\text{--}103^\circ$ by acting on trimethylethylamine, prepared in the same way, with silver nitrite, and called it trimethylethyl alcohol. The substance obtained by them has properties identical with those of the tertiary amyl alcohol, dimethylethylcarbinol, CMe_2EtOH , first obtained by Wurtz. Trimethylethyl alcohol is prepared by the reduction of trimethylacetic chloride with sodium amalgam. A mixture of 10 grams of the chloride with 20 grams of trimethylacetic acid is dropped on 250 grams of 3 per cent. sodium amalgam, and well agitated. After 24 hours, on addition of water, saturation with potash, and distillation, about 8 grams of an oily liquid is obtained, which can be fractionated into portions boiling at from $65\text{--}80^\circ$, $105\text{--}120^\circ$, $150\text{--}180^\circ$, and above 180° . The fraction passing over at $105\text{--}120^\circ$, when rectified, forms a crystalline mass without action on polarised light (compare trimethylacetic acid), which melts at $48\text{--}50^\circ$, boils at $112\text{--}113^\circ$, and exerts a considerable vapour tension, even at the ordinary temperatures. It dissolves in a very small quantity of ether, and has all the characters of an alcohol. It yields trimethylacetic acid on oxidation with chromic acid. The velocity and limit of etherification, determined at $153\text{--}154^\circ$, using equivalent proportions of glacial acetic acid and the alcohol, were as follows:—

Velocity .. $40\cdot75$; $40\cdot69$; $40\cdot71$. Limit .. $66\cdot99$; $67\cdot2$.

The fraction passing over between 150° and 180° on rectification yields *trimethylethyl trimethylacetate*, a colourless liquid of agreeable odour, boiling at $164\text{--}166^\circ$. On boiling with dry potash, it is rapidly decomposed into trimethylethyl alcohol and potassium trimethylacetate. By the action of glacial acetic acid, or of acetic chloride on trimethylethyl alcohol in sealed tubes, the *acetate* is obtained; it is a colourless liquid, boiling at about 126° , and having an odour of apples.

The first fraction obtained reduces ammoniacal nitrate of silver, and forms a compound with sodium hydrogen sulphite, from which, after purification, the *aldehyde* CMe_2COH may be prepared; it is a liquid boiling at $74\text{--}75^\circ$, melting at $+3^\circ$, and having sp. gr. $0\cdot7927$ at 18° .

It is proposed to continue the study of trimethylethyl alcohol and its derivatives. W. T.

Constitution of the Oxygen Compounds in Petroleum. By R. ZALOZIECKI (*Der.*, 24, 1808—1815).—In this paper the author gives an account of the oxygen compounds obtained from petroleum in a works at Kolomea, and which were sent to him in the form of sodium salts. These were separated from the petroleum still present by repeated treatment with alkalis, and reprecipitation by acids; the resulting brown oil was treated with hydrogen chloride in alcoholic solution, and the mixture of ethyl salts thus obtained subjected to fractional distillation. Three of the fractions appear to be approximately homogeneous, and yield the corresponding acids on hydrolysis. From the analysis of both acids and ethyl salts, it would appear that the former have the composition $C_{10}H_{16}O_2$, $C_{11}H_{20}O_2$, and $C_{12}H_{22}O_2$, that is, they belong to a series having the general formula $C_nH_{2n+2}O_2$, which is in agreement with the results of previous investigators (this Journal, 1875, 248; *J. Russ. Chem. Soc.*, 1883, 237; Abstr., 1887, 648).

The compound $C_{10}H_{16}O_2$, on treatment with phosphorus and iodine, yields a substance containing iodine. The formula of the latter, as deduced simply from a determination of the iodine, is $C_{10}H_{17}IO$, and not $C_{10}H_{17}IO_2$, and hence the author concludes that these compounds do not contain the carboxyl group, but are hydroxylactones or lacto-alcohols, and proposes for the compound $C_{10}H_{16}O_2$ the following constitutional formula:—

H. G. C.

Preparation of Disodium Erythroside. By DE FORCAND (*Compt. rend.*, 112, 1006—1009).—The monosodium and monopotassium compounds have been previously described (see Abstr., 1890, 935). To prepare *disodium erythroside*, $C_4H_6Na_2O_4 \cdot 4H_2O$, three equivalents of soda are added to one equivalent of erythrol, both being in concentrated aqueous solution, and the mixture is allowed to evaporate for two or three days in presence of phosphoric anhydride; or powdered erythrol is dissolved directly in the most concentrated soda solution by a gentle heat. Stellate groups of crystals separate, which are freed from the mother liquor by draining on porous tiles. When heated at 135—140° in a current of hydrogen, the water is entirely driven off, and pure dry disodium erythroside, $C_4H_6Na_2O_4$, remains as a white, amorphous, very hygroscopic mass. This is the first disodium alkylxide that has been prepared pure.

If the quantity of soda be increased to five equivalents, crystals are obtained of the formula $C_4H_4Na_5O_4 + 2NaOH + 9.5H_2O$. By a study of the thermal properties of this substance, it is evident that it is not a mixture. The anhydrous compound $C_4H_4Na_5O_4 \cdot 2NaOH$, obtained as above described, decomposes at temperatures higher than 160°.

The first and second alcoholic hydrogen atoms are readily replaced by sodium, but the remaining two such atoms in erythrol are not removable in the same manner; this fact is of importance in connection with the constitution of polybasic alcohols, particularly as the

author has previously prepared disodium glyceroxide, but has been unable to substitute the third alcoholic hydrogen by sodium.

The question suggests itself whether the secondary alcohols form true alcoholates, as it is already known that secondary aldehydes do not react with bases in the same way as do the primary aldehydes.

The author proposes to investigate isopropyl alcohol to ascertain this point.

W. T.

Refractive Power of Levulose and Invert-sugar. By H. O. R. (Ber., 24, 1636—1645).—The differences in the refractive power of levulose observed by various chemists have led the author to carry out fresh determinations. The sugar employed was prepared from inulin, and was crystallised from absolute alcohol three or four times; the product is anhydrous, is not hygroscopic, and decomposes slowly at 100°. Heating is without effect on the refractive power of neutral aqueous or alcoholic levulose solutions.

For solutions containing 3 to 30 per cent. by weight of levulose the refractive power is given by the formula $(\alpha)_{20}^{20} = -(91.90 + 0.111p)$, where p is the percentage of sugar in grams. Those results are higher than those of Honig and Jesser for solutions containing less than 25 per cent. of the sugar; for concentrations above this, the results are somewhat lower. The values of Jungfleisch and Grimbart are about 3 per cent. lower throughout, apparently pointing to the presence of some inactive impurity in their preparations.

A comparison was instituted between the actual refractive powers of various solutions of equal parts of levulose and dextrose, and the theoretical values calculated from the author's numbers for levulose and those of Tollens for dextrose; the agreement is very close, and the numbers would be almost identical if Tollens' figures should prove to be slightly too high, in consequence of some decomposition of the dextrose having taken place while being dried at 60—70°.

Comparative experiments were instituted to show the amount of monosaccharoses decomposed during the inversion of sucrose by means of hydrochloric acid, acetic acid, and oxalic acid of various concentrations and at different temperatures. Acetic acid decomposes levulose at ordinary temperatures, as does also 0.1 per cent. hydrochloric acid at 100°; the best results are obtained by heating the sugar at 60° for 1.5 hours with 2 per cent. solution of oxalic acid, or for 4 hours with 1 per cent. solution; the presence of the oxalic acid is without effect on the refractive power of invert-sugar.

The results of Grubbe are thus confirmed, whilst those of Jungfleisch and Grimbart are shown to be incorrect.

J. B. T.

Trehalose. By MAQUENNE (*Compt. rend.*, 112, 947—950).—Solutions containing 16 and 8 per cent. of trehalose solidify at -0.895° and -0.43° respectively, and hence the molecular weight is about 350, a result which shows that trehalose does not belong to the trioses.

Trehalose, completely inverted by sulphuric acid, was treated with phenylhydrazine and compared with a solution of glucose of equal reducing power in the manner previously described; they gave the

same amount of glucosazone under the same conditions, and it follows that glucose is the sole product of the inversion of trehalose, and that the molecule of the latter contains C_{12} .

When boiled with excess of acetic anhydride in presence of a small quantity of zinc chloride, trehalose yields an octacetin,

which, after crystallisation from alcohol, melts at $97-98^\circ$, is distinctly volatile, burns with a beautiful white flame, and is rapidly hydrolysed by baryta at 100° .

It follows from these results that trehalose is an octohydric alcohol, isomeric with the true saccharoses, and very similar to maltose in its molecular constitution, but differing from the latter in that it has no aldehydic function.

C. H. B.

Xylose from Maize Cobs. By W. E. SPOFFORD and D. LOEY (*Ber.*, 24, 1657—1658).—If maize cobs are treated with 1 per cent. ammonia, and then extracted for eight hours with boiling sodium hydroxide (2 per cent.) and alcohol added to the extract, a brown, voluminous precipitate is obtained. $2\frac{1}{2}$ kilos. of material yield 200 grams of this product. The product dissolves in acids, and is precipitated on addition of alcohol; after being treated in this manner several times, it still contains 0.76 per cent. of ash. It is easily soluble, and blackens on exposure to air. When distilled with hydrochloric acid (sp. gr. = 1.06), it yields 48—50 per cent. of furfuraldehyde. When heated for eight hours with sulphuric acid (2 per cent.) on the water-bath, a sweet syrup is obtained which deposits crystals after a time. These were identified as xylose by determining their optical activity, $[\alpha]_D = 19.55^\circ$, and by preparing the phenylhydrazide, which melts at $159-160^\circ$, and is strongly levorotatory. The yield is small, and further experiments showed that most of the product yielding furfuraldehyde remains in the material.

Action of Nitric Acid on Vegetable Fibres. By C. F. CROSS and E. J. BEVAN (*Der.*, 24, 1772—1776; see also *Proc. Chem. Soc.*, 1891, 61).—In a recent paper (this vol., p. 814), Lifschütz has described the action of a dilute mixture of nitric and sulphuric acids on pine-wood, chiefly with a view to the preparation of pure cellulose, and without considering intermediate products obtained from the lignin constituents of the wood. From their researches in a somewhat wider field, although these are yet far from being completed, the authors are in a position to state that Lifschütz's conclusions cannot be applied to vegetable fibres in general. They have already shown in previous researches that with the typical lignocellulose jute fibre moderately concentrated acid yields yellow acid compounds with a small proportion of nitrogen (*Abstr.*, 1880, 666), whilst with 5 per cent. nitric acid the fibres are converted into cellulose, oxalic acid, and gaseous products (*Trans.*, 1889, 199). They have shown that the jute fibre contains a closed chain of carbon atoms, probably having the formula $\begin{array}{c} \text{CH}\cdot\text{CO}\cdot\text{C}(\text{OH})_2 \\ | \quad | \\ \text{CH}\cdot\text{CH}_2\cdot\text{C}(\text{OH})_2 \end{array}$, and that three of these have

combined together by oxygen condensation, forming a complex of 18 carbon atoms.

When the fibres are heated with dilute nitric acid (5—10 per cent.) at 50—60°, a gas is evolved which consists for the most part of nitrous oxide, and only contains small quantities of nitric oxide; later on, the evolution of hydrocyanic acid is also observed, and on boiling the product with alkali, ammonia and more hydrocyanic acid are formed. Oxalic acid is also obtained, even at as low a temperature as 40—50°.

The reaction is extremely complicated, but it appears very probable that the substance is hydrolysed at the points where aldehyde condensation has taken place, nitrous acid being also formed, which then attacks the ketone ring with formation of oximes; these are then decomposed by excess of nitrous acid in the following manner:—

The result, therefore, is an increase in the number of oxygen atoms in the molecule, and the ring is then split with formation of compounds of lower molecular weight. The process is not to be regarded, with Lifschütz, as a simple oxidation.

In continuing these investigations, the authors also intend to examine the physiological side of the question. H. G. C.

Dissymmetry and Optical Activity of Alkyl Derivatives of Ammonium Chloride. By J. A. LE BEL (*Compt. rend.*, 112, 724—726).

—No physical isomerides have hitherto been obtained by the substitution of any number of alkyl radicles less than four for the hydrogen in ammonium chloride. This absence of isomerides may be due to one of two causes: firstly, only one of the isomerides geometrically possible may satisfy the necessary dynamical conditions of equilibrium and possess an invariable form; secondly, the radicles united to the nitrogen may be able to make permutations amongst themselves.

The action of moulds on methylethylpropylamine hydrochloride yields no product with any optical activity, and it follows that in this case the radicles are able to make permutations among themselves similar to those which take place at high temperatures in the case, for example, of sodium amyloxide.

The author has previously shown that an invariable geometric form of a molecule arises from repulsions between its constituent particles (*Bull. Soc. Chim.* [3], 2, 788), and it would follow that by the introduction of more complex radicles with larger spheres of repulsion, stability might be given to a particular geometric form which, with simpler radicles, is unstable. This condition seems to be realised in trimethylisobutylammonium chloride (*Abstr.*, 1890, 475).

Isobutylpropylethylmethylammonium chloride, when subjected to the action of moulds, gave two products, which in concentrated solution had rotatory powers exceeding -7° and -8° . The active salt is somewhat stable, and if neutral can be obtained in the solid form. It can be converted into an active acetate by means of silver acetate, but not into an active sulphate. The optical activity disappears when the mercuriochloride or platinochloride is treated with hydrogen

sulphide, but does not quite disappear in the case of the aurochloride. The alteration in the rotatory power in these cases is probably due to the action of the liberated hydrochloric acid. There is some indication of the existence of an isomeride with a dextro-rotatory power.

The action of moulds on the chlorides of ethylpropyldimethylammonium, ethyldipropylmethylammonium, ethyldipropylisobutylammonium, and ethylpropyldiisobutylammonium yields products which are either inactive or show very feeble optical activity. If any active isomerides exist, they form only a very small fraction of the products obtained under these conditions. C. H. B.

Action of Hydroxyhydrocarbon Derivatives on Nitrides and Hydronitrides. By R. VIDAL (*Compt. rend.*, 112, 950—951).—When vapours of methyl or ethyl alcohol are passed over phospham, PN_2H , previously heated at 150 — 200° , a metaphosphate of a primary amine is formed, together with some alcohol and a secondary amine. The primary action is $\text{PN}_2\text{H} + \text{ROH} = \text{PO}_4(\text{NH}_2\text{R}_2)_2$, but the phosphate decomposes under the influence of heat in accordance with the equation $\text{PO}_4(\text{NH}_2\text{R}_2)_2 = \text{ROH} + \text{PO}_2\text{NHR} + \text{NHR}_2$.

The reaction is more distinct in sealed tubes; ether yields the same products as alcohol, but aldehyde yields resinous and ammoniacal products, the nature of which has not yet been determined.

Boron nitride seems to behave in a similar manner, and the behaviour of the higher alcohols, phenols, and polyhydric alcohols is under investigation. C. H. B.

Chloralimido-compounds. By R. MOSCHELES (*Ber.*, 24, 1803—1805).—When chloralurethane, $\text{CCl}_3\text{CH}(\text{OH})\cdot\text{NH}\cdot\text{COOEt}$, is treated with benzoic chloride and aqueous alkali, it does not, as expected, yield the benzoyl compound $\text{CCl}_3\text{CH}(\text{OBz})\cdot\text{NH}\cdot\text{COOEt}$, but simply loses water forming *ethyl chloralimidocarboxylate*, $\text{CCl}_3\text{CH:N}\cdot\text{COOEt}$, which melts at 143° . Other acid chlorides and anhydrides have the same effect. Different substituted chloralimido-compounds can be prepared in a similar manner from the substituted chloral-ammonias having the general formula $\text{CCl}_3\text{CH}(\text{OH})\cdot\text{NHX}$. The following derivatives have been prepared: *formylchloralimide*, $\text{CCl}_3\text{CH:N}\cdot\text{CHO}$, melting at 193° ; *acetylchloralimide*, $\text{CCl}_3\text{CH:N}\cdot\text{Ac}$, melting at 207° ; and *benzoylchloralimide*, $\text{CCl}_3\text{CH:N}\cdot\text{Bz}$, which decomposes at 142° . They are all insoluble in water, but dissolve readily in alcohol and acetic acid, and are distinguished by the ease with which they crystallise. On animals they have no physiological action whatever.

H. G. C.

Action of Ethylenediamine on Thiamides. By G. FORSELL (*Ber.*, 24, 1846—1847).—Dithioamide combines with 2 molecules of ethylenediamine, ammonia being evolved and an intermediate compound of the formula $\text{NH}_2\cdot\text{C}_2\text{H}_4\cdot\text{NH}\cdot\text{CS}\cdot\text{CS}\cdot\text{NH}\cdot\text{C}_2\text{H}_4\cdot\text{NH}_2$ probably first formed; this is, however, unstable, and immediately passes into the closed compound $\begin{array}{c} \text{CH}_2-\text{N} \\ | \quad \quad | \\ \text{CH}_2\cdot\text{NH} \end{array} > \text{C} \cdot \text{C} < \begin{array}{c} \text{N}-\text{CH}_2 \\ | \quad \quad | \\ \text{NH}\cdot\text{CH}_2 \end{array}$, hydrogen sulphide being

eliminated. This compound is a powerful base, and combines with two equivalents of acids to form stable salts.

In a similar manner, ethylenebenzylidiamine is prepared from ethylenediamine and thiobenzamide. Ethylenediamide also reacts with thiocarbamide, and with xanthogenamide, but the products have not yet been further investigated. J. B. T.

Action of Ethylenediamine on Ethyl Dibromosuccinate. By G. FORSNELL (*Ber.*, 24, 1847—1848).—Ethyl dibromosuccinate is mixed with anhydrous ethylenediamine (2 mols.) in absolute alcoholic solution; after warming for some time on the water-bath, the crystals of ethylenediamine hydrobromide which separate are removed, and the alcohol allowed to evaporate spontaneously; the residue crystallises from alcohol in colourless needles, melts at 161° , and has the formula $\text{COOEt}\cdot\text{C}\cdot\text{C}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_2\text{H}_4\cdot\text{NH}_2$. The potassium salt crystallises in needles; the copper salt is very unstable.

Phenylpropionic acid is formed by the interaction of ethyl cinnamate and ethylenediamine. J. B. T.

Derivatives of Amylene Nitrosate. By O. WALLACH and J. WAHL (*Annalen*, 262, 324—339).—*Amylenenitrolamine*,

can be obtained by dissolving amylen nitrosate (*Abstr.*, 1888, 37) in warm alcoholic ammonia, then adding a sufficient quantity of potassium carbonate to combine with the nitric acid present as ammonium nitrate, evaporating to dryness, and extracting the organic base with chloroform. It is, however, best prepared by dissolving amylen nitrosochloride (*Abstr.*, 1888, 1098) in warm, concentrated alcoholic ammonia, filtering from the precipitated ammonium chloride and evaporating the alcohol under reduced pressure; the residue is then extracted with boiling chloroform, when the base passes into solution, whilst the hydrochloride of the base remains in an almost pure condition.

Amylenenitrolamine melts at $99\text{--}100^{\circ}$, boils at $218\text{--}220^{\circ}$, and sublimes when gently heated in long, lustrous needles; it is very readily soluble in water, alcohol, and chloroform, but more sparingly in ether, and insoluble in light petroleum. An aqueous solution of the base has a strongly alkaline reaction, and gives very characteristic reactions with solutions of metallic salts; on the addition of nickel sulphate, for example, there is obtained a yellow solution from which well-defined, yellow crystals are deposited on evaporation; cobalt nitrate produces a reddish-brown, and ferric chloride a yellowish-brown coloration. When aqueous solutions of equal quantities of the base and of copper sulphate are mixed, a dark, reddish-violet coloration is produced, and, on evaporating the solution, dark-violet crystals, which are very readily soluble in water but insoluble in alcohol and ether, are deposited. The compound $(\text{C}_6\text{H}_{13}\text{N}_2\text{O})_2\cdot\text{AgNO}_3$ is precipitated on adding a concentrated solution of silver nitrate to an aqueous solution of the base; it melts and takes fire when heated strongly, and rapidly darkens on exposure to the air. The *hydro-*

chloride, $C_5H_4N_2O \cdot HCl$, separates from alcohol in deliquescent crystals, is very readily soluble in water, and melts at $186-187^\circ$ with decomposition; the vapours evolved on heating the salt impart a red colour to a pine-chip moistened with hydrochloric acid.

Dibenzoylamylenenitrolamine, $NHBz \cdot CMe_2 \cdot CMe \cdot N \cdot OBz$, prepared by shaking the base with potash and benzoic chloride, crystallises well from ethyl acetate, melts at $142-143^\circ$, and is readily soluble in ether, but only sparingly in cold alcohol, and insoluble in water and alkalis. The *benzoyl* derivative, $NHBz \cdot CMe_2 \cdot CMe \cdot NOH$, is formed when the dibenzoyl derivative (5 grams) is boiled with an alcoholic solution of potash (0.6 gram) for an hour; it crystallises from boiling alcohol, melts at $184-185^\circ$, and is soluble in alkalis, but only very sparingly soluble in boiling water.

Benzoylamyleneketamine, $NHBz \cdot CMe_2 \cdot COMe$, is obtained when benzoylnitrolamine is boiled for a short time with dilute (1:19) sulphuric acid; it separates from alcohol in crystals, melts at $120-121^\circ$, and is readily soluble in alcohol and ether, but only sparingly in cold water, and insoluble in alkalis.

The *hydrurone*, $NHPh \cdot CMe_2 \cdot CMe \cdot N_2HPh$, is deposited in yellow crystals, when a concentrated aqueous solution of the ketoanilide $NHPh \cdot CMe_2 \cdot COMe$, previously described (Abstr., 1888, 37), is treated with phenylhydrazine; it melts at $96-97^\circ$, and is insoluble in water, but readily soluble in ether and hot alcohol.

Amylenenitrol- α -naphthylamine, $C_{10}H_7 \cdot NH \cdot CMe_2 \cdot CMe \cdot NOH$, can be obtained by boiling amylenenitrosate with an alcoholic solution of α -naphthylamine; it separates from boiling alcohol in well-defined, colourless crystals, melts at $173-174^\circ$, and is readily soluble in ether, but only sparingly in cold alcohol, and insoluble in water.

Amylenenitrolorthanidoquinoline, $C_9NH_7 \cdot NH \cdot CMe_2 \cdot CMe \cdot NOH$, prepared in like manner, crystallises in reddish plates, melts at $153-154^\circ$, and is readily soluble in ether, but only sparingly in alcohol.

F. S. K.

Decomposition of Amylene Nitrosate with Sodium Ethoxide. By O. WALLACH and P. ENGELS (*Annalen*, 262, 339-354).—Three oximes having the empirical formula C_6H_4NO are formed when amylenenitrosate (32 grams) is added to a cool solution of sodium (4.6 grams) in absolute alcohol (120 c.c.) and the mixture warmed for a short time to complete the reaction. Water is then added, the precipitated oil separated, and the residual alcoholic solution submitted to distillation with steam; the distillate is saturated with sodium chloride, extracted with ether, the ether evaporated, and the residue mixed with the original oil. This product contains the three compounds, which are separated as follows:—The mixture is distilled with steam, when the α -oxime, together with small quantities of the β -compound, passes over first in an oily condition; the distillate is saturated with sodium chloride, extracted with ether, and the α -oxime isolated by fractional distillation under reduced pressure. After some time, crystals of the β -oxime begin to collect in the condenser, but, on further distillation, the oily distillate solidifies more slowly; at this stage the process is stopped and the oil in the residue is extracted with

ether; on evaporating the ethereal solution, the γ -oxime is obtained in crystals together with an oily mixture of the α - and β -compounds.

The α -oxime crystallises in transparent, colourless plates, melts at 45° , boils at $83-84^\circ$ (55 mm.) and is very readily soluble in ether, alcohol, benzene, chloroform, and light petroleum, but more sparingly in water; it dissolves in soda, yielding, under suitable conditions, a crystalline sodium derivative, and with hydrogen chloride in ethereal solution it gives a colourless precipitate. A vapour density determination by V. Meyer's method, and molecular weight determinations by Raoult's and by Raoult and Beckmann's methods, gave results agreeing with those required by a compound of the molecular formula C_8H_8NO . The *benzoyl* derivative, $C_8H_8N \cdot OBz$, prepared by shaking an alkaline solution of the oxime with benzoic chloride, crystallises from dilute alcohol in lustrous needles and melts at $68-69^\circ$. The *dibromide*, $C_8H_8NOBr_2$, is formed when bromine is added to a well-cooled glacial acetic acid solution of the oxime until a permanent coloration is produced; it melts at 58° , and turns green when treated with soda, but the colour soon disappears again.

The *ketone*, C_8H_8O , is obtained when the oxime is heated with dilute sulphuric acid; it is an oil having an agreeable but rather pungent odour, and boils at $98-102^\circ$. It combines readily with bromine in ethereal or glacial acetic acid solution, and it is immediately oxidised by potassium permanganate; when treated with hydroxylamine, it is converted into the α -oxime (m. p. 45°).

The β -oxime is the principal product of the action of sodium ethoxide on amylene nitrosate; it separates from alcohol in well-defined, transparent crystals, melts at $67-68^\circ$, and boils at $129-131^\circ$ under a pressure of 25 mm., and at $120-122^\circ$ under a pressure of 11 mm.; it is insoluble in soda. Its molecular weight was determined by Raoult's methods and its vapour density by Meyer's method, employing the vapour of amyl acetate and of diphenylamine; the results showed beyond doubt that the compound has the molecular formula $C_{10}H_{18}N_2O_2$, but clearly indicated a dissociation of the molecule under the conditions of the experiment; the solid compound obtained by the condensation of the vapour of the β -oxime, which had been heated to the boiling point of diphenylamine, was found to be the α -oxime. The *dibromide*, $C_{10}H_{18}N_2O_2Br_2$, prepared by treating the β -oxime with bromine in glacial acetic acid solution, separates from dilute alcohol in crystals melting at 102° ; when boiled with alcoholic potash, it loses 1 mol. of hydrogen bromide, and is converted into the *bromo*-derivative, $C_{10}H_{17}N_2O_2Br$, which crystallises in colourless prisms and melts at 87° .

The γ -oxime crystallises from alcohol in colourless needles, melts at 111° , and is only moderately easily soluble in cold alcohol, and insoluble in water and alkalis. Molecular weight determinations by Raoult's method gave results agreeing with those required by a compound of the molecular formula $C_{12}H_{27}N_3O_3$, but the complex molecule easily undergoes dissociation on heating, the compound being converted into the α -oxime. The *dibromide*, $C_{12}H_{27}N_3O_3Br_2$, separates from dilute alcohol in crystals and melts at 82° ; when heated for a short time with alcoholic potash, it is converted into the

bromo-derivative, $C_5H_{20}N_3O_5Br$, which crystallises from alcohol in needles and melts at 102° . F. S. K.

Condensation of Guanidine with Ethereal Salts of β -Ketonic Acids. By J. JAEGER (*Annalen*, 262, 365—372).—Imidomethyluracil, $CH \begin{smallmatrix} \text{CO}-NH \\ \diagup \quad \diagdown \\ CMe \cdot NH \end{smallmatrix} > C:NH$, is deposited in crystals when guanidine carbonate (8 grams) is heated for four hours with an alcoholic solution of ethyl acetoacetate (12 grams) (compare Kohler, *Ber.*, 19, 220). It crystallises in prisms, melts at 270° with decomposition, and is readily soluble in alkalis and hot water, but only sparingly in alcohol and cold water, and insoluble in ether. The *hydrochloride*, $C_5H_7N_3O_5 \cdot HCl$, forms long, colourless crystals and melts at 295° . The *acid sulphate*, $C_5H_7N_3O_5 \cdot H_2SO_4$, crystallises in small plates and melts at 180° . The *nitrate*, $C_5H_7N_3O_5 \cdot HNO_3$, crystallises from warm, dilute nitric acid in colourless, lustrous needles, explodes at 120° , and is decomposed by boiling water.

Bromimidomethyluracil, $C_5H_4BrN_3O_5$, is obtained when imidomethyluracil is treated with excess of anhydrous bromine; it is a yellowish powder, only very sparingly soluble in water, and when heated with concentrated ammonia at 200° , it is converted into an amido-compound which melts at 275° .

Dibromohydroxyimidomethyluracil, $NH \begin{smallmatrix} C(NH) \cdot NH \\ \diagup \quad \diagdown \\ CO-CBr_2 \end{smallmatrix} > CMe \cdot OH$, is formed, together with the bromo-derivative just described, when imidomethyluracil is suspended in water and bromine added until a permanent coloration is produced; it crystallises from water in colourless needles, melts at 160° , and is decomposed by boiling alcohol, being converted into bromimidomethyluracil.

A compound of the composition $(C_5H_6N_3OMe)_2 \cdot HI$ is obtained when imidomethyluracil is heated with excess of methyl iodide for some hours at 140° , the solution evaporated, and the residue recrystallised from hot water; it melts at 212° , and is decomposed by potassium carbonate yielding *methylimidouracil*, $C_5H_6N_3OMe$, which crystallises from hot water in long, lustrous prisms and melts at 312° . The *hydrochloride*, $C_5H_6N_3OMe \cdot HCl + H_2O$, is a crystalline compound readily soluble in water. The *sulphate*, $(C_5H_6N_3OMe)_2 \cdot H_2SO_4$, is crystalline and melts at 270° . When methylimidomethyluracil is heated with a solution of barium hydroxide, it is decomposed with evolution of methylamine.

Imidodimethyluracil, $CMe \begin{smallmatrix} CO-NH \\ \diagup \quad \diagdown \\ CMe \cdot NH \end{smallmatrix} > C:NH$, can be prepared by heating guanidine carbonate with an alcoholic solution of ethyl methylacetoacetate; it separates from alcohol in spherical aggregates, melts at 320° , and is almost insoluble in water, alcohol, and ether. The *acid sulphate*, $C_5H_6N_3O_5 \cdot H_2SO_4$, crystallises in small, colourless needles, and melts at 265° . The *nitrate*, $C_5H_6N_3O_5 \cdot HNO_3$, crystallises from warm dilute nitric acid in lustrous plates melting at 200° .

Imidophenyluracil, $C_{10}H_8N_3O_5$, prepared by treating guanidine carbonate with ethyl benzoylacetate, is an amorphous powder; it melts at

294°, and is insoluble in water, alcohol, and ether, but soluble in acids, forming salts. F. S. K.

"Rubeanic Acid." By O. WALLACH and G. REINHART (*Annalen*, 262, 351—364).—The following experiments show that the red compound ("rubeanic acid, rubeanwasserstoff") obtained by the combination of cyanogen and hydrogen sulphide behaves in many reactions as if it were dithioxamide, $\text{NH}_2\cdot\text{CS}\cdot\text{CS}\cdot\text{NH}_2$ (compare Ephraim, this vol., p. 831); the sodium derivative, on the other hand, has doubtless the constitution $\text{SNa}\cdot\text{C}(\text{NH})\cdot\text{C}(\text{NH})\cdot\text{SNa}$ (compare Wallach, *Ber.*, 13, 528).

Dibenzylldithioxamide, $\text{C}_7\text{H}_7\cdot\text{NH}\cdot\text{CS}\cdot\text{CS}\cdot\text{NH}\cdot\text{C}_7\text{H}_7$, is formed, with evolution of ammonia, when dithioxamide (rubeanic acid) is heated with benzylamine in alcoholic solution, and also when dibenzyl-oxamide (m. p. 219°) is melted with phosphorus pentasulphide; it separates from hot ethyl acetate in yellowish-red crystals, melts at 115°, and is only sparingly soluble in warm alcohol, but more readily in ether. It is insoluble in aqueous, but readily soluble in alcoholic potash, the salt thus obtained being decomposed by carbonic anhydride; its alcoholic solution gives precipitates with lead acetate and mercuric chloride.

Dimethyldithioxamide, $\text{NHMe}\cdot\text{CS}\cdot\text{CS}\cdot\text{NHMe}$, can be prepared by warming dithioxamide with methylamine in dilute alcoholic solution, and also by treating the compound $\text{NHMe}\cdot\text{CCl}_2\cdot\text{CCl}_2\cdot\text{NHMe}$ (compare Wallach and Pirath, *Ber.*, 12, 1063) with hydrogen sulphide; it forms yellow crystals, melts at 140°, and is readily soluble in alkalis, but only sparingly in alcohol. When boiled with benzylamine, it is converted into dibenzylldithioxamide with evolution of methylamine.

Diethyldithioxamide, $\text{NHEt}\cdot\text{CS}\cdot\text{CS}\cdot\text{NHEt}$, prepared by analogous reactions, forms yellowish-red crystals, melts at 58°, and is readily soluble in alcohol, ether, benzene, and chloroform, but more sparingly in light petroleum, and almost insoluble in water; it dissolves freely in cold alkalis yielding compounds which are decomposed by carbonic anhydride.

Diamyldithioxamide, $\text{C}_4\text{H}_9\cdot\text{NH}\cdot\text{CS}\cdot\text{CS}\cdot\text{NH}\cdot\text{C}_4\text{H}_9$, prepared by warming dithioxamide with amylamine in alcoholic solution, crystallises in red prisms and melts at 60°.

Isodimethyldipropyldithioxamide, $\text{SPr}\cdot\text{C}(\text{NMe})\cdot\text{C}(\text{NMe})\cdot\text{SPr}$, can be obtained by boiling dimethyldithioxamide with sodium ethoxide (2 mo's.) and propyl chloride (2 mols.) until the separation of sodium chloride is at an end; it is a yellowish oil.

Isotetrethylldithioxamide, $\text{SEt}\cdot\text{C}(\text{NEt})\cdot\text{C}(\text{NEt})\cdot\text{SEt}$, can be prepared from diethyldithioxamide and ethyl iodide in like manner; it is an oil. F. S. K.

Isomerism of Thioaldehydes. By E. BAUMANN and E. FROMM (*Ber.*, 24, 1419—1430; compare next abstract and p. 1050).—Formaldehyde and acetone each yield only one trithio-derivative; acetaldehyde and benzaldehyde, however, yield three, as will be shown later (this vol., pp. 1010 and 1050). Marckwald's γ -trithioacetaldehyde is merely impure α -trithioacetaldehyde. The compound at present termed α -trithiobenzaldehyde is in reality a polymorphic derivative of

high molecular weight, whilst the γ -trithiobenzaldehyde (m. p. 167°) of the authors, from its close analogy with α -trithioacetaldehyde, will in future be termed the α -form. The trithiobenzaldehydes, on heating with copper, are decomposed quantitatively into cinnamens, but this is no proof of their having the formula $\text{CHPh} \langle \text{S} \rangle \text{CHPh}$, since similarly constituted compounds, by simple heating, are converted into substances of lower molecular weight. It has also been shown that the formation of polymeric thioaldehydes, by the action of hydrogen sulphide on aldehydes in aqueous solution, is not direct, but is preceded by the formation of mercaptans or hydroxy-mercaptans; under the influence of condensing agents, these compounds then polymerise with elimination of hydrogen sulphide or water respectively.

Molecular weight determinations have proved that, by the interaction of hydrogen sulphide and aldehydes, in presence of hydrochloric acid, trithio-derivatives are exclusively formed, and that they exist in two isomeric modifications, the α - or lower melting isomerides are obtained in largest quantity at low temperatures, and are converted into the β -modifications by the action of iodine and similar substances; the more stable isomerides are formed in greatest proportion in excess of hydrochloric acid, and crystallise with 1 mol. benzene.

The researches of Klinger have shown that the trithioacetic aldehydes are substitution products of trithioformaldehyde (trithio-methylene), which has the formula $\text{S} \langle \text{CH}_2 \cdot \text{S} \rangle \text{CH}_2$; the isomerism of the compounds is evidently geometric, and is not dependent on the sulphur atoms. These substances may therefore be regarded as affording the simplest example of isomerism, similar to that developed by v. Baeyer in the case of the hydrophthalic acids, and his system of nomenclature may be conveniently employed to distinguish the various modifications.

Mono-substitution derivatives of trimethylene or trithiomethylene can only exist in one form; di- and tri-substitution products may exist in two forms unless two substitution groups are linked to the same carbon atom; tetra-substituted derivatives resemble the di-substitution products; whilst penta- and hexa-derivatives are incapable of occurring in geometrically different forms. The foregoing applies only when the substituting groups are alike; if unlike, the number of isomerides is considerably increased.

The following diagrams represent the possible forms of trisubstituted trithiomethylene; the present β -trithioaldehydes, being the more stable compounds are ranged in the trans- or fumaroid class. The carbon atoms are assumed to occupy the corners of the triangle, the thin lines representing methylene hydrogen, the thick ones the substituting groups:—

 α -Cis- or maleinoid form. β -Trans- or fumaroid form.

No isomerism.

Besides the difference in physical properties, the two forms may further be distinguished by the fact that, on oxidation, the cis-compound could only yield one disulphone sulphide, whilst the trans-derivative should give two, corresponding with the formulæ

&

respectively.

The following table shows all the trithioaldehydes at present known; those marked * are described for the first time by the authors in the following papers:—

Aldehyde.	α - or cis-form.	β - or trans-form.
Acetic	α -trithioacetaldehyde (m. p. 101°)	β -trithioacetaldehyde (m. p. 125°).
Benzoic	* α -trithiobenzaldehyde (m. p. 167°)	β -trithiobenzaldehyde (m. p. 225°).
Paramethoxybenzoic .	* α -trithioparamethoxybenzaldehyde (m. p. 127°)	* β -trithioparamethoxybenzaldehyde (m. p. 183°).
Orthomethoxybenzoic.	* α -trithioorthomethoxybenzaldehyde (m. p. 157°)	* β -trithioorthomethoxybenzaldehyde (m. p. 221°).
Orthisobutoxybenzoic.	* α -trithioorthisobutoxybenzaldehyde (m. p. 142°)	* β -trithioorthisobutoxybenzaldehyde (m. p. 163°).
Cinnamic	* α -trithiocinnamaldehyde (m. p. 167°)	* β -trithiocinnamaldehyde (m. p. 213°).
Formic	trithiomethylene (m. p. 216°).	
Acetone	trithioacetone (m. p. 24°).

Trithio-derivatives of Acetaldehyde and Polymeric Thioformaldehyde. By E. BAUMANN and E. FROMM (*Ber.*, 24, 1457 1459; compare preceding abstract).—Marckwald has stated that three products are formed on heating thialdine thiocyanate in aqueous solution; these are thiactaldehyde, γ -trithioacetaldehyde, and a compound of the formula $\text{NH}_2\text{C} < \begin{smallmatrix} \text{S-CHMe} \\ \text{S-CHMe} \end{smallmatrix} > \text{S}$. The authors have repeated this work, and have found that, during the decomposition of the thialdine salt, hydrogen sulphide is evolved. Marckwald's thiactaldehyde contains ordinary aldehyde, and may be separated by treatment with water, which converts the thiactaldehyde into a hydroxymercaptan; the constitution of this is uncertain, but it is undoubtedly a complicated polymeride of hydroxyethylidene mercaptan, $\text{SH}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{OH}$.

On treatment of this compound with concentrated hydrochloric acid, α -trithiacetaldehyde is formed (m. p. 101—102°), instead of the γ -derivative, and is readily purified by crystallisation from acetone. Thiacetaldehyde, on treatment with hydrochloric acid, also yields α -trithiacetaldehyde, and not the γ -compound as stated by Marckwald. An examination of the second product (see above) obtained by the decomposition of thialdine thiocyanate shows that it is simply impure α -trithiacetaldehyde; three different preparations melted at 71—72°, 73—74°, and 76—77°, but, after recrystallisation from acetone, they all melted at 101°. The impurity, although sufficient to lower the melting point, does not affect the analytical results. A compound (m. p. 75—76°) prepared by Poleck and Thümmel by the action of hydrogen sulphide on vinylmercuric oxychloride in hydrochloric acid solution is also without doubt α -trithiacetaldehyde.

The polymeric thioformaldehyde of Wohl is insoluble in all menstrua, including naphthalene; it is not volatile with steam, decomposes on heating slightly above its melting point, and is oxidised with difficulty, yielding sulphuric acid and methylenedisulphonic acid. The trithioaldehydes of the aliphatic series are all converted on oxidation into disulphone sulphides or trisulphones. Wohl's substance is rather to be regarded as a complicated polymeric compound or as a mixture, since different preparations melt at various temperatures between 175° and 186°.

Trithiacetaldehyde is therefore proved only to exist in two forms, corresponding in this respect with the aromatic trithioaldehydes, whilst only one trithioformaldehyde is known. J. B. T.

Dimethylacrylic Acid from Isovaleric Acid. By E. DUVILLIER (*Compt. rend.*, 112, 1012).—In the preparation of amido-acids from isovaleric acid, the yield was less satisfactory than in the case of normal butyric or propionic acids. It was thought that this was due to the formation of dimethylacrylic acid, as in the action of trimethylamine on ethyl bromisovalerate (*Abstr.*, 1890, 956). Preparing the amide in the usual manner from isovaleric acid, before liberating the amido-acid, the liquid was distilled; the distillate yielded an oily liquid scarcely soluble in water, distilling at 175—195°, absorbing bromine and iodine, and partially crystallising. The crystals have the composition and properties of dimethylacrylic acid. The action of ammonia on normal α -bromo-acids has not given unsaturated acids. Ammonia, acting on bromisobutyric acid, yields an unsaturated acid, which is now under investigation. W. T.

Distillation of the Potassium Hydrogen Salts of some Acids of the Oxalic Series. By G. WISBAR (*Annalen*, 262, 219—232).—It has been stated by Claus (*Annalen*, 191, 48) that at a high temperature glutaric acid is decomposed into carbonic anhydride and butyric acid; the authors made a number of experiments under various conditions in order to ascertain whether both normal and isobutyric acid are formed on heating pure glutaric acid, but they were unable to detect the presence of either compound in the products of decomposition.

The behaviour of several potassium hydrogen salts, at a temperature of about 260° , was then investigated qualitatively and quantitatively, the dry salt being heated in a glass distilling flask in the vapour of amyl benzoate, and the gaseous and liquid products collected.

Anhydrous potassium hydrogen oxalate is quickly decomposed into potassium oxalate, water, formic acid, carbonic oxide, and carbonic anhydride.

Anhydrous potassium hydrogen malonate is also quickly decomposed, the principal products being potassium acetate and carbonic anhydride, but a small quantity undergoes decomposition into potassium malonate, acetic acid, and carbonic anhydride.

Potassium hydrogen succinate is much more slowly decomposed, yielding carbonic anhydride, an aqueous and an oily distillate, and non-volatile compounds. When the distillate is boiled with water, a very small quantity of an acid, probably propionic acid, passes over, together with a brown, neutral oil, which has approximately the composition $C_{10}H_{14}O$, and a little succinic acid remains in solution. The non-volatile residue contains potassium succinate and one or more acid substances of high molecular weight.

One of these acids can be isolated by extracting the residue with boiling alcohol, evaporating the cold, filtered solution, dissolving the residue in sodium carbonate, and then acidifying with hydrochloric acid, when it is deposited in the form of an amorphous, light-coloured precipitate; it is dissolved in alcohol, fractionally precipitated from the solution with light petroleum, dissolved in ammonia, and then reprecipitated with hydrochloric acid. It is thus obtained in the form of a brownish, amorphous powder, which has the composition $C_{11}H_{10}O_5$, is insoluble in water, and decomposes on heating; the silver salt, $C_{11}H_9AgO_5$, is a reddish-brown, jelly-like substance. The portion of the original residue which is not dissolved by the boiling alcohol also contains amorphous substances of high molecular weight, two of which were isolated and analysed; the one gave results agreeing with those required by a compound of the composition $C_{16}H_{14}O_6$ or $C_{16}H_{12}O_6$, and had an acid character; the other is a brown powder, insoluble in alkalis, the composition of which may be represented by the formula $C_{27}H_{20}O_8$.

Potassium hydrogen glutarate is decomposed at 260° with evolution of carbonic anhydride; the distillate contains only traces of a volatile acid, and the residue consists of potassium glutarate and dark, acid, condensation products.

F. S. K.

Ethyl Hydrogen Malonate and Ethyl Potassium Malonate. By G. MASSOL (*Compt. rend.*, 112, 734—735).—Ethyl hydrogen malonate is obtained by adding to ethyl potassium malonate the calculated quantity of sulphuric acid, evaporating in a vacuum in presence of sulphuric acid, and extracting with ether. The ethereal solution is first distilled, and afterwards allowed to evaporate spontaneously. Ethyl hydrogen malonate is left as a slightly viscous liquid with a feeble, aromatic odour; sp. gr. at 0° = 1.201; refractive index at 22° , for white light = 1.333, for D = 1.337; heat of dissolution +0.60 Cal.; heat of neutralisation by potash +13.45 Cal., a number

practically the same as the heat of neutralisation of potassium hydrogen malonate.

Potassium ethyl malonate is obtained in colourless lamellæ, very soluble in water, by evaporating a solution of ethyl hydrogen malonate that has been exactly neutralised with potash. Heat of dissolution, -0.65 , and hence $C_2H_3EtO_2$ liq. + KOH sol. = $C_2H_3O_4KEt$ sol. + H_2O sol. develops $+28.6$ Cal., a number practically identical with the heat of formation of hydrogen potassium malonate, $+27.5$ Cal., but distinctly greater than the heat of formation of normal potassium malonate from hydrogen potassium malonate, $+20.7$ Cal.

C. H. B.

Decomposition of Glutaric Acid and Succinic Acid by Sunlight in Presence of a Uranium Salt. By G. WISBAE (*Annalen*, 262, 232—236).—According to Seekamp (*Annalen*, 133, 254), an aqueous solution of glutaric acid undergoes decomposition in sunlight in presence of a uranyl salt, with formation of butyric acid and evolution of carbonic anhydride. The authors have investigated this reaction more closely, and find that normal butyric acid, but no isobutyric acid, is formed, with evolution of carbonic anhydride and small quantities of propane; the last-named compound is produced by the decomposition of some of the butyric acid in presence of sunlight and uranyl nitrate.

F. S. K.

Hydrolysis of Ethereal Salts of Polybasic Acids. By W. LÖNNEN and A. KÜHLER (*Annalen*, 262, 196—219).—The following experiments were made with the object of ascertaining whether the course of hydrolysis of a mixed ethereal salt, such as methyl ethyl succinate, is dependent on the nature of the alcohol radicles, and also, whether in the case of such ethereal salts as methyl ethyl glutarate, of which there exist theoretically two isomerides, the course of hydrolysis is determined by the nature of the alcohol radicle, as well as by the structure of the molecule.

The method of preparation of many of the ethereal salts which were examined in this research has been previously described by Wieser (*Abstr.*, 1890, 102).

When methyl ethyl succinate (45 grams, 2 mols.) is shaken with a solution of barium hydroxide (43 grams, 1 mol.) in water (1 litre) until the reaction is complete, barium succinate (15.2 grams) is formed by the complete hydrolysis of a portion (9.6 grams) of the ethereal salt, but an equal quantity (9.6 grams) remains undecomposed, and a large quantity (about 26 grams) is converted into a mixture of ethyl and methyl barium succinates, of which the former is present in the larger proportion; a quantitative examination showed that methyl and ethyl alcohols were liberated in the hydrolysis in the molecular proportion 100 : 72, approximately.

When ethyl propyl succinate (47 grams, 2 mols.) is treated in like manner with a solution of barium hydroxide (38.3 grams, 1 mol.) in water (1 litre), about one-half of the ethereal salt is completely converted into barium succinate, the remainder being undecomposed; when a more dilute solution of barium hydroxide is employed, a con-

siderable quantity of a mixture of ethyl and propyl barium succinate is also formed.

It has been observed by Salomon (*Ber.*, 8, 1508) that methyl potassium oxalate is formed on treating ethyl oxalate with a methyl alcoholic solution of potassium methoxide; the authors find that an analogous reaction takes place in the case of other oxalates. Propyl oxalate, for example, is converted into methyl potassium oxalate by an anhydrous methyl alcoholic solution of potassium methoxide, and into ethyl potassium oxalate by an ethyl alcoholic solution of potassium ethoxide. When ethyl oxalate is treated with a solution of potassium propoxide in propyl alcohol, propyl potassium oxalate is formed; methyl oxalate is converted into ethyl potassium oxalate by an alcoholic solution of potassium ethoxide, and when treated with a solution of potassium in propyl alcohol, it yields propyl potassium oxalate. Such reactions as these, taking place as they do in presence of excess of a particular alcohol, may be modified considerably by changing the conditions, as is shown by the following facts:—(1.) When propyl oxalate is treated with a methyl alcoholic solution of potassium methoxide mixed with three volumes of propyl alcohol, a mixture of methyl and propyl potassium oxalate is deposited. (2.) On treating a mixture of propyl alcohol and propyl oxalate with an alcoholic solution of potassium ethoxide, both propyl and ethyl potassium oxalates are formed; if, on the other hand, a mixture of methyl alcohol and methyl oxalate is treated with a solution of potassium propoxide in propyl alcohol, methyl potassium oxalate is deposited in an almost pure condition. (3.) When excess of ethyl oxalate is treated with a small quantity of a methyl alcoholic solution of potassium methoxide, the principal product is ethyl potassium oxalate.

When ethyl oxalate is treated with anhydrous potassium ethoxide, a small quantity of a liquid, having the properties of ethyl ether, is obtained; it would seem therefore that the formation of the alkyl potassium oxalate in the reactions described above may be expressed by the equation $C_2O_4Et_2 + KOEt = C_2O_4EtK + Et_2O$.

When ethyl propyl oxalate is treated with phosphorus pentachloride, both ethyl chloride and propyl chloride are evolved, and there remains a mixture of the chlorides of ethyl hydrogen and propyl hydrogen oxalate.

Methyl carbonate is decomposed by an alcoholic solution of potassium ethoxide, yielding a mixture of methyl and ethyl potassium carbonates; under the same conditions, ethyl glutarate yields small quantities of ethyl potassium glutarate, and a large quantity of potassium glutarate; when methyl glutarate is treated with barium methoxide, barium glutarate is formed in large quantities, together with the barium methyl salt.

Ethyl dihydrogen phosphate can be obtained by decomposing the barium ethyl salt, $BaEt_2PO_4 + 6H_2O$, with the theoretical quantity of dilute sulphuric acid, and evaporating the filtered solution; it is a very deliquescent, readily fusible, crystalline compound.

Barium diethyl phosphate is easily prepared by decomposing triethyl phosphate with an aqueous solution of barium hydroxide, and evapo-

rating the filtered solution; the free acid could not be obtained in crystals, but the silver salt, AgEt_2PO_4 , crystallises in needles.

Methyl silver phosphate is a colourless, crystalline compound sparingly soluble in water.

Barium dimethyl phosphate, $(\text{Me}_2\text{PO}_4)_2\text{Ba}$, prepared from the trimethyl salt, is readily soluble in water, but is precipitated from the solution on the addition of alcohol; the corresponding silver salt, AgMe_2PO_4 , crystallises from water, in which it is readily soluble, in plates.

Dibenzyl hydrogen phosphate, $(\text{C}_7\text{H}_7)_2\text{HPO}_4$, can be prepared by shaking tribenzyl phosphate with hot, very concentrated potash, and decomposing the potassium salt obtained in this way with hydrochloric acid; it crystallises in needles or prisms, melts at $78-79^\circ$, and is readily soluble in alcohol and ether, but only sparingly in water. The calcium salt, $[(\text{C}_7\text{H}_7)_2\text{PO}_4]_2\text{Ca} + 6\text{H}_2\text{O}$, and the barium salt are crystalline, and soluble in hot water, but the silver salt is only sparingly soluble. The normal salts of dibenzyl hydrogen phosphate are very stable; potassium dibenzyl phosphate, for example, is not decomposed even on prolonged heating with excess of concentrated potash.

Tribenzyl phosphate, $(\text{C}_7\text{H}_7)_3\text{PO}_4$, is prepared by warming silver phosphate with an ethereal solution of benzyl chloride; it forms large, prismatic crystals, melts at 64° , and is soluble in the ordinary organic solvents, but insoluble in water.

Ethyl dimethyl phosphate, EtMe_2PO_4 , can be obtained by treating ethyl disilver phosphate with methyl iodide, or by treating silver dimethyl phosphate with ethyl iodide; it boils at 203.3° , and its specific gravity is 1.1752 at 0° . On hydrolysis with an aqueous solution of barium hydroxide, it is easily converted into barium ethyl methyl phosphate with liberation of methyl alcohol; ethyl methyl hydrogen phosphate is, however, a very stable compound, and is not decomposed by bases, so that it would seem from these facts that one of the alkyl groups in the normal ethereal salts is combined differently to the others.

Methyl diethyl phosphate, MeEt_2PO_4 , prepared from methyl disilver phosphate, or from silver diethyl phosphate, is a colourless liquid of sp. gr. 1.1282 at 0° , and boils at 208.2° under a pressure of 759.7 mm.; on hydrolysis with a solution of barium hydroxide, it yields methyl ethyl barium phosphate.

Methyl dibenzyl phosphate, $\text{Me}(\text{C}_7\text{H}_7)_2\text{PO}_4$, is formed when an ethereal solution of benzyl chloride is warmed with methyl disilver phosphate, and when silver dibenzyl phosphate is treated with methyl iodide; it is a brownish oil of sp. gr. 1.2005 at 0° , and cannot be distilled. It is much more difficult to hydrolyse than the ethereal salts described above, but when shaken with hot, very concentrated potash, it is converted into potassium dibenzyl phosphate. F. S. K.

Symmetrical Dimethylglutaric Acid and Trimethylsuccinic Acid. By K. ATWERS and E. KÖNIGER (*Ber.*, 24, 1923—1937).—The authors have determined the nature of the acid obtained by the action of α -bromisobutyric acid on ethyl sodium methylmalonate and hydro-

lysis of the product by boiling with acids, concerning which acid many different opinions have been put forward. They find that this acid is identical with the symmetrical dimethylglutaric acid (m. p. 102—104°) which Zelinsky (Abstr., 1890, 132) has prepared from ethyl α -cyano-propionate and methylene iodide. They have prepared some quantity of the acid from α -bromisobutyric acid and ethyl sodium methylmalonate. It melts at 102—103°, yields an anhydride melting at 95°, and the latter, when boiled with water, is converted to an acid which melts at 127.5—128°. Both these acids yield the same anhydride. By heating the acid melting at 127—128° with hydrochloric acid at 200°, it is converted into the acid melting at 102—103°. These results leave no doubt that the acid is dimethylglutaric acid. Anwers and Jackson (Abstr., 1890, 1098) have put forward an explanation of the above reaction. They assume that in the presence of an alcoholic alkaline solution, the α -bromisobutyric acid is converted into methylacrylic acid, and that the latter condenses with the ethyl sodium methylmalonate to yield a product which, on hydrolysis, gives dimethylglutaric acid. The authors have obtained dimethylglutaric acid from methylacrylic acid. An analogous reaction takes place between ethereal salts of crotonic acid and ethyl sodium malonate when β -methylglutaric acid is formed instead of ethylsuccinic acid.

Symmetrical dimethylglutaric acid (m. p. 102—103°) is best prepared as follows:—Ethyl α -bromisobutyrate (195 grams) is warmed on the water-bath and added to a hot, alcoholic solution of ethyl methylmalonate (170 grams) and sodium (22.5 grams); a brisk reaction takes place; the mixture is digested on the water-bath for five hours, and the alcohol distilled off. The ethyl tricarboxylate so obtained is hydrolysed by heating with concentrated hydrochloric acid ($\frac{3}{4}$ vol.) and water ($\frac{3}{4}$ vol.). On cooling, the acid separates in pure white, prismatic crystals, and is purified by crystallisation from benzene, and finally by dissolution in chloroform and fractional precipitation with light petroleum. It melts at 102—103°, crystallises in small, shining prisms, and is easily soluble in water, chloroform, ether, alcohol, and acetic acid, sparingly in cold benzene, and insoluble in light petroleum. The *anhydride* is obtained by digesting the acid with acetic chloride on the water-bath, or by heating it in a sealed tube with acetic chloride at 100°. It crystallises from light petroleum in feathery needles, and melts at 95°. When the acid is heated for some time at 200° and the product distilled, washed with soda, and crystallised from petroleum, a substance is obtained which melts at 82—83°; this the authors believe is a mixture of the anhydrides of the two isomeric dimethylglutaric acids.

Dimethylglutaric acid (m. p. 127.5—128°) is obtained by boiling the above anhydride (m. p. 95°) with a little water. It crystallises in long, lustrous needles, melts at 127.5—128°, and is crystallographically identical with Zelinsky's high-melting dimethylglutaric acid. When heated with acetic chloride, it yields the same anhydride as the low-melting acid, and when heated with concentrated hydrochloric acid for 18 hours at 200°, it is converted into the low-melting acid.

The above acids have also been prepared from methylacrylic acid.

Ethyl methylacrylate is prepared by digesting silver methylacrylate,

ether, and ethyl iodide for six hours in a reflux apparatus, and is purified by fractional distillation. It boils at $115-120^{\circ}$, and has a strong, pleasant odour. Dimethylglutaric acid (m. p. $102-103^{\circ}$) is obtained when ethyl methylacrylate (15 grams) is added to a warm solution of ethyl methylmalonate (23 grams) and sodium (3 grams) in absolute alcohol, and the mixture heated for five hours on the water-bath. The product is purified by fractional distillation, and hydrolysed with hydrochloric acid. E. C. R.

Methyl Methylcyanosuccinate; Methyl Methyleneyltricarboxylate. By L. BARTHÉ (*Compt. rend.*, 112, 1013—1015).—In a previous communication, it has been shown that methyl cyanosuccinate is obtained by treating methyl sodiocyanacetate with methyl monochloracetate (this vol., p. 43). This substance reacts readily, and it is easy to prepare its substitution derivatives.

Methyl methylcyanosuccinate, $\text{COOMe} \cdot \text{CMe}(\text{ON}) \cdot \text{CH}_2 \cdot \text{COOMe}$, is prepared by dissolving 20 grams of methyl cyanosuccinate in 60 grams of methyl alcohol and adding a solution of 2.38 grams of sodium in 100 grams of methyl alcohol; to this mixture is added 16.6 grams of methyl iodide rectified at 43° , and the whole is heated on a water-bath in a reflux apparatus for five hours. The temperature should be kept at from $70-75^{\circ}$. The precipitated sodium iodide is filtered off, and the alcohol separated by distillation. A reddish oil is precipitated from the residue by water and taken up by ether. The ethereal solution, dried by calcium chloride, is then distilled on the water-bath, and finally, under reduced pressure, on the oil-bath, when the methyl salt passes over at $195-200^{\circ}$ (60 mm.) as an oily, colourless liquid. The same compound is formed in attempting to produce ethyl methylcyanosuccinate, if methyl alcohol be employed as the solvent. The author has not succeeded in obtaining methyl ethyl cyanosuccinate.

Methyl methyleneyltricarboxylate, $\text{COOMe} \cdot \text{CH}_2 \cdot \text{CMe}(\text{COOMe})_2$.—The above compound has been saponified by treatment with methyl alcohol saturated with hydrochloric acid, in sealed tubes at 75° , for one or two hours. The reaction does not take place in the cold, even after a long time. The liquid is evaporated on the water-bath, and then washed with sodium carbonate solution. The oily substance precipitated is taken up with ether, dried by calcium chloride, and distilled under reduced pressure. The greater part of the product distils over at 217° under 0.05 atmos. pressure. The properties of methyl cyanosuccinate and its substitution derivatives resemble those of ethyl cyanosuccinate and its derivatives. Other new compounds obtained with ethereal cyanacetates and cyanosuccinates will be described in a succeeding communication. W. T.

Isomeric Pimelic Acid from Amylene Bromide. By C. HELL (*Ber.*, 24, 1389—1399).—Amylene bromide is boiled for 70 hours with an alcoholic solution of potassium cyanide; the product is hydrolysed, and the resulting acid crystallised from petroleum; it melts at 104° . During the purification a viscid liquid is obtained in small quantity, which Bauer and Schuler supposed to be an isomeric

amorphous pimelic acid, but which crystallises on exposure in thin films, and proves to be identical with the chief product. The yield is 5 grams from 2 kilos. of amylene bromide. The salts are generally crystalline; the anhydrous *nickel salt* is yellow; two greenish-yellow salts are also formed, containing 1 mol. H_2O and $2\frac{1}{2}$ mols. H_2O respectively. On heating the acid at 135° , water is eliminated, and the *anhydride* is obtained; it is a viscid liquid, boiling above 200° without decomposition. Acetic acid is the sole oxidation product of the acid. It is probable that this acid is unsymmetrical ethylmethylsuccinic acid, and that its formation is due to the presence of a little ethylmethylethylene bromide in the amylene bromide, the bulk of which certainly consisted of trimethylethylene bromide, since the amylene employed for its preparation boiled at $35-38^\circ$; this would account for the exceedingly small yield. The absence of propionic acid in the oxidation products of the acid was the chief reason for the author's previously suggesting that it might be trimethylsuccinic acid.

The paper closes with some observations in reply to a recent paper of Zelinsky and Besrodka (this vol., p. 669). J. B. T.

Preparation of Glyceryl Pyruvate. By C. BÜTTINGER (*Annalen*, 263, 216-247).—Glyceryl pyruvate, previously known as pyruvin or glycuvic acid, can be very easily prepared by heating finely-divided potassium hydrogen sulphate (5 grams) with pyruvic acid (2.5 c.c.) and glycerol (2.5 c.c.) for a short time over a small flame. The product is extracted with ether, the extract evaporated, and the thick, colourless syrup obtained in this way agitated with an equal volume of water, when pure glyceryl pyruvate is quickly deposited in lustrous plates. The portion insoluble in ether is extracted with boiling alcohol, the solution concentrated by evaporation, mixed with water, and extracted with ether; the residue obtained on evaporating the ether is then treated with an equal volume of water, when a second crop of crystals of glyceryl pyruvate is obtained.

F. S. K.

Constitution of Aqueous Solutions of Tartaric Acid. By AIGNAN (*Compt. rend.*, 112, 951-953).—The results of Biot's observations on the rotatory power of aqueous solutions of tartaric acid may be explained on the assumption either that tartaric acid forms in solution a definite hydrate, which exists in a partially dissociated condition, or that the physical molecule is double the chemical molecule, but is likewise partially dissociated in solution. If the first assumption is true, Biot's results show that the proportion of tartaric acid which combines in a fixed ratio with n molecules of water in the form of non-dissociated hydrate is equal to the proportion of water in the solution, and in this case the osmotic pressure will be

$$\pi_1 = RT \frac{n}{150} c.$$

In the second case, the results show that the proportion of the compound $(C_4H_4O_6)_2$ dissociated by dissolution is equal to the proportion of the solvent in the liquid examined; or, the weight of the active compound $(C_4H_4O_6)_2$ dissociated by dissolution is equal to the

product of the weight of the solvent by the concentration c of the solution, and the osmotic pressure will be

$$\pi_2 = RT \frac{c}{150} \left(c - \frac{c^2}{2} \right).$$

A solution of tartaric acid containing 49.47 grams per kilogram (49 gr. = 1.02241) is isotonic with a solution of sugar containing 112.47 grams per litre. and hence tartaric acid exists in solution in the form of the polymeride, $(C_4H_6O_6)_2$, which is partially dissociated, in accordance with the law already stated. C. H. B.

Combinations of Tartaric Acid and Potash, or Soda, in Solution. By AIGNAN (*Compt. rend.*, 112, 1009—1011).—From the observation of the rotation of the plane of polarisation ω , given by a column of solution of length l , the quantity $[\omega] = M\omega/Pl$, where M = mass of solution containing a weight P of the active substance, δ = the specific gravity of the solution, was calculated by Biot for solutions containing tartaric acid mixed with various amounts of potash or soda respectively. He found the values of $[\omega]$ obtained to be represented graphically by an equilateral hyperbola, and concluded that combinations were formed in the solutions examined in continuously varying quantities (*Mém. Inst. France*, 16).

According to the author's theory, the line representing the values of $[\omega]$ should consist of arcs of curves crossing in angular points. To verify this conjecture, a series of observations have been taken sufficiently numerous to afford many more points than Biot obtained. The solutions used contained 150 grams, or one molecular weight of tartaric acid, with a proportion of soda varying from 0 to 22/5 of an equivalent in a mass $M = 4000$ grams.

As tartaric acid forms, with potash and soda, 1st, an acid tartrate, 2nd, a normal tartrate, two angular points could be predicted; the author finds, on plotting out his results with weights of soda along x as abscissæ—

(1.) For varying quantities of soda from 0 to 1 equivalent, $[\omega]$ is represented by a curve which departs but little from a right line, and is convex towards the axis of x .

(2.) Between 1 and 2 equivalents, $[\omega]$ is represented by a right line, cutting the first arc of the curve at an open angle. This angular point indicates the formation of sodium hydrogen tartrate, as predicted.

(3.) From 2 to 3 equivalents, the curve is of different character, and clearly cuts the preceding at the point corresponding with the formation of the normal tartrate. This arc shows that $[\omega]$ attains a maximum value at about 11/5 equivalents of soda, and then decreases slowly.

(4.) At 3 equivalents, a third angular point occurs, indicating that further combination of the soda and tartaric acid takes place, then $[\omega]$ again increases slightly, and finally decreases slowly, apparently to a limiting value.

The existence of a third compound might have been foreseen, as Berthelot found the third equivalent of soda, added to tartaric acid,

liberated 0.3 Cal. It is probably a true alcoholate, and from the author's observations partially dissociates in solution. W. T.

Formation of Inactive Tartaric Acid by the Oxidation of Phenol with Potassium Permanganate. By O. DOEBNER (*Ber.*, 24, 1753—1757).—Kekulé and Anschütz have shown that when fumaric acid is oxidised with potassium permanganate, racemic acid is formed, whilst maleic acid yields inactive tartaric acid under the same circumstances. It would, therefore, appear that the carbon chain in inactive tartaric acid has the same stereochemical structure as that of maleic acid, and as, further, the chain $\text{CH}:\text{CH}:\text{CH}:\text{CH}$, which exists in benzene, according to Kekulé's configuration, stands in stereochemical relation to the generally accepted formula for maleic acid, it was to be expected that inactive tartaric acid would be formed by oxidising benzene with alkaline potassium permanganate; experiments proved, however, that the two are almost without action, and the author, therefore, substituted phenol for benzene with the following results:—Phenol (10 grams) is neutralised with a solution of sodium hydroxide, and the solution diluted with water to 1 litre; it is then cooled to $0-3^{\circ}$, and potassium permanganate (40 grams), in water (3 litres), gradually added. After several hours, the mixture is filtered from manganese dioxide; on adding an excess of hydrochloric acid to the filtrate from several experiments, and concentrating, a brownish-yellow, amorphous substance separates, which is filtered off. On treating the hot filtrate with calcium carbonate, and subsequently reacidifying with acetic acid, calcium oxalate remains undissolved, and the calcium salt of inactive tartaric acid separates from the filtrate; it is purified by dissolving in very dilute hydrochloric acid, adding ammonia, and then an excess of hot acetic acid; 90 grams of phenol yield calcium tartrate (9 grams), and oxalate (24 grams), besides carbonic anhydride. The production of inactive tartaric acid from phenol is, therefore, best explained by Kekulé's benzene formula, and the last-mentioned chemist has already shown (*Abstr.*, 1884, 41) that tetrahydroxysuccinic acid is obtained by the oxidation of catechol with nitrous acid. Experiments are in progress with other benzene derivatives. A. R. L.

Substitution of Halogens in Aromatic Hydrocarbons. By G. ERRERA (*Gazzetta*, 21, 103—110).—The author compares the results previously obtained by himself (*Abstr.*, 1887, 1103) with Srpek's conclusions (this vol., p. 44) as to the constitution of the products of the bromination of benzyl chloride, and of the chlorination of parabromotoluene. The author maintains that the solid products consist mainly of a mixture of chloride and bromide of parabromobenzyl, and contain no chlorine in the nucleus.

S. B. A. A.

Action of Chromyl Dichloride on Cymene. By G. ERRERA (*Gazzetta*, 21, 76—94).—*Paramethylhydrotropaldehyde*,

prepared by the action of chromyl dichloride on cymene (*Abstr.*,

1884, 1342) and purified by combination with sodium hydrogen sulphite, is a liquid which boils at 233—234° and, according to the author, does not crystallise even after several months exposure to the air. The *aldoxime*, $C_6H_4Me \cdot CHMe \cdot CH:NOH$, is a heavy, colourless, uncrystallisable liquid insoluble in water.

Paramethylhydratropnitrile, $C_6H_4Me \cdot CHMe \cdot CN$, is readily obtained by the action of acetic anhydride on the aldoxime. It is a light, colourless liquid with a pleasant odour; it boils at 216.5—247.5° and is insoluble in water.

Paramethylhydratropic acid, prepared by Miller and Röhde (Abstr., 1890, 978) by the direct oxidation of the aldehyde, may also be obtained by boiling the preceding compound with aqueous potash. It melts at 40—41°, boils at about 280°, and yields a barium salt very soluble in water.

α-Methylhomoterephthalic acid, $COOH \cdot C_6H_4 \cdot CHMe \cdot COOH$, is formed, together with terephthalic acid, when paramethylhydratropic acid is oxidised in alkaline solution with potassium permanganate. When pure, it crystallises in colourless, silvery plates, melts at 222—223°, dissolves sparingly in water and more freely in alcohol, but is insoluble in benzene and light petroleum. The *barium* salt is very soluble in water; the *lead* salt is almost insoluble; the *methyl* derivative, $C_{10}H_8O_4Me$, is a liquid insoluble in water and has a pleasant odour resembling methyl paratoluato. The *amide*,

crystallises in brilliant plates, melts at 227—229°, dissolves readily in boiling water and alcohol, but is sparingly soluble in the cold.

Paramethylhydratropyl alcohol, $C_6H_4Me \cdot CHMe \cdot CH_2 \cdot OH$ [1 : 4], is obtained by reducing a dilute alcoholic solution of the aldehyde with sodium amalgam. It is a light liquid with a pleasant odour, boiling at 239° and very sparingly soluble in water. The *acetate* is a colourless liquid with a fruity odour, which boils at 242—244° and is insoluble in water. The *chloride*, $C_6H_4Me \cdot CHMe \cdot CH_2 \cdot Cl$, boils at 225° with partial decomposition, and is also insoluble in water.

β-Paratolylpropylene, $C_6H_4Me \cdot CMe \cdot CH_2$, prepared by boiling the preceding compound with alcoholic potash, is a light, colourless, aromatic liquid which boils at 198—200° and is insoluble in water. It yields a liquid uncrystallisable additive compound with bromine, but, unlike *α*-paratolylpropylene, $C_6H_4Me \cdot CH:CHMe$ (Abstr., 1885, 654 and 772), it does not yield a solid polymeride on contact with calcium chloride.

The product of the action of chromyl chloride on cymene contains, besides paramethylhydratropaldehyde, a mixture of substances which do not combine with sodium hydrogen sulphite, and from which by repeated crystallisation, a compound identical with paratolylmethylketone, $C_6H_4Me \cdot COMe$ (Abstr., 1882, 970), may be isolated. The *metanitro-derivative* of this ketone [$COMe : NO_2 : Me = 1 : 3 : 4$], obtained by dissolving it in strongly cooled nitric acid (sp. gr. = 1.51), crystallises in long, yellow needles when pure, melts at 61°, and dissolves freely in alcohol. It combines with phenylhydrazine, and the product crystallises from alcohol in garnet-red prisms having a

composition corresponding with the formula $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{CMe}\cdot\text{N}_2\cdot\text{HPh}$. On oxidation with nitric acid, the nitroketone yields metanitropropion-toluic acid.

Synthesis of Parapropyltoluene and Parisopropyltoluene.

By A. TOLL (*Ber.*, 24, 1649—1653).—The author has repeated some of Widman's work on parapropyltoluene (this vol., p. 686) in the hope of reconciling the differences between his results and the earlier ones of Jacobsen. Parapropyltoluene from parabromotoluene and propyl bromide yields two barium salts; the yield of hydrocarbon is 32 per cent. Widman's conclusions are thus confirmed.

Parapropyltoluene from parabromotoluene and propyl iodide is identical with the preceding compound, and boils at $183\text{--}184^\circ$, instead of $175\text{--}176^\circ$ as stated by Jacobsen; the yield is nearly 8 per cent. The purification of the hydrocarbon is a matter of extreme difficulty, and this probably accounts for Jacobsen's error in regard to the barium sulphinate.

Parisopropyltoluene from parabromisopropylbenzene and methyl iodide agrees in its properties with Widman's description.

J. B. T.

Paradiisopropylbenzene. By M. FILETTI (*Gazzetta*, 21, 22—28).—*Paradiisopropylbenzene* is best prepared by the action of metallic sodium on a mixture of parabromopropylbenzene and propyl bromide in ethereal solution in a manner analogous to that employed for the preparation of propylisopropylbenzene (see next abstract). The yield is 60 per cent. It boils at $220\text{--}221^\circ$ (mercury column in the vapour) under a pressure of 745 mm. By oxidising paradiisopropylbenzene with dilute nitric acid, Körner (*Abstr.*, 1883, 321) found that paradiisopropylbenzoic acid is formed. In addition to this acid, the author has isolated from the products of oxidation terephthalic acid, an azotised compound which melts at 172° and crystallises from alcohol in slender, yellowish needles, and a small quantity of a substance melting at 79° .

Dinitrodibromoparadiisopropylbenzene crystallises from light petroleum in colourless or pale-yellowish, oblique prisms, melts at 145° , and dissolves freely in benzene, chloroform, and carbon bisulphide, moderately in ether, and sparingly in alcohol.

α -Diparapropylbenzenesulphonic acid was the only sulphonic acid isolated by Körner (*loc. cit.*) from diparapropylbenzene; the barium salt appears to contain 1 mol. H_2O ; the magnesium salt ($\text{C}_{12}\text{H}_{17}\text{SO}_3$) $\cdot\text{Mg}\cdot 7\text{H}_2\text{O}$, crystallises in long plates or tabular prisms, and dissolves readily in boiling water; the zinc salt ($\text{C}_{12}\text{H}_{17}\text{SO}_3$) $\cdot\text{Zn}\cdot 8\text{H}_2\text{O}$, resembles the magnesium salt. The amide already prepared by Remsen and Keiser (*Abstr.*, 1884, 457) crystallises from carbon bisulphide in brilliant, well-defined rhombohedra.

β -Diparapropylbenzenesulphonic acid.—Small quantities of this acid are obtained in the preparation of the α -acid, and may be separated from it by taking advantage of the greater solubility of the β -lead salt. The amide crystallises from carbon bisulphide in orthorhombic, nacreous plates, melts at $106\text{--}107^\circ$, dissolves readily in alcohol, ether, &c., but not at all in water.

The corresponding sulphonic salts of dipropylbenzene and of propyl-isopropylbenzene exhibit very marked analogies to each other and are probably isomeric.

S. B. A. A.

Parapropylisopropylbenzene. By M. FILELLI (*Gazzetta*, 21, 4—22).—Paterno and Spica (this Journal, 1877, i, 77; Abstr, 1878, 296) first prepared isopropylpropylbenzene by the action of zinc ethyl on cumyl chloride. It is, however, more readily obtained in quantity by gently warming a mixture of dry ether (50 grams), metallic sodium (9 grams), parabromocumene (25 grams), and propyl bromide (31 grams). The reaction is sluggish at first, but soon becomes violent, and must be moderated by cooling with ice-cold water if necessary; it is completed in a few hours. The mass is then heated on the water-bath for some time, allowed to cool, sodium (3 grams) and propyl bromide (8 grams) added, the whole heated in a reflux apparatus for a couple of hours and fractionated. The yield is 59 per cent. The purified product boils at 213.5 to 215.5 (mercury column in the vapour) at a pressure of 74.5 mm. On oxidising parapropylisopropylbenzene with dilute nitric acid, the products consist of parapropylbenzoic acid crystallising in white, flattened needles melting at 139.5—140°, and impure terephthalic acid yielding on purification the characteristic methyl ether melting at 1.39—1.40°; but homoterephthalic acid does not appear to be formed, as stated by Paterno and Spica.

Mononitropropylisopropylbenzene, $C_{12}H_{17}NO_2$.—A yellow, oily compound of the above composition, rather heavier than water and decomposed on distillation, is obtained by treating the hydrocarbon with nitric acid (sp. gr. = 1.48), the whole being well cooled. The product is, however, a mixture of two isomeric compounds, as on reduction with ammonium sulphide, two *amido-derivatives* are obtained; one of these boils at 260—265°, and yields an acetyl derivative crystallising in slender needles and melting at 70—71°; the other is formed in less quantity, boils between 240° and 260°, and yields an acetyl derivative which crystallises in micaceous plates and melts at 87—88°. The *dinitro-derivative*, $C_{12}H_{15}(NO_2)_2$, is a yellow, oily compound heavier than water, and decomposes on distillation. The *monobromo-derivative*, $C_{12}H_{17}Br$, is a heavy, colourless liquid which boils at 265° (mercury column in the vapour) at a pressure of 738.6 mm. It probably has the constitution $C_6H_4BrPr^aPr^b$ [$Pr^a : Pr^b = 1 : 2 : 5$], since one of its products of oxidation is metabromocumic acid. On oxidising the bromo-derivative with dilute nitric acid, the products consist of ortho- and meta-parapropylbenzoic acids. On prolonging the oxidation for 25 hours, these acids are partially converted into metabromocumic acid.

Orthobromoparapropylbenzoic acid, $C_6H_4BrPrCOOH$, crystallises when pure from light petroleum in long needles melting at 130—130.5°; on reduction with sodium, it yields parapropylbenzoic acid. The *metabromo-acid* crystallises from dilute alcohol in minute rhomboidal plates, but separates in an oily form from concentrated solutions. It melts at 108—109° and dissolves in all ordinary solvents except water. On reduction with sodium amalgam, parapropyl-

benzoic acid is formed together with a small quantity of a product melting at 291—292°.

Dibromopropylisopropylbenzene, $C_{12}H_{16}Br_2$, obtained by brominating the hydrocarbon in presence of iodine, is a heavy, colourless liquid which decomposes on distillation, and does not solidify in a mixture of ice and salt. *Dinitrodibromopropylisopropylbenzene*, $C_{12}H_{14}Br_2(NO_2)_2$, crystallises from light petroleum in tufts of slender, colourless or yellowish needles, melts at 124—125°, and dissolves freely in benzene, chloroform, carbon bisulphide, ether, and alcohol.

α -Propylisopropylbenzenesulphonic Acid.—On sulphonating propylisopropylbenzene, a mixture of the α - and β -sulphonic acids is obtained and is separated into its constituents by fractionally dissolving the mixed magnesium salts in boiling water. The α -acid is a white, crystalline, deliquescent compound which melts at 74° and dissolves in alcohol, ether, and benzene. The *sodium salt*, $(C_{12}H_{17}SO_3Na)_2 \cdot 4H_2O$, crystallises in large plates very soluble in water; the *lead salt*, $(C_{12}H_{17}SO_3)_2Pb \cdot H_2O$, crystallises from boiling water in tufts of needles or in nodules; the *barium salt*, $(C_{12}H_{17}SO_3)_2Ba \cdot H_2O$, forms thin needles; the *magnesium salt*, $(C_{12}H_{17}SO_3)_2Mg \cdot 7H_2O$, crystallises from an aqueous solution in long, nacreous plates or tabular prisms, dissolves readily in boiling water but only very sparingly in the cold; the *zinc salt*, $(C_{12}H_{17}SO_3)_2Zn \cdot 8H_2O$, crystallises in elongated plates. The *acid chloride*, obtained by the action of phosphoric chloride on the dry sodium salt, is a yellowish liquid. The *amide*, $C_{12}H_{17}SO_2NH_2$, obtained by the action of gaseous ammonia on an ethereal solution of the chloride, crystallises from light petroleum in needles, melts at first at 93—94°, but after melting and resolidifying, the melting point falls to 79—80°. It dissolves readily in alcohol, ether, chloroform, and benzene, but is insoluble in cold water. The *anilide*, $C_{12}H_{17}SO_2NHPh$, forms nodular masses, melts at 107—109°, and dissolves in alcohol, chloroform, carbon bisulphide, and benzene, but not in water.

β -Propylisopropylbenzenesulphonic Acid.—The *magnesium salt*, $(C_{12}H_{17}SO_3)_2Mg \cdot 6H_2O$, forms crystalline tufts and is readily soluble in cold water. The *amide* crystallises from carbon bisulphide in nacreous plates, melts at 100—101°, and is freely soluble in alcohol, ether, &c., but is insoluble in cold water. S. B. A. A.

Reactions of Sodium Alkylloxides and Phenoxides with Tri.bromodinitrobenzene and Tribromotrinrobenzene. By O. L. JACKSON and W. H. WARREN (*Amer. Chem. J.*, 13, 164—193; compare *Abstr.* 1889, 781; 1890, 377, 497, 772, 982, 983).—These reactions take place in four different ways:—(1.) A simple replacement of each atom of bromine by the radicle of the alkylxide or phenoxide. (2.) The replacement of two atoms of bromine by two of the radicle of the alkylxide or phenoxide, the third atom of bromine remaining unaltered. (3.) The replacement of two atoms of bromine by the radicle and the third by hydrogen. (4.) The replacement of one, two, or, perhaps, three of the nitro-groups by the radicle, the three bromine atoms remaining unaffected.

The authors regard their data as affording insufficient ground for

theoretical explanation; they point out that in case (4) the reaction is contrary to Laubenheimer's rule that a nitro-group is removed only when it is in the ortho-position to another nitro-group (*Ber.*, 9, 766, 1828; this *Journal*, 1876, ii, 294; 1877, i, 594).

Diethylbromodinitroresorcinol, $C_6H_3Br(OEt)_2(NO_2)_2$, is the product of the action of sodium ethoxide on tribromodinitrobenzene (m. p. 192°) in the cold; full details of its preparation are given. It crystallises from alcohol in rather thick, flattened, yellowish-white needles, and from benzene in long, slender, efflorescent prisms; it melts at 184° , and is slightly soluble in alcohol, methyl alcohol, hot water, ether, and glacial acetic acid, freely soluble in acetone, less freely in benzene and chloroform, nearly insoluble in carbon bisulphide, and quite so in light petroleum. Hot and cold acids are without action on it. During its preparation a semi-liquid bye-product was obtained, but this proved of uncertain composition.

Diethyldinitroresorcinol, $C_6H_3(OEt)_2(NO_2)_3$, isomeric with Aronheim's compound (m. p. 75° , *Abstr.*, 1879, 465) is formed when sodium ethoxide, dissolved in benzene, is heated with tribromodinitrobenzene (m. p. 192°) in alcohol. It crystallises in long, slender needles or flattened prisms with a sharp point, in some cases forming characteristic curling, hair-like crystals; it melts at 133° , dissolves best in chloroform, glacial acetic acid, and acetone, and forms a yellow solution in cold, strong sulphuric acid, but a colourless one in hot, strong nitric acid; hydrochloric acid has no action on it. It is noteworthy that this reaction is another example of the replacement of bromine by hydrogen in preference to its replacement by a radical combined with sodium (compare *Abstr.*, 1890, 497).

Diethylbromodinitroresorcinol may be converted into *diethyldinitroresorcinol* by heating it with sodium ethoxide in alcohol at the boiling point, showing that the replacement of the third bromine atom by hydrogen is the principal action of the hot sodium ethoxide.

Dimethylbromodinitroresorcinol was obtained, although not quite pure, when a solution of tribromodinitrobenzene in benzene was heated with a solution of sodium methoxide in methyl alcohol; it crystallises in prisms which, when deposited by cooling from glacial acetic acid, are terminated by a single rhombic plane at an acute angle to the sides of the prism, which are so short that the crystal looks like a rhombohedron; it melts at $237-238^\circ$, and is only slightly soluble in the common solvents. The *anilide*,

forms bright yellow needles or very slender prisms, melts at 196° , and dissolves best in alcohol.

Dimethyldinitroresorcinol, $C_6H_3(OMe)_2(NO_2)_3$, is formed together with the bromo-derivative in the last-mentioned reaction whether the mixture is hot or cold. It crystallises (with 1 mol. alcohol) in bunches of white needles or slender prisms, which turn purplish-brown in air; also without alcohol in short, thick, broad, monoclinic (?), lemon-yellow prisms which are not altered by air; the former crystals are converted into the latter by recrystallisation from chloroform. It melts at 167° , but at 165.5° when it contains alcohol. It dissolves

best in boiling alcohol; strong acids have little action on it. It is isomeric with Hönig's compound, which melts at 67° (Abstr., 1878, 727).

Diphenylbromodinitroresorcinol, $C_6HBr(OPh)_2(NO_2)_2$, is obtained, together with an oily substance and a small quantity of another crystalline substance (m. p. 158°), when tribromodinitrobenzene (1 mol.), dissolved in a mixture of benzene and alcohol, is heated with sodium phenoxide (3 mols.) in a reflux apparatus for 12 hours; it forms woolly masses of irregularly radiating, white needles which turn pale-brown in air; it melts at 165°, and dissolves best in a mixture of alcohol and benzene; it is apparently not acted on by strong sulphuric acid or hydrochloric acid, but is dissolved by strong nitric acid and precipitated by dilution as a new nitro- (?) derivative melting above 200°. Attempts to replace the bromine atom by hydrogen, as was done with the alkyl derivatives, proved futile.

Diethyltribromonitroresorcinol, $NO_2C_6H_2Br_3(OEt)_2$, is obtained by the action of sodium ethoxide on tribromotrinitrobenzene (m. p. 285°) in alcohol, care being taken to avoid a rise of temperature; it crystallises in well-developed, white, flat prisms, usually with square ends, but sometimes terminated by two planes at an obtuse angle; it melts at 101°, and dissolves best in hot alcohol; the strong acids seem to have no action on it.

Tribromodinitrophenetyl, $C_6H_2Br_3(NO_2)_2OEt$, is formed if benzene as well as alcohol is used, and no care is taken to keep down the temperature, in the last mentioned reaction. This crystallises in white, well-formed, slender, nearly square prisms, melts at 147°, dissolves best in hot alcohol, and is not acted on by strong acids.

Dimethyltribromonitroresorcinol, $C_6H_2Br_3NO_2(OMe)_2$, obtained in the same manner as the diethyl compound, forms white, flattened prisms, melts at 126°, and is much less soluble in alcohol than the corresponding ethyl compound. Strong acids apparently have no action on it.

Triphenyltrinitrophenylglucinal, $C_6(NO_2)_3(OPh)_3$, is the product of the reaction of sodium phenoxide on tribromotrinitrobenzene in a mixture of alcohol and benzene at the temperature of the water-bath. It crystallises in long, very slender, white needles, felted together in woolly masses; it becomes brown in air, melts at 175°, and dissolves easily in acetone, chloroform, benzene, and glacial acetic acid, but slightly in other solvents. The strong acids have no apparent action on it. It is to be noted that the phenoxyl group is the most acid one which has been substituted for the three bromine atoms, the other groups which have been so substituted having been basic in character (compare Abstr., 1888, 1276; 1890, 247).

Neither sodium acetate, sodium picrate, nor sodium nitromethane has any but a slight action on tribromodinitrobenzene or tribromotrinitrobenzene.

It was previously shown (Abstr., 1890, 377, 485) that in the reaction between ethyl sodiomalonate and tribromodinitrobenzene the bromine atom replaced by hydrogen is between two nitro-groups, and experiments were made (Abstr., 1890, 983) which seemed to show that the ease with which the bromine is removed does not depend

only on this position. These experiments have now been confirmed, and it is conclusively proved that ethyl malonate has no action on tribromodinitrobenzene.

A. G. B.

Chloranil. By C. GRAEBE (*Annalen*, **263**, 16—31).—Chloranil (tetrachloroquinone) is best prepared by gradually adding potassium chlorate (250 grams) in coarse crystals to paraphenylenediamine hydrochloride (100 grams) suspended in water (250 c.c.) and hydrochloric acid (800 c.c.), or to the finely powdered base (60 grams) suspended in water (170—180 c.c.) and hydrochloric acid (920—950 c.c.). The addition of the chlorate lasts one day, and the temperature is maintained at 20—30°. On the following day, the mixture is slowly raised to the full temperature of the water-bath, and the heating is continued until all the chlorate is decomposed, when the crude chloranil is collected and washed. It appears to contain 25 per cent. of trichloroquinone, and when heated in a capillary tube filled with the substance and sealed at both ends, it usually melts at 220—240°; the yield is 115 grams. It is next heated on the water-bath for 1—2 hours with concentrated hydrochloric acid (350—400 c.c.), when a portion of the trichloroquinone is converted into tetrachloroquinol, and the remainder reacts with this, forming tetrachloroquinone and trichloroquinol. On oxidising the washed product with an acid solution of potassium dichromate, it is generally found to melt above 270°, and is then further purified by crystallisation from toluene. When quite pure, it melts at 290° (mercurial column entirely in the bath) to a clear, transparent liquid, whilst those specimens containing a slight quantity of impurity melt below this temperature, and darken considerably at their melting point.

Chloranilic acid is obtained when chloranil (10 grams) is moistened with alcohol and added to a solution of sodium hydroxide (9 grams) in water (200—220 c.c.) heated to 80°, or to a solution of potassium hydroxide (12 grams) in water (250 c.c.). After remaining 1—2 hours, common salt (20 grams) is added, and the precipitated sodium derivative is washed with a 10 per cent. solution of common salt until the filtrate is colourless; it is then redissolved in water, and the chloranilic acid precipitated with hydrochloric acid. The yield is 62 per cent. of the weight of the chloranil. The compound is conveniently prepared from the crude chloranil (m. p. above 270°); the moist product derived from 100 grams of paraphenylenediamine is treated with sodium hydroxide (100 grams) dissolved in water (2 litres); the yield is 46—50 grams. Chloranilic acid crystallises with 2 mols. H_2O , which it loses at 100°; 100 parts of water dissolve 0.19 part at 13.5°, and 1.41 parts at 99°; 1.77 parts of the potassium salt at 20°, and 9.25 parts at 98.6°; 1.06 parts of the sodium salt at 21°, and 6.19 parts at 99°.

When a mixture of trichloro- and tetrachloro quinone is suspended in water (10 parts), and sulphurous anhydride is passed through for 10 minutes, the trichloro-derivative is converted into the quinol, and goes into solution, whilst the tetrachloro-derivative is scarcely attacked; the latter is collected and washed with water and cold alcohol. Tetrachloroquinol is formed when the quinone (10 grams) is

heated for a short time on the water-bath with amorphous phosphorus (1 gram), water (15 c.c.), and 50 per cent. hydriodic acid (3—4 c.c.); it is filtered while hot, and the colourless mass dissolved in alcohol to free it from phosphorus. Hexachlorobenzene is obtained in accordance with the equation $C_6Cl_4O_2 + PCl_5 + PCl_3 = C_6Cl_6 + 2POCl_3$, when equal weights of chloranil, phosphorus pentachloride and trichloride are heated together in a sealed tube at 190—200° for four hours; as no gaseous products are formed, comparatively large quantities of material can be employed. When chloranil is heated with phosphorus pentachloride, with or without the addition of phosphorus oxychloride, hexachlorobenzene, a compound containing phosphorus, and probably the so-called hexachlorophenol are formed, and on treating the mixture with water, pentachlorophenol (m. p. 185—186°) may be separated.

A. R. L.

Bromanil. By C. GRAEBE and L. WELTNER (*Annalen*, 263, 31—38).—Bromanil (tetrabromoquinone) is prepared by dissolving paraphenylenediamine (10 grams) in glacial acetic acid (40 c.c.), and carefully adding bromine (40 c.c.) by degrees to the solution kept cold by water. A solid mass soon forms, and it is advisable to shake from time to time; on the following day the product is heated on the water-bath until the evolution of hydrogen bromide and bromine slackens; water is then added, the heating continued for a short time, and the dark-brown substance collected, washed, and dried. It is then heated on the water-bath with nitric acid (sp. gr. 1·35, 40 c.c.) for some hours, and evaporated to dryness, after which it is again heated with fuming nitric acid (40 c.c.) for 2—3 hours, poured into water, and the yellow compound collected and washed; the yield is 30—32 grams, and the melting point of the product ranges from 280° to 285°. It is purified by crystallisation from toluene, and when quite pure melts at 300° (mercurial column entirely in the bath). When hexabromobenzene (2 grams) is heated with a mixture of nitric acid (sp. gr. 1·5, 25 c.c.) and sulphuric acid (15 c.c.) in a reflux apparatus for 15 hours, only a trace of bromanil is produced; whereas hexachlorobenzene, under similar conditions, yields half its weight of chloranil (compare Istrati, *Abstr.*, 1890, 882).

Bromanilic acid is conveniently prepared from the crude moist bromanil. The product from 10 grams of paraphenylenediamine is dissolved in a solution of sodium hydroxide (20 grams) in water (450—500 c.c.), heated to 80°, and, after one or two hours, common salt (40—50 grams) is added, and the remainder of the operation conducted as with chloranilic acid (preceding abstract). When crystallised bromanil is used, 10 grams are moistened with alcohol and added to a solution of sodium hydroxide (6·2—6·5 grams) or potassium hydroxide (7·5 grams) in water (150 c.c.); the yield of bromanilic acid is 5·4 grams. The compound loses its water of crystallisation slowly at the ordinary temperature, but more quickly at 100°; 100 parts of water dissolve 0·145 part at 15·5°, and 2·25 parts at 99°; 5·06 parts of the potassium salt at 14°; 2·95 parts of the sodium salt at 21°.

When bromanil (1.5 grams) is heated at 190—200° for four hours with phosphorus pentachloride (3.8 grams) and phosphorus oxychloride (3—4 grams), hexachlorobenzene is obtained. It is quantitatively converted into hexabromobenzene when heated with four times its weight of a mixture of equal weights of phosphorus pentabromide and tribromide at 260—280° for four hours.

When dissolved in concentrated solutions of potassium sulphite, bromanil yields the potassium salt of thiocronic acid, whilst, when 1 gram is gently heated with a solution of potassium hydrogen sulphite (2.8 grams) in water (40 c.c.) until it dissolves, the potassium salt of *dibromoquinoldisulphonic acid*, $C_6Br_2(OH)(SO_3K)_2 + 2H_2O$, separates in colourless needles on concentrating the solution; it is easily soluble in hot water and in alcohol, and its solutions are coloured violet on addition of ferric chloride.

The *barium salt* is precipitated in colourless needles containing 1 mol. H_2O on adding barium chloride to a solution of the potassium salt; it is very slightly soluble in cold, but more so in hot, water.

A. R. L.

Note by Abstractor.—The abstractor wishes to point out that he was the first to determine the melting point of bromanil (Trans., 1887, 148), but his value (288°) is too low, probably on account of the presence of a trace of impurity. He has redetermined the melting point of bromanil, and can confirm Graebe and Weltner's results, and also the melting point given by Graebe for chloranil (preceding abstract).

Phthaleins. By R. MEYER (*Ber.*, 24, 1412—1418).— β -Naphthol combines with phthalic chloride to form *naphtholphthalein anhydride*, $CO < \begin{smallmatrix} C_6H_4 \\ -O- \end{smallmatrix} > C < \begin{smallmatrix} C_{10}H_6 \\ C_{10}H_8 \end{smallmatrix} > O + \frac{1}{2}H_2O$; after treatment with acetic anhydride; this crystallises from alcohol in colourless, rhombic plates or needles, and melts at 115—117°. The compound dissolves in concentrated sulphuric acid, and the solution exhibits an intense roddish-yellow fluorescence. This is in accordance with the formula

previously advanced by the author for fluorescein.

Attempts to eliminate the amido-groups by the action of nitrous acid on the compound $C_{20}H_{15}N_3O_5$, which is formed by the interaction of ammonia and fluorescein at high temperatures, and has been already described, led to no definite result.

An investigation of residues obtained in the manufacture of phenolphthalein showed that they contained considerable quantities of phenolphthalein anhydride; this was deposited in crystals melting at 130—132°, they were, however, not homogeneous, and all the components have not yet been isolated.

Phenolphthalein anhydride melts at 180°, not at 173—175° as stated by Baeyer, and sublimes at much lower temperatures; it is readily soluble in alcoholic potash, and is not precipitated on dilution

with water; after elimination of the alcohol, however, part is deposited immediately, and the remainder on addition of hydrochloric acid; this behaviour points to the formation of an unstable hydroxy-acid of the formula $\text{COOH} \cdot \text{C}_6\text{H}_4 \cdot \text{C}(\text{OH}) < \text{C}_{60}\text{H}_{10} > \text{O}$. J. B. T.

Compounds of Metallic Sulphites with Aniline. By G. DENIGÈS (*Compt. rend.*, 112, 802—805).—Normal metallic sulphites, with the exception of zinc sulphite, do not form compounds with aniline, but the hydrogen sulphites readily combine to form anhydrous double salts of the general formula $\text{M}''\text{SO}_3 \cdot \text{H}_2\text{SO}_3 \cdot 2\text{PhNH}_2$. The mercuric salt is an exception, and has the composition

They are obtained by adding sodium hydrogen sulphite to an acid solution of a sulphate or nitrate of the metal previously mixed with aniline; they form distinct hexagonal lamellæ, very slightly soluble in water and other neutral solvents. Aldehyde and acetone dissolve small quantities, but some chemical changes take place at the same time.

The cuprous compound is yellowish-white, and does not alter when exposed to air and light; it dissolves in ammonia and in hydrochloric acid. The cadmium and zinc compounds are white; the manganese salt has a pink tint, and the cobalt salt a beautiful rose colour; the ferrous salt is yellow, and the nickel salt greenish-yellow; the mercuric salt is white. C. H. B.

Some Compounds Formed by Mercuric Chloride. By G. ANDRÉ (*Compt. rend.*, 112, 995—998).—A number of compounds are formed on the same type as the substance $\text{HgCl}_2 \cdot 2\text{NH}_3$, described in a former paper (*Abstr.*, 1889, 570 and 827). A white compound of aniline and mercuric chloride, $\text{NH}_2\text{Ph} \cdot \text{HgCl}_2$, yields a little water on heating in a test-tube; hence it probably contains a little mercuric oxide, which would explain the excess of mercury obtained on analysis. A similar additive compound is obtained with benzylamine, $\text{CH}_2\text{Ph} \cdot \text{NH}_2 \cdot \text{HgCl}_2$. Similar substances, in which HgCl_2 is replaced by ZnCl_2 , are represented by the formulae $4\text{ZnCl}_2 \cdot \text{HgCl}_2 \cdot 10\text{NH}_3 + 2\text{H}_2\text{O}$ and $2\text{ZnCl}_2 \cdot \text{HgCl}_2 \cdot 6\text{NH}_3 + \frac{1}{2}\text{H}_2\text{O}$. These salts, when heated in a tube, give off water, melt, and finally yield a white sublimate together with free ammonia; they dissolve easily in hydrochloric acid, but are decomposed by boiling water.

Several new substitution compounds have also been prepared. The compound $5\text{NHPh} \cdot \text{HgCl} + 2\text{HgCl}_2$ is analogous to the substance $\text{NH}_2 \cdot \text{HgCl} + \text{HgCl}_2$, obtained by Millon; it is very stable; when boiled with water or alcohol for several hours, it yields the salt $3\text{NHPh} \cdot \text{HgCl} + 2\text{HgCl}_2$.

The substitution compound, $\text{CH}_2\text{Ph} \cdot \text{NH} \cdot \text{HgCl}$, is insoluble in boiling water; the benzylamine addition compound is readily soluble. W. T.

Symmetrical Tri-substitution Derivatives of Benzene. By R. BADER (*Ber.*, 24, 1658—1655).—*Symmetrical dinitramine* is prepared by dissolving trinitrobenzene (15 grams) in absolute alcohol

(450 c.c.), and slowly adding to the boiling solution 90 c.c. of ammonium sulphide solution; after heating for $1\frac{1}{2}$ hours on the water-bath, the liquid is poured into ice-water; the product is deposited from hot water in yellow crystals, melts at 159° , and is readily soluble in ordinary media. Attempts to prepare the corresponding phenol by means of the diazo-reaction were unsuccessful.

Dinitrochlorobenzene [$\text{NO}_2 : \text{NO}_2 : \text{Cl} = 1 : 3 : 5$] is obtained from the preceding compound by means of Sandmeyer's reaction; it crystallises from alcohol or ether in colourless needles, melts at 53° , and is volatile with steam. On warming with very dilute alkalis, a blood-red colour is produced.

J. B. T.

Combination of Metallic Sulphites with Amines of the Benzene Series. By G. DENIGES (*Compt. rend.*, 112, 870—873).—Orthotoluidine, paratoluidine, and α -metaxylylidine yield with metallic hydrogen-sulphites compounds strictly analogous to those formed by aniline (preceding page), they are obtained in the same manner, have the same colours and the same form. No compound of nickel hydrogen sulphite with orthotoluidine could, however, be obtained, and zinc hydrogen sulphite behaves in an abnormal manner. The general formula is $\text{M}''\text{SO}_3 \cdot \text{H}_2\text{SO}_3 \cdot 2\text{NH}_2\text{R}$, but in the case of the mercuric compounds it is $\text{HgSO}_3 \cdot \text{H}_2\text{SO}_3 \cdot \text{NH}_2\text{R} + \text{H}_2\text{O}$.

C. H. B.

Nitro-derivatives of Dimethylorthanisidine. By E. GRIMMAUX and L. LEFÈVRE (*Compt. rend.*, 112, 727—730).—*Mononitrodimehylorthanisidine* [$\text{NMe}_2 : \text{NO}_2 : \text{OMe} = 1 : 4 : 6$] is obtained, together with a small quantity of a di- or tri-nitro-derivative, by adding 1 part of the base to 5 or 6 parts of nitric acid cooled in a freezing mixture, or, better, by dissolving 1 part of the base in 2 parts of sulphuric acid diluted with 10 parts of water, and adding gradually 3.2 parts of sodium nitrite dissolved in 60 parts of water. The product is purified by crystallisation from alcohol, and forms long, slender, lemon-yellow needles which melt at 99° ; it is very slightly soluble in cold alcohol, but dissolves readily in boiling alcohol. When reduced with zinc and hydrochloric acid, it yields a base that crystallises in slender, colourless needles melting at 83° , and rapidly becomes rose-coloured when exposed to air.

Trinitrodimehylorthanisidine is obtained by heating dimethylorthanisidine with ordinary nitric acid until nitrogen oxides begin to come off, and then precipitating immediately with water. It crystallises from boiling alcohol in groups of colourless, somewhat bulky prisms, melts at 135° , and is only slightly soluble in cold alcohol. Only two of the NO_2 groups are in the benzene nucleus, and when the compound is boiled with potash, alkaline vapours are evolved and dinitroguaiacol, melting at 121 — 123° , is obtained. This decomposition indicates the position of the radicals, namely

since von Romburgh has shown that only diortho-, or ortho- and para-derivatives of acids of the benzene series yield phenols when heated with potash.

If trinitrodimethylorthanisidine is boiled with 15 to 20 parts of ordinary nitric acid until nitrogen oxides are no longer evolved, it is converted into *trinitromonomethylorthanisidine*, which is the ultimate product of the action of nitric acid on dimethylorthanisidine. It is also obtained by the prolonged action of fuming nitric acid on dimethylorthanisidine at 0°. It crystallises from 8 parts of boiling alcohol in colourless or yellowish lamellæ, melts at 118–119°, and is only slightly soluble in ether or in cold alcohol, but dissolves readily in acetone. When trinitromonomethylorthanisidine is heated for two or three hours with a 10 per cent. solution of potash, alkaline vapours are evolved, and the calculated quantity of dinitroguaiacol is obtained (m. p. 121–122°). This decomposition shows that the nitro-derivative has the constitution $[\text{NMeNO}_2 : \text{NO}_2 : \text{NO}_2 : \text{OMe} = 1 : 2 : 4 : 6]$, and at the same time establishes the constitution of mononitrodimethylorthanisidine and dinitroguaiacol.

The results show that in the action of nitric acid on dimethylorthanisidine, it is the group NMe, that influences the position of the NO_2 groups, the latter taking up ortho- and para-positions, as in the case of dimethylaniline.

C. H. B.

1-4-6-Trimethylparaphenylenediamine. By E. BAMBERGER (*Ber.*, 24, 1645–1649).—The author has recently obtained a paramidotohydro- α -naphthaquinoline of the formula

the method of formation of this compound will be described later. Although a derivative of naphthaquinoline, its properties show it to be a benzeneparadiamine. For purposes of comparison, trimethylphenylenediamine $[\text{Me}_3 = 1 : 4 : 6; (\text{NH}_2)_3 = 2 : 5]$ was prepared from pseudocumidine $[\text{Me}_3 = 1 : 4 : 6; \text{NH}_2 = 2]$ by means of diazobenzenesulphonic acid; the resulting dye is deposited in reddish-brown, lustrous crystals, sparingly soluble in water. On reduction with stannous chloride, the diamine is obtained, crystallising from a mixture of ether and light petroleum in colourless, highly lustrous, flat needles melting at 78°. The diamine gives a dark, orange-red colour with hydrochloric acid, hydrogen sulphide, and ferric chloride (thionine); a deep-green, indamine colour with acetic acid, aniline hydrochloride, and potassium dichromate; on boiling, the solution changes to greenish-brown, then to reddish-brown, and smells of quinone. The base gives with metatolylenediamine the tolylene-blue and tolylene-red reactions; whilst with alkaline α -naphthol solution, a blue indophenol derivative is formed.

J. B. T.

Alkyl Derivatives of Hydroxylamine. By R. BEHREND and E. KÖNIG (*Annalen*, 263, 175–223 and 339–358).—At the present

time there are three hypotheses regarding the structure of the stereochemically isomeric alkyl derivatives of hydroxylamine, namely, that of Hantzsch and Werner, that of Behrend, and that of Auwers and Meyer; they all account for the existence of two structurally identical but stereochemically isomeric forms, which bear to one another the same relationship as that existing between the two optically active modifications of tartaric acid. According to all three hypotheses, β -benzylhydroxylamine, for example, should exist in two enantiomorphous forms, which may be expressed by the symbols $C_7H_7\begin{smallmatrix} N \\ \diagup \\ H \end{smallmatrix}OH$

and $H\begin{smallmatrix} N \\ \diagdown \\ C_7H_7 \end{smallmatrix}OH$ respectively. Now, although this compound has been prepared by three totally different methods, the three preparations are absolutely identical; it must be assumed then, either that they all have the same configuration, expressed by one of the above symbols, or that they are all composed of equal parts of the two isomerides. If the latter assumption is true, it is probable that the two forms could be separated by suitable methods; the authors' attempts to effect a separation by combining the base with optically active acids were, however, unsuccessful, as were also the analogous experiments carried out by Kraft (this vol., p. 51). Experiments were also made to test the validity of the first assumption, namely, that the known β -benzylhydroxylamine is one only of the theoretically possible forms. For this purpose, β -benzylhydroxylamine was treated with nitrobenzyl chloride, and thus converted into β -benzylnitrobenzylhydroxylamine; β -nitrobenzylhydroxylamine, prepared by methods exactly similar to those employed in the preparation of the β -benzylhydroxylamine, was treated with benzyl chloride, and in this way also β -nitrobenzylbenzylhydroxylamine obtained. According to the hypothesis, the two compounds should be enantiomorphous, but it was found that they are identical in physical properties, and that both give the same products in the same proportion on oxidation; it follows, therefore, that assuming that no intramolecular change has occurred in any of the reactions, and that a second modification of benzylnitrobenzylhydroxylamine has not escaped observation, that the two supposed enantiomorphous forms of benzyl- and of benzylnitrobenzylhydroxylamine are identical, or, which is less probable, that their separation has not yet been accomplished.

β -Benzylhydroxylamine tartrate, $(C_7H_7NO)_2 \cdot C_4H_6O_6$, is precipitated in needles when an alcoholic solution of the base (1 mol.) is treated with an alcoholic solution of tartaric acid (1 mol.); on evaporating the mother liquors, a second crop of crystals of the normal salt is obtained, and on further evaporation, the acid tartrate, $C_7H_7NO \cdot C_4H_6O_6$, is deposited. The latter forms colourless, rhombic crystals, $a : b : c = 0.3561 : 1 : 0.2475$, is readily soluble in alcohol, and melts at about 117° ; the former is sparingly soluble in alcohol, but more readily in water, and melts at $125-130^\circ$.

β -Benzylhydroxylamine mandelate crystallises from hot alcohol in colourless needles, melts at $115-118^\circ$, and is rather sparingly soluble in cold alcohol and water.

β -Diparunitrobenzylhydroxylamine, $(C_7H_7NO_2)_2 \cdot N \cdot OH$, is obtained

when hydroxylamine hydrochloride is boiled with paranitrobenzyl chloride and sodium carbonate in alcoholic solution; it separates from boiling acetone in large, yellow, asymmetric crystals, melts at 157—158°, and is readily soluble in hot alcohol, glacial acetic acid, and acetone, but very sparingly in cold alcohol, ether, benzene, and chloroform, and almost insoluble in light petroleum and carbon bisulphide. The *hydrochloride*, $C_{11}H_{13}N_3O_5 \cdot HCl$, is crystalline, and is decomposed by water.

Paranitrobenzylisoparanitrobenzaldoxime,

prepared by oxidising the preceding compound with potassium dichromate and acetic acid, crystallises in light-yellow, microscopic needles, and is sparingly soluble or insoluble in most ordinary solvents, except hot acetic acid and boiling nitrobenzene; it melts at 227—228° with decomposition, but even when kept at 200° for some time, it gradually sinters together and turns brown. When boiled with 20 per cent. hydrochloric acid, it is decomposed into paranitrobenzaldehyde and β -nitrobenzylhydroxylamine (m. p. 120—125°), identical with the compound obtained by Behrend and Leuchs from α -benzyl- β -nitrobenzylhydroxylamine in like manner.

β -Paranitrobenzylbenzylhydroxylamine, prepared by treating the β -paranitrobenzylhydroxylamine obtained by the decomposition of α -benzyl- β -nitrobenzylhydroxylamine with benzyl chloride, is identical in chemical and physical properties with the compound formed by treating the β -nitrobenzylhydroxylamine, obtained from paranitrobenzylisoparanitrobenzaldoxime with benzyl chloride, and also with that produced by the action of nitrobenzyl chloride on β -benzylhydroxylamine.

Nitrobenzylisobenzaldoxime exists in two modifications, both of which are formed when benzaldehyde is digested with β -nitrobenzylhydroxylamine hydrochloride and sodium carbonate in alcoholic solution; the original product melts at 104—106°, but when recrystallised from hot alcohol it yields a mixture of slender needles melting at 113.5—114.5°, and hexagonal plates melting at 105—106°. Those two forms can be easily converted one into the other by recrystallisation from various solvents, and when either modification is heated at its melting point it is converted into a mixture of the two which melts at 107—112°. When equal quantities of nitrobenzylisobenzaldoxime and benzylisobenzaldoxime are dissolved in hot alcohol and the solution concentrated, a mixture of the two compounds is deposited in plates melting at 93—94°; this mixture is identical with that obtained by the oxidation of paranitrobenzylbenzylhydroxylamine (Abstr., 1890, 1412).

Nitroso- β -benzylhydroxylamine, $C_7H_9N_2O_2$, is obtained when β -benzylhydroxylamine hydrochloride is treated with sodium nitrite in aqueous solution at 0°; it crystallises from a mixture of ether and light petroleum in flat, transparent prisms, melts at 77—78°, and is readily soluble in alcohol, ether, soda, and sodium carbonate, but more sparingly in light petroleum and very sparingly in water; it gives the

nitroso-reaction. The *benzyl* derivative, $C_{14}H_{14}N_2O_3$, is formed, together with an oil of unknown composition, when the sodium derivative of nitrosobenzylhydroxylamine is boiled with benzyl chloride in alcoholic solution; it crystallises from a mixture of ether and light petroleum in lustrous plates, melts at $58-59^\circ$, and gives Liebermann's reaction. When α -dibenzylhydroxylamine hydrochloride is treated with sodium nitrite, it is converted into a compound which crystallises in needles and melts at $73-74^\circ$.

Impure nitroso- β -benzylhydroxylamine is unstable, and decomposes on keeping with liberation of red fumes, yielding dinitrosylbenzyl (previously described as dinitrosotoluene, Abstr., 1890, 1122) and an oil having a peculiar, penetrating odour; when treated with glacial acetic acid, the nitroso-compound is decomposed into dinitrosylbenzyl and an oil, which consists principally of benzyl acetate and benzyl nitrite.

Nitroso- β -paranitrobenzylhydroxylamine, $NO_2 \cdot C_6H_4 \cdot N(NO) \cdot OH$, is precipitated in crystals when a freshly-prepared, well-cooled solution of β -paranitrobenzylhydroxylamine hydrochloride is treated with a slight excess of the theoretical quantity of sodium nitrite; it sinters together at 125° , melts at $130-131^\circ$, and is readily soluble in alcohol, acetone, sodium carbonate, and glacial acetic acid, but more sparingly in chloroform and ether; it gives Liebermann's reaction. When dissolved in glacial acetic acid and treated with a trace of fuming nitric acid, it is decomposed, with evolution of brown fumes, yielding dinitrosylparanitrobenzyl, paranitrobenzyl acetate (m. p. $76-77^\circ$), and a compound melting at about 67° , which seems to be paranitrobenzyl nitrite.

Dinitrosylparanitrobenzyl, $C_{14}H_{12}N_4O_6$, is a colourless, semi-crystalline powder, melts at $135-140^\circ$, and is almost insoluble in the ordinary solvents; when treated with phenol and sulphuric acid, it gives a brownish-violet coloration, which changes to brownish-yellow on the addition of alkalis, and then to an olive-brown on diluting with water.

β -Paranitrobenzaldoxime, $C_7H_6N_2O_3$, is obtained, together with an equal quantity of the α -compound (m. p. $128-129^\circ$) when dinitrosylparanitrobenzyl is warmed with dilute soda (or boiled for a long time with alcohol); on saturating the alkaline solution with carbonic anhydride, the two isomerides are precipitated in crystals, and can be separated by recrystallisation from hot water, in which the β -compound is the more sparingly soluble. The β -oxime crystallises from hot water in thin, iridescent, rectangular plates, sinters together at about 170° , melts at $173-175^\circ$, and is readily soluble in glacial acetic acid, chloroform, and hot alcohol, but more sparingly in ether; when heated at its melting point, or when treated with hydrogen chloride in ethereal solution, it is almost completely converted into the α -oxime, and it is readily decomposed by warm mineral acids yielding nitrobenzaldehyde and hydroxylamine. When the acetyl derivative of the β -oxime is treated with sodium carbonate, it is converted into paranitrobenzonitrile, whereas the acetyl derivative of the α -oxime is simply reconverted into the oxime (m. p. $128-129^\circ$) under the same conditions.

Benzylparanitrobenzaldoxime, $NO_2 \cdot C_6H_4 \cdot CH:N \cdot OC_6H_5$, is formed

when the α -oxime is treated with sodium ethoxide and benzyl chloride in cold alcoholic solution; it crystallises from alcohol in lustrous, yellowish needles, melts at $117.5-118.5^\circ$, and differs slightly in crystalline form from the isomeride (m. p. $117-118^\circ$) previously described (Abstr., 1890, 1412), than which it is rather more sparingly soluble in hot alcohol; it is not acted on by boiling dilute acids, whereas the isomeride is quickly decomposed into nitrobenzaldehyde and β -benzylhydroxylamine.

When β -paranitrobenzaldoxime is treated with sodium chloride and benzyl chloride in alcoholic solution at the ordinary temperature, it yields benzylisoparanitrobenzaldoxime and paranitrobenzylisobenzaldoxime.

Dinitrosobenzyl (*loc. cit.*) is completely decomposed by warm soda, yielding approximately equal quantities of α - and β -benzaldoxime.

F. S. K.

Azo-derivatives. By H. LIMPRICHT (*Annalen*, 263, 224-245).—Azobenzenesalicylic acid, $\text{N}_2\text{Ph}\cdot\text{C}_6\text{H}_3(\text{OH})\cdot\text{COOH}$, prepared by treating salicylic acid with diazobenzene chloride in alkaline solution (compare Stebbins, Abstr., 1880, 715), crystallises from benzene in yellow needles, melts at 218° , decomposes at a slightly higher temperature, and is readily soluble in alcohol, ether, and acetone, but more sparingly in boiling chloroform and carbon bisulphide, and almost insoluble in water. The sodium salt, $\text{C}_{13}\text{H}_9\text{N}_2\text{O}_3\text{Na}$, crystallises in small, yellow plates; the barium salt, $(\text{C}_{13}\text{H}_9\text{N}_2\text{O}_3)_2\text{Ba}$, crystallises in golden needles, and is very sparingly soluble in cold water. The acid is quickly decomposed by stannous chloride into aniline and paramidosalicylic acid; the last-named compound is also formed when the azo-acid is warmed with zinc-dust and soda. The ethereal salts of azobenzenesalicylic acid can be obtained by warming the acid with an alcohol and concentrated sulphuric acid; by dissolving the acid in the alcohol, and heating the solution at 100° with the corresponding alkyl iodide, and also by treating ethereal salts of salicylic acid with diazobenzene chloride in alkaline solution. The methyl salt,

crystallises in reddish-yellow plates, melts at 108° , and is readily soluble in alcohol, ether, and soda. The ethyl salt, $\text{C}_{15}\text{H}_{13}\text{N}_2\text{O}_3$, crystallises in yellowish needles or plates, melts at 101° , and is readily soluble in alcohol, ether, and dilute soda; it distils at a high temperature with only slight decomposition, and is decomposed by stannous chloride yielding ethyl amidosalicylate. The phenyl salt, $\text{C}_{18}\text{H}_{14}\text{N}_2\text{O}_3$, is formed, together with phenyl bi-azobenzenesalicylate, when an ice-cold alkaline solution of phenylsalicylate is treated with diazobenzene chloride; it separates from ether in yellowish-red needles, and from cold alcohol in well-defined crystals, melts at 121° , and is readily soluble in ether, chloroform, and benzene, but more sparingly in alcohol, acetone, carbon bisulphide, glacial acetic acid, and soda.

Phenyl bi-azobenzenesalicylate, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{N}_2\text{Ph})_2\cdot\text{COOPh}$, forms compact, granular crystals, melts at 148° , and is readily soluble in alcohol, ether, chloroform, benzene, acetone, glacial acetic acid, and soda.

Azobenzene-salicylamide, prepared by heating the methyl or ethyl salt of the acid with ammonia, crystallises in light-yellow needles, and melts at 240° , not at 236° , as stated by Tummely. The *anilide*, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{N}_2\text{Ph})\cdot\text{CO}\cdot\text{NHPh}$, can be obtained by treating salicylamide with diazobenzene chloride in alkaline solution; it crystallises from alcohol in brown plates, melts at $188\text{--}189^{\circ}$, and is readily soluble in alcohol, ether, benzene, chloroform, and glacial acetic acid; it dissolves in concentrated sulphuric acid with a blood-red coloration.

Azobenzene-chlorobenzamide, $\text{N}_2\text{Ph}\cdot\text{C}_6\text{H}_3\text{Cl}\cdot\text{CO}\cdot\text{NH}_2$, is formed when azobenzene-salicylic acid is heated with phosphorus pentachloride, and the product treated with ammonia; it separates from alcohol in yellow crystals melting at 210° . The corresponding *anilide*,

prepared in like manner, separates from alcohol in yellowish, nodular crystals, and melts at 198° .

Azobenzene-metahydroxybenzoic acid, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{N}_2\text{Ph})\cdot\text{COOH}$, separates from benzene in golden crystals, melts at 213° , and is readily soluble in alcohol, ether, chloroform, acetone, glacial acetic acid, and soda, but only sparingly in benzene; when warmed with stannous chloride, it yields *metahydroxyamidobenzoic acid* [$\text{OH}:\text{COOH}:\text{NH}_2 = 1:3:4$], a colourless, crystalline compound, which darkens at 230° , and melts at 235° ; when this amido-acid is diazotised, and the product warmed with hydriodic acid, *iodometahydroxybenzoic acid* is obtained. This compound crystallises from water in large, yellowish needles, sublimes at $160\text{--}170^{\circ}$, melts at 196° , and seems to have the composition $\text{C}_7\text{H}_5\text{IO}_3 + \frac{1}{2}\text{H}_2\text{O}$; when treated with sodium amalgam, it is converted into metahydroxybenzoic acid.

When parahydroxybenzoic acid is treated with diazobenzene chloride in ice-cold, alkaline solution, bi-azobenzene-phenol (m. p. 130°), and azobenzene-phenol (m. p. $150\text{--}151^{\circ}$) are formed, but no azo-derivative of hydroxybenzoic acid is produced. The compound, obtained by treating parahydroxybenzoic acid with diazosulphanilic acid in ice-cold alkaline solution, has not the constitution

as supposed by Griess (*Ber.*, 15, 2190), but is the sodium salt of a hydroxy-parazobenzene-sulphonic acid of the constitution

This acid is identical with the compound formed by the combination of phenol and diazosulphanilic acid; its *sodium* salt crystallises in reddish-yellow, lustrous scales, is readily soluble in hot water, and has the composition $\text{OH}\cdot\text{C}_6\text{H}_3\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_3\text{Na} + 2\text{H}_2\text{O}$; its *barium* salt crystallises from hot water in red, lustrous, rhombic plates ($+ \text{H}_2\text{O}$), and in yellow needles ($+ \frac{1}{2}\text{H}_2\text{O}$), and is very sparingly soluble in cold water.

Azo-derivatives of paramethoxybenzoic acid could not be obtained.

Azobenzene- β -resorcylic acid, $\text{N}_2\text{Ph}\cdot\text{C}_6\text{H}_3(\text{OH})_2\cdot\text{COOH}$, is formed, together with bi-azobenzene-resorcinol (m. p. 217°) when β -resorcylic acid is treated with diazobenzene chloride in ice-cold, alkaline solution; it crystallises from acetone in dark-red needles, melts at

about 189° with evolution of carbonic anhydride, and is readily soluble in chloroform and hot alcohol, but more sparingly in ether, benzene, and acetone, and insoluble in water; it is partially decomposed by recrystallisation from acetone, yielding bi-azobenzenoresorcinol, with evolution of carbonic anhydride. F. S. K.

Orthohydroxyazo-dyes. By S. v. KOSTANECKI and J. D. ZIBELL (*Ber.*, 24, 1695—1699).—The authors have studied the azo-dyes from the hydroxybenzoic acids, and find that the action of diazobenzene chloride on parahydroxybenzoic acid is quite different to its action on the ortho- and meta-acids.

Phenylazosalicylic acid and phenylazometahydroxybenzoic acid are best obtained by adding diazobenzene chloride to the hydroxybenzoic acid in the presence of sodium carbonate. The dye is precipitated from the soda solution with acid, and crystallised from alcohol. Phenylazosalicylic acid decomposes at 211° ; phenylazohydroxybenzoic acid at 205° . The latter does not dye mordanted cotton.

Parahydroxybenzoic acid and diazobenzene chloride yield a product which is only partly soluble in sodium carbonate. The soluble portion crystallises from dilute alcohol, in which it is easily soluble, in orange tablets, melts at 150° , and was identified as phenylazophenol. The insoluble portion crystallises from alcohol in brownish-red leaflets, melts at 131° , and was identified as phenyldisazophenol. Thus parahydroxybenzoic acid reacts with diazobenzene chloride in the same way as β -naphtholcarboxylic acid (m. p. 157°), which also loses the carboxyl group.

Griess (*Abstr.*, 1883, 182; 1884, 1013) has stated that parahydroxybenzoic acid reacts with diazosulphanilic acid in the same way as salicylic and metahydroxybenzoic acids. The authors, however, find that when diazosulphanilic acid is added to a solution of parahydroxybenzoic acid containing sodium carbonate, a compound is obtained crystallising in golden-yellow leaflets, which answers to the description of the compound obtained by Griess, and gives on analysis numbers agreeing with his numbers. These numbers, however, agree with the formula $\text{SO}_3\text{Na}\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{OH} + 2\text{H}_2\text{O}$. The authors have made a complete analysis of the compound, and find that it is identical with the sodium salt of the compound obtained from diazosulphanilic acid and phenol.

The authors were unable to obtain azo-dyes of parahydroxybenzoic acid by the action of diazobenzene chloride or diazosulphanilic acid on parahydroxybenzoic acid, under many varying conditions.

E. C. R.

Tetrazotic Acids, Oxy- and Dioxytetrazotic Acids. By W. LOSSEN (*Annalen*, 263, 73—80).—The author and Mierau have previously shown that an acid of the composition $\text{C}_7\text{H}_4\text{N}_4\text{O}_2$ can be obtained by treating benzenylamidine nitrite with mineral acids; the further investigation of this subject has brought to light the following facts.

Other amidines containing the atomic complex $\text{NH}\cdot\text{C}\cdot\text{NH}_2$ give acids analogous in composition to that produced from benzenylamidine, but those amidines in which the hydrogen of the amido- or imido-

group has been substituted by an alkyl group give no such compounds.

The acids prepared from the amidines have the general formula $X \cdot CN_2O_2H$; on treatment with sodium amalgam, they lose either one or two atoms of oxygen, yielding acids having the composition $X \cdot CN_2OH$ and $X \cdot CN_4H$ respectively.

The oxygen-free compound obtained from benzenylamidine has the molecular formula $C_7H_5N_3$, and is a strong monobasic acid. Judging from its decomposition products, it contains the unchanged benzenyl group, and may, therefore, be named benzenyltetrazotic acid; the compound of the composition $C_7H_5N_4O$ may be termed benzenyloxytetrazotic acid, and the compound of the composition $C_7H_5N_4O_2$ benzenyldioxytetrazotic acid.

The dioxytetrazotic acids are very unstable in the free state, and have not yet been isolated; their salts are much more stable in solution, but all the metallic salts are highly explosive in the dry state, and must be handled with the greatest care; they are also decomposed by concentrated sulphuric acid with explosive violence.

The only oxytetrazotic acid yet prepared is benzenyloxytetrazotic acid; as regards stability, it seems to be intermediate between benzenyltetrazotic acid and benzenyldioxytetrazotic acid; the anhydrous compound readily decomposes, but when in combination with 1 mol. of water of crystallisation it is stable.

The tetrazotic acids are very stable; benzenyltetrazotic acid is decomposed by concentrated hydrochloric acid and by potash only at a high temperature.

The constitution of these new compounds has not yet been determined, and there are but few facts from which any conclusions can be drawn. It is probable, in the first place, that since benzenyldioxytetrazotic acid gives benzonitrile on decomposition, it contains the group $CPh \equiv$, and since it is formed by the action of nitrous acid on the amidine, its constitution is probably represented by the formula $NO \cdot N : CPh \cdot N : N \cdot OH$; this view is in accordance with the fact that substituted amidines give no analogous compound, and also with the reactions of the acid and with those of its derivatives. Benzenyltetrazotic acid is probably also a benzenyl derivative, as it is formed by the action of sodium amalgam on a cold dilute solution of the dioxytetrazotic acid: when heated with concentrated hydrochloric acid, it is decomposed into aniline, carbonic anhydride, nitrogen, and ammonia, and its ethyl salt under the same conditions gives benzoic acid, ammonia, nitrogen, a little carbonic anhydride, and probably also aniline, ethylamine, and ethyl chloride; it may possibly be a tetrazole

derivative of the constitution $CPh \begin{smallmatrix} N-N \\ \diagdown \quad \diagup \\ NH \cdot N \end{smallmatrix}$, or it may have the con-

stitution $NH : CPh \cdot N \begin{smallmatrix} N \\ \diagup \quad \diagdown \\ N \end{smallmatrix}$, in which case it would be the imido-derivative of Curtius' benzoylazoimide, $C_6H_5 \cdot CO \cdot N \begin{smallmatrix} N \\ \diagup \quad \diagdown \\ N \end{smallmatrix}$ (this vol., p. 56).

An account of the experimental work on this subject is given in the following abstracts.

F. S. K.

Benzenyldioxytetrazotic Acid. By W. LOSSEN and F. MIEBAU (*Annalen*, 263, 81—87).—*Benzenylamidine benzenyldioxytetrazotate*, $C_7H_5N_2, C_7H_5N_4O_2$, is best prepared by mixing an aqueous solution (80 c.c.) of potassium nitrate (80 grams) with a solution of benzenylamidine hydrochloride (20 grams) in water (100 grams) heated at 60—70°, and then adding, drop by drop, sulphuric acid of sp. gr. 1.2 (20 c.c.); after keeping for two hours, the precipitated salt is separated by filtration. The yield is, at the most, 37 grams from 100 grams of the hydrochloride; during the process nitric oxide and nitrogen are evolved, and some of the product undergoes decomposition with formation of benzonitrile. It crystallises from boiling alcohol in lustrous plates, explodes at about 178°, and is readily soluble in hot alcohol, but only sparingly in hot water, and almost insoluble in ether. The *potassium* salt, $C_7H_5N_4O_2K$, is deposited in crystals when the benzenylamidine salt is treated with alcoholic potash, or with an alcoholic solution of potassium acetate; it crystallises in needles or plates, explodes violently when heated, when rubbed, or when brought into contact with concentrated sulphuric acid, and is very readily soluble in water, but only sparingly in cold alcohol, and insoluble in ether. The *silver* salt, $C_7H_5N_4O_2Ag$, is obtained as a white precipitate on adding a solution of silver nitrate to a solution of the potassium salt; it is very explosive. In solutions of the potassium salt, barium chloride, lead acetate, and mercurous nitrate produce colourless precipitates, which are explosive in the dry state; solutions of ammonium chloride, hydroxylamine hydrochloride, and methylaniline hydrochloride give crystalline precipitates, and a solution of rosaniline gives a voluminous, dark-red precipitate.

The free *benzenyldioxytetrazotic* acid is very unstable; on adding a mineral acid to a solution of the potassium salt, the liquid turns yellow, but becomes colourless again on warming, nitrogen and nitric oxide being evolved, with formation of benzonitrile.

F. S. K.

Metanitrobenzenyldioxytetrazotic Acid. By W. LOSSEN and M. NEUBERT (*Annalen*, 263, 87—92).—*Potassium metanitrobenzenyldioxytetrazotate*, $NO_2C_7H_4N_4O_2K$, is deposited in crystals, together with the corresponding amidine salt, when a solution of metanitrobenzenylamidine hydrochloride is mixed with excess of a concentrated solution of potassium nitrite, and nitric acid added to the mixture until a regular evolution of gas takes place; the two compounds can be separated by treating the mixture with hot water or hot alcohol, in both of which the amidine salt is almost insoluble. The potassium salt can also be obtained by boiling the amidine salt with a concentrated solution of potassium nitrite, or by agitating it with alcoholic potash. It crystallises from hot alcohol in small, moss-like needles, is very explosive, gives Liebermann's reaction, and is only sparingly soluble in cold water and cold alcohol. The free acid could not be isolated; when a solution of the potassium salt is treated with strong mineral acids, and when the lead salt is decomposed with hydrogen sulphide, metanitrobenzonitrile is formed with evolution of gas. The *barium* salt, $(NO_2C_7H_4N_4O_2)_2Ba$, prepared by

precipitating a solution of the potassium salt with barium chloride, is a colourless, explosive compound almost insoluble in water and alcohol. The *silver* salt, $\text{NO}_2 \cdot \text{C}_7\text{H}_4\text{N}_4\text{O}_2\text{Ag}$, is a dirty-white, explosive compound, very sensitive to light. The *ammonium* salt,

is precipitated in needles on adding ammonium chloride to a solution of the potassium salt; it is sparingly soluble in water, but readily in alcohol, and explodes at about 152° . The *hydroxylamine* salt, $\text{NO}_2 \cdot \text{C}_7\text{H}_4\text{N}_4\text{O}_2 \cdot \text{NH}_2 \cdot \text{OH}$, crystallises in needles, and is rather explosive. The *phenylhydrazine* salt, $\text{NO}_2 \cdot \text{C}_7\text{H}_4\text{N}_4\text{O}_2 \cdot \text{N}_2\text{H}_5\text{Ph} + \text{H}_2\text{O}$, crystallises in yellowish needles, and melts at about 130° with decomposition; in solutions of the potassium salt, the hydrochlorides of aniline and metaphenylenediamine also produce crystalline precipitates. The *metanitrobenzenylamidine* salt, $\text{NO}_2 \cdot \text{C}_7\text{H}_4\text{N}_4\text{O}_2 \cdot \text{NO}_2 \cdot \text{C}_7\text{H}_7\text{N}_2$ (see above), is a yellow, crystalline powder which melts at about 176° , and is insoluble in the ordinary solvents; it is rapidly decomposed by concentrated sulphuric acid, but only slowly by dilute hydrochloric acid. The ethyl salt seems to be decomposed by alcohol. F. S. K.

Phenethenyldioxytetrazotic Acid. By W. and C. LOSSEN (*Annalen*, 263, 92—95).—*Phenethenylamidine phenethenyldioxytetrazotate*, $\text{C}_7\text{H}_{10}\text{N}_2 \cdot \text{C}_8\text{H}_8\text{N}_4\text{O}_2$, is gradually precipitated when a solution of phenethenylamidine nitrite (10 grams) in water (150—200 c.c.) at about 60° is mixed with a saturated solution (10—15 c.c.) of potassium nitrite, and then dilute sulphuric acid added until the evolution of gas commences; the yield is, at the most, 20 grams from 100 grams of the amidine salt. It crystallises from hot alcohol in slender needles, and from water in well-defined, rhombic crystals, $a : b : c = 0.551 : 1 : 0.407$, is moderately easily soluble in alcohol, but only sparingly in ether, and almost insoluble in cold water; it is decomposed by boiling water with formation of phenylacetoneitrile. The *potassium* salt, $\text{C}_8\text{H}_7\text{N}_4\text{O}_2\text{K}$, prepared by triturating the amidine salt with alcoholic potash, crystallises from boiling alcohol in large, nacreous plates, and is readily soluble in water, but only sparingly in cold alcohol, and insoluble in ether; its aqueous solution undergoes decomposition on boiling, with formation of phenylacetoneitrile, and the dry compound is highly explosive. The *silver* salt, $\text{C}_8\text{H}_7\text{N}_4\text{O}_2\text{Ag}$, is obtained as a reddish precipitate on adding silver nitrate to a solution of the potassium salt; it first becomes colourless, but on exposure to light again turns reddish, then brown, and finally black; it is highly explosive, and is very readily decomposed by alkalis.

F. S. K.

Reduction of Benzenyldioxytetrazotic Acid. By W. and C. LOSSEN (*Annalen*, 263, 96—108).—*Benzenyloxytetrazotic acid* and *benzenyldioxytetrazotic acid* are both produced when an aqueous solution of the potassium salt of benzenyldioxytetrazotic acid is reduced with sodium amalgam; the two products cannot be easily separated. When a warm concentrated solution of the potassium salt of the dioxy-acid is treated with excess of sodium amalgam, benzenyloxytetrazotic acid

is the sole product, whereas when a cold 6—8 per cent. solution of the potassium salt is employed, only a small quantity of benzenyloxynitrazotic acid is formed, the principal product being benzenylnitrazotic acid.

Benzenyloxynitrazotic acid, $C_7H_5N_4O + H_2O$, crystallises from boiling water in needles, and from cold dilute alcohol in reddish-yellow, rhombic or monosymmetric forms; it loses its water at 150° , melts at 175° with explosive decomposition, and is soluble in alcohol and ether, but is reprecipitated from the solutions on the addition of light petroleum. The anhydrous acid readily undergoes decomposition, on keeping, with evolution of nitrous fumes; it seems, also, to be decomposed by anhydrous solvents, such as benzene, even at the ordinary temperature, but it is not acted on by boiling hydrochloric acid or dilute sulphuric acid. Concentrated nitric acid decomposes it in the cold, but concentrated sulphuric acid has no action until the temperature rises to about 250° ; the solution in hot sulphuric acid gives Liebermann's reaction, whereas the undecomposed acid does not. The results of molecular-weight determinations in phenol solution were in accordance with those required by a compound of the molecular formula given above. The *potassium* salt, $C_7H_5N_4OK$, separates from alcoholic ether in crystals, is readily soluble in water and alcohol, and explodes when heated. The *barium* salt, $(C_7H_5N_4O)_2Ba + 3H_2O$, crystallises in plates, loses its water at 105° , and is readily soluble in water, but more sparingly in alcohol. The *silver* salt, $C_7H_5N_4OAg$, is insoluble in water, and darkens on exposure to light. In solutions of the potassium salt, the nitrates of lead and mercury produce a colourless, copper sulphate a light-green, and ferric chloride a reddish-brown precipitate.

Benzenylnitrazotic acid, $C_7H_5N_4$, crystallises from hot water in long, colourless needles, and from cold alcohol in rhombic forms, melts at $212\text{—}213^\circ$ with decomposition, and is moderately easily soluble in alcohol, but only sparingly in ether, and almost insoluble in benzene, light petroleum, and cold water. When the acid is carefully heated at its melting point, it turns wine-red, and, on cooling, the liquid solidifies to a colourless mass, in which is imbedded a small quantity of a purple-red substance, insoluble in water, and only sparingly soluble in dilute alcohol; when heated quickly, the acid decomposes suddenly, with development of light and heat, yielding a thick, dark-green, very stable liquid, which is readily soluble in alcohol. Molecular-weight determinations in phenol solution gave results in accordance with those required by the molecular formula $C_7H_5N_4$. The *potassium* salt, $C_7H_5N_4K$, crystallises from alcoholic ether in nacreous plates, and decomposes on heating. The *barium* salt, $(C_7H_5N_4)_2Ba + 3H_2O$, crystallises in thin plates. The *silver* salt, $C_7H_5N_4Ag$, is colourless, and moderately stable in the light. Copper sulphate, silver nitrate, and the two nitrates of mercury produce precipitates in an aqueous solution of the acid, and, with a solution of the potassium salt, mercuric chloride and lead nitrate give a colourless, cobalt nitrate a bright-red, and ferric chloride a yellowish-brown precipitate. The *ethyl* salt, $C_7H_5N_4Et$, prepared by heating the acid with an alcoholic solution of potassium ethoxide and ethyl iodide, is a moder-

ately thick oil, insoluble in water, but soluble in alcohol, ether, and concentrated hydrochloric acid; it cannot be distilled.

F. S. K.

Orthochlorophenylhydrazine. By C. WILLEROUDT (*Ber.*, 24, 1660—1662).—Orthochlorophenylhydrazine hydrochloride is obtained by reduction of orthochlorodiazobenzene chloride with stannous chloride and hydrochloric acid. It is a white, crystalline compound, and decomposes about 200°.

Orthochlorophenylhydrazine is obtained as a white, crystalline mass on adding excess of strong ammonia to an aqueous solution of the hydrochloride. It is soluble in hot water, alcohol, ether, and benzene, and is fairly stable to light, air, and a gentle heat.

Picrylorthochlorophenylhydrazine is obtained by mixing hot alcoholic solutions of the hydrazine hydrochloride and picryl chloride. It crystallises in thick, red prisms, and melts at 160°. From benzene, it crystallises in yellow plates containing 1 mol. of benzene, which it loses when heated at 100°. From pseudocumene, or from an alcoholic solution of pseudocumene, it crystallises in thick, yellow prisms containing 1 mol. of the hydrocarbon, which it loses when heated at 100°.

Dinitronitrosophenylorthochlorazobenzene. $C_6H_4Cl \cdot N_1 \cdot C_6H_3(NO_2)_3 \cdot NO$, is obtained by boiling picrylorthochlorophenylhydrazine with acetic acid in a reflux apparatus. It crystallises in yellowish-red prisms, melts at 244—245°, and is quite insoluble in benzene. E. C. R.

Configuration of *o*-Isonitroacetophenone (Benzoylformoxime). By H. G. SÖDERBAUM (*Ber.*, 24, 1381—1388).—An acetyl derivative could not be obtained by the interaction of benzoylformoxime and acetic anhydride; benzoic cyanide was the only product; its formation, however, proves that the oxime belongs to the β -series,

and has the formula
$$\begin{array}{c} \text{Bz} \cdot \text{C} \cdot \text{H} \\ \parallel \\ \text{N} \cdot \text{OH} \end{array}$$
 On treating the oxime with acetic chloride at the ordinary temperature, a compound is deposited of the formula $C_{10}H_9NO_3Cl$; Claisen and Manasse, who first prepared it, supposed it to be the acetyl derivative; in all probability, however, it is either the *oximacetate hydrochloride*, $\text{BzCH:N} \cdot \text{OAc} \cdot \text{HCl}$, or a hydroxychloride of the same oximacetate, of the formula

By the action of water at the ordinary temperature, the hydrate of *benzoylformoxime acetate*, $\text{CPh}(\text{OH})_2 \cdot \text{CH:N} \cdot \text{OAc}$ is formed, crystallising from chloroform in colourless, lustrous needles which melt at 131°. The oxime is regenerated on warming with dilute hydrochloric acid or by treatment with concentrated sulphuric acid at the ordinary temperature. The acetyl derivative yields phenylhydroxyacetic acid on hydrolysis with dilute soda; with sodium carbonate solution, however, *diphenylhydroxytriketone*, $\text{OH} \cdot \text{CHBz} \cdot \text{COBz}$, is formed, and crystallises from benzene in yellow, microscopic needles melting at about 170°; the molecular weight, determined by Raoult's method, agrees with the formula.

The above oximacetate appears to be the α -modification $\text{Bz} \cdot \text{C}(\text{OH}) \text{AcO} \cdot \text{N}$, and is probably formed from the intermediate β -derivative by molecular rearrangement induced by the action of hydrogen chloride. The formation of the peculiar hydrolysis products may be explained by assuming that the α -oxime is first formed; this, being unstable, decomposes into hydroxylamine and the aldehyde, the latter compound being afterwards further changed in the manner shown.

J. B. T.

The Induline Group. By O. FISCHER and E. HEPP (*Annalen*, 262, 237—264).—*Rosindulines*.—It has been shown in a previous paper (Abstr., 1890, 908) that rosindulines are produced by the action of a large number of naphthaleneazo-derivatives, or nitroso-naphthalene derivatives on aniline or analogous bases; in the preparation of these dyes quinoneanilides, such as anilidonaphthaquinoncanil, are formed as intermediate products just as dianilidoquinonedianil (azophenine) is formed in the preparation of the blue indulines of the benzenic series. In order to obtain a good yield of the rosinduline, it is not necessary to work under conditions which are favourable to the production of quinoneanilides; on the contrary, the yield is considerably larger when the quinoneanilide is obtained in only small quantities, because it is only when in the nascent state that it is readily transformed into a rosinduline. The conditions favourable to the formation of a quinoneanilide are (1) a comparatively low temperature in the fusion process, and (2) the presence of some diluent; consequently when aniline is boiled with benzencazo- α -naphthylamine hydrochloride in glacial acetic acid solution, and when nitrosophenyl- α -naphthylamine is heated with aniline in 50 per cent. acetic acid solution, anilidonaphthaquinoncanil is formed in large quantities.

In preparing phenylrosinduline from benzeneazo- α -naphthylamine and aniline (*loc. cit.*), benzeneazo- α -phenylnaphthylamine (*loc. cit.*) is first formed; as the last-named compound dissolves in sulphuric acid yielding a blue solution, whereas the rosinduline gives a green solution, the course of the reaction can be easily followed.

Anilidoisonaphthylrosinduline, $\text{C}_{28}\text{H}_{26}\text{N}_4$, is formed in small quantities in preparing phenylrosinduline as previously described (Abstr., 1888, 1291, and 1890, 909), and remains undissolved on extracting the melt with benzene. It crystallises from hot alcoholic xylene in bronze-coloured needles, melts at a very high temperature, and is very sparingly soluble in all ordinary solvents; it dissolves in concentrated sulphuric acid yielding a green solution in which an indigo-blue, flocculent precipitate is produced on the addition of water. The *hydrochloride*, $\text{C}_{28}\text{H}_{26}\text{N}_4 \cdot \text{HCl}$, crystallises from alcohol, in which it is sparingly soluble, in bronze-coloured plates. When anilidoisonaphthylrosinduline is heated at 180—200° with a mixture of glacial acetic acid and concentrated hydrochloric acid, it is decomposed into aniline and a base of the composition $\text{C}_{28}\text{H}_{18}\text{N}_2\text{O}_2$, which is probably a hydroxy-derivative of the isonaphthylrosindone (hydroxyphenyldinaphthazine) previously described (Abstr., 1890, 910). This new

base dissolves in alcoholic benzene yielding a rose-coloured solution which shows an intense orange-yellow fluorescence; its hydrochloride crystallises in green plates, is unstable, and dissolves in alcohol yielding a solution having a greenish-yellow fluorescence.

Rosindulines can be prepared from α -amidoazo- α -naphthylamine: When α -amidoazo- α -naphthylamine hydrochloride (1 part) is heated with aniline (2 parts) and aniline hydrochloride (1 part) at 150–180°, phenylrosinduline and isonaphthylrosinduline (Abstr., 1890, 908) are obtained.

Phenylrosindulinesulphonic acid, $C_6H_5 \cdot \langle \overset{N}{\text{---}} \rangle_{NPh} \cdot C_{10}H_7 \cdot \overset{1}{N} \cdot C_6H_4 \cdot \overset{3}{SO_3H}$, is formed when phenylrosinduline is heated at 100° with concentrated sulphuric acid; it is a red, very sparingly soluble powder. The sodium, potassium, and ammonium salts are only very sparingly soluble in boiling water, from which they crystallise in thin plates. When the acid is heated with water at 200°, it is decomposed into rosindone and metamidobenzenesulphonic acid.

Rosindone can be converted into a sulphonic acid by treating it with sulphuric anhydride; this acid dyes silk a yellowish-red shade which shows a fiery-red fluorescence, and its salts are readily soluble.

Bromorosindone, $C_{22}H_{13}N_2OBr$, is deposited in the form of a red powder on adding bromine (2 mols.) to a well-cooled glacial acetic acid solution of rosindone; it crystallises from alcoholic benzene in bright-red prisms, and is almost insoluble in cold glacial acetic acid, but more readily in alcohol and chloroform. Both bromorosindone and its sulphonic acid are eosin-coloured dyes; the shades obtained are brilliantly fluorescent. When chlorine is passed into an acetic acid solution of rosindone, the colour gradually disappears, and a colourless compound containing chlorine, probably a ketochloride, is deposited on the addition of water.

Rosindonic acid, $C_{22}H_{14}N_2O_3$, is formed when rosinduline, rosindulinesulphonic acid, or rosindone is warmed with a glacial acetic acid solution of chromic acid until the solution becomes colourless. It separates from a mixture of benzene and light petroleum in colourless crystals, melts at 209°, and is insoluble in water and only sparingly soluble in alcohol, but readily in ether and benzene; it dissolves in concentrated sulphuric acid yielding an intensely yellow solution, which becomes colourless on the addition of water. The silver salt, $C_{22}H_{13}N_2O_3Ag$, crystallises from hot water in shining plates; the potassium salt and the sodium salt are readily soluble in water, but the barium salt and the calcium salt are only sparingly soluble, and the copper salt and the lead salt are insoluble.

Anilidonaphthaquinonedianil, $NHPh \cdot C_{10}H_6(NPh)_2[(NPh)_2:NHPh = 1:4:2]$, is formed as an intermediate product in the oxidation of trianilidonaphthalene to phenylrosinduline by mercuric oxide (Abstr., 1890, 908); it crystallises from benzene or alcohol in orange-yellow prisms, melts at 159°, and on reduction with zinc-dust and acetic acid is converted into trianilidonaphthalene.

Quinoneanilides and Azophenines.—When orthonitrophenol (1 part) is boiled for a few hours with aniline (2 parts) in 50 per cent. acetic

acid solution, a considerable quantity of dianilidoquinoneanil, identical with the compound obtained by Zincke and Hagen from quinone and aniline (*Ber.*, 18, 788), is deposited. The compound obtained from dibromonitrosophenol and previously described by the authors as hydroxyazophenine (*Abstr.*, 1888, 456) and the substance prepared by Kohler from paranitrosometahydroxydiphenylamine (*Abstr.*, 1888, 587) are both identical with Zincke and Hagen's dianilidoquinoneanil.

Toluazophenine, $C_6H_2(NC_7H_7)_2(NHC_7H_7)_2$ [$(NC_7H_7)_2 : (NHC_7H_7)_2 = 1:4:2:5$], was first prepared by Kimich (*Ber.*, 8, 1031), who erroneously assigned to it the composition $C_{40}H_{37}N_5O$; when boiled with methyl alcohol and concentrated sulphuric acid, it is decomposed into paratoluidine and diparatoluidoquinone.

The compound prepared by Nölting and Witt (*Ber.*, 17, 82) from orthamidoazotoluene and paratoluidine has the composition $C_{35}H_{34}N_4$ and not $C_{42}H_{41}N_5$; when boiled with methyl alcohol and concentrated sulphuric acid, it is decomposed into ditoluidotoluquinone, $C_6HO_2Me(NHC_7H_7)_2$, and paratoluidine. This ditoluidotoluquinone, crystallises from alcohol in brown needles, melts at 178° , and is isomeric with the symmetrical compound (m. p. 241°) previously obtained by the authors from toluquinone and paratoluidine (*Abstr.*, 1890, 912); its constitution is, therefore, represented by one of the two formulæ $[Me : O_2 : (NHC_7H_7)_2 = 1:2:5:3:4 \text{ or } = 1:2:5:4:6]$, so that the original compound of the composition $C_{35}H_{34}N_4$ is an *azotoline* of the constitution

The compound of the composition $C_{18}H_{14}N_2O_2$, obtained by Fèvre (*Abstr.*, 1883, 734) from nitrosoresorcinol and aniline, is probably a hydroxyanilidoquinoneanil of the constitution $[O : OH : NPh : NPh = 1:3:4:6]$; when boiled with methyl alcohol and sulphuric acid, it is decomposed into aniline and a crystalline compound of the composition $C_{13}H_{11}NO_3$, which melts at 189° , and is probably methoxyanilidoquinone.

Benzeneindulines.—Amidoazobenzeneinduline, (*Abstr.*, 1890, 764) melts at 125° . The *hydrochloride*, $C_{18}H_{14}N_3HCl$, crystallises in brownish-red prisms; the *hydrobromide*, $C_{18}H_{14}N_3HBr$, crystallises in yellow, lustrous needles and is rather sparingly soluble in water. The *nitrate*, $C_{18}H_{14}N_3HNO_3$, is a bronze-coloured, crystalline powder which dissolves in water yielding a reddish-violet solution.

Amidophenylinduline, the preparation of which is described in the German patent, No. 50,534, crystallises from alcohol or benzene in greenish prisms, melts at $150\text{--}152^\circ$ (not at $255\text{--}260^\circ$ as stated in the patent), and is only sparingly soluble in benzene; the hydrochloride is very sparingly soluble in water. The *nitrate*, $C_{24}H_{18}N_4HNO_3$, crystallises in green, and the *aurochloride*, $C_{24}H_{18}N_4HAuCl_4$, in bronze-coloured plates. When the base is heated with concentrated hydrochloric acid at 150° , it is decomposed into ammonia, aniline, and a hydroxy-compound which is only very sparingly soluble in alcohol, yielding a reddish-violet solution.

Phenylinduline, $C_{24}H_{17}N_3$, is obtained when amidophenylinduline is

diazotised in alcoholic solution, the solution of the product heated to boiling, diluted with water, and the base precipitated with ammonia. It crystallises from a mixture of methyl alcohol and benzene in thick, red plates, melts at 230—231°, and is readily soluble in benzene, but only sparingly in methyl alcohol, and almost insoluble in light petroleum; it dissolves in concentrated hydrochloric acid and sulphuric acid with a blue, in dilute mineral acids with a bluish-violet, and in acetic acid with a red coloration. The hydrochloride and the sulphate crystallise in green prisms.

Further investigation has shown that the compound (m. p. 229—230°) obtained by heating azophenine with concentrated hydrochloric acid, and which was first thought to be anilidoquinonedianil, $C_{24}H_{19}N_3$ (Abstr., 1890, 912), is identical with the phenylinduline just described; this fact shows that phenylinduline must have the con-

stitution $NPh:C_6H_5 \begin{smallmatrix} \text{N} \\ \text{NPh} \end{smallmatrix} > C_6H_5$. The benzeneindulines are, there-

fore, like the rosindulines, derivatives of paraquinone, whereas the safranines and eurhodines are derivatives of orthoquinone.

The blue compound obtained by boiling amidazobenzene hydrochloride with aniline hydrochloride in aqueous solution contains oxygen, and does not belong to the same class of compounds as the indulines.

Indazine, a blue dye obtained by treating nitrosodimethylaniline with diphenylmetaphenylenediamine, is the hydrochloride of a base which has many properties in common with the saffranine bases, but which, like the indulines, is free from oxygen; the free base, $C_{26}H_{22}N_4$, crystallises from benzene in compact bronze-coloured prisms, melts at 218—220°, and effloresces on exposure to the air owing to loss of benzene. It is readily soluble in alcohol and benzene, but only sparingly in ether, light petroleum, and hot water, and insoluble in alkalis; it dissolves in concentrated sulphuric acid yielding a green solution which turns yellow on the addition of water. The hydrochloride and the sulphate dissolve freely in water giving bluish-violet solutions, but the nitrate is only sparingly soluble.

Nitrosoaniline combines with diphenylmetaphenylenediamine forming a violet indazine; nitrosodiphenylamine and the meta-base give a blue compound.

F. S. K.

Dichloromaleinanil Chloride. By R. ANSCHÜTZ and C. BEAVIS (*Annalen*, 263, 156—163).—*Dichloromaleinanil chloride*,

is easily obtained in a pure condition by heating succinanil (1 mol.) with phosphorus pentachloride (4 mols.) at 130°, until the reaction is at an end, and then distilling the product under greatly reduced pressure. It crystallises from light petroleum and glacial acetic acid in colourless, transparent prisms, melts at 123—124°, boils at 179° under a pressure of about 11 mm., and is very readily soluble in chloroform, carbon bisulphide, and acetone; when treated with boiling water, it is gradu-

ally converted into dichloromaleinanil (m. p. 203°), the compound which Kauder considered to be produced directly by the action of phosphorus pentachloride on succinanil (Abstr., 1885, 651).

Dichloromaleinanil dimethyl ether, $\begin{array}{c} \text{CCl} \cdot \text{C}(\text{OMe}) \\ | \\ \text{CCl} \end{array} \text{--- CO} > \text{NPh}$, is deposited in colourless needles, when the preceding compound is dissolved in warm alcohol, and the solution then allowed to cool; it melts at 110° and is gradually converted into dichloromaleinanil when boiled with a mixture of methyl alcohol and hydrochloric acid. The corresponding *diethyl ether*, $\text{C}_{14}\text{H}_{15}\text{Cl}_2\text{NO}$, crystallises from alcohol in colourless, lustrous prisms, melts at 96–97°, and is converted into dichloromaleinanil by boiling alcoholic hydrochloric acid.

A compound of the composition $\text{C}_{11}\text{H}_7\text{Cl}_2\text{NO}$, which has possibly the constitution $\begin{array}{c} \text{CCl} \cdot \text{CCl}(\text{OMe}) \\ | \\ \text{CH} \cdot \text{CO} \end{array} > \text{NPh}$, is formed when succinanil (1 mol.) is warmed with phosphorus pentachloride and the product treated with methyl alcohol; it melts at 91°. F. S. K.

Formation of Thianhydro-compounds. By P. JACOBSON and A. FRANKENBACHER (*Ber.*, 24, 1400–1411).—Amidophenylmercaptomethylmercaptan, $\text{C}_6\text{H}_5\text{---}\overset{\text{N}}{\text{S}}\text{---C}\cdot\text{SH}$, which was first obtained by Hofmann, may be prepared by heating azobenzene with 2.5 parts of carbon bisulphide in a sealed tube for five hours at 260–270°; the product is purified by solution in soda and crystallisation from alcohol; the yield is 60 per cent. of the azobenzene employed. It is proposed to term the compound *thiocarbamidothiophenol*; its formation is probably preceded by a decomposition of the azobenzene and carbon bisulphide into phenylthiocarbimide and sulphur; these, however, combine to form the unstable intermediate product $\text{SH}\cdot\text{C}_6\text{H}_5\cdot\text{N}\cdot\text{CS}$, from which the thiophenol is obtained by intramolecular rearrangement; this theory is supported by the fact that the thiophenol may be prepared by the direct interaction of sulphur and phenylthiocarbimide at 260–270°. The thiophenol does not react with aniline, and yields no acetyl derivative; the *mercuriochloride*, $\text{C}_7\text{H}_5\text{NS}_2\cdot\text{HgCl}_2$, is colourless and crystalline.

Thiocarbamidothiophenol is prepared in a similar manner by heating α -naphthylthiocarbimide with sulphur for 4–5 hours at 220–230°; it is identical with the compound formed by the action of carbon bisulphide on diamidodiphenyl bisulphide; on oxidation, the corresponding bisulphide is formed, together with a small quantity of a second compound which crystallises from benzene in plates, and melts at 180°; it is isomeric with the first compound, and is probably derived from a 1.1'-thiocarbamidonaphthol. The *mercuriochloride* is deposited in transparent, tabular crystals melting at 209–210°.

β -Naphthylthiocarbimide reacts with sulphur in a similar manner to the α -derivative; the product is represented by the formula $\text{C}_{10}\text{H}_7\text{---}\overset{\text{N}}{\text{S}}\text{---C}\cdot\text{SH}$ [$\text{N}:\text{S} = 3:4$ or $3:2$], the former positions being

the more probable: it crystallises in small needles, and melts at 232° with decomposition.

The *bisulphide*, $C_{10}H_8 \begin{smallmatrix} \text{N} \\ \text{S} \end{smallmatrix} \text{C} \cdot \text{S}_2 \cdot \text{C} \begin{smallmatrix} \text{N} \\ \text{S} \end{smallmatrix} C_{10}H_8$, prepared by oxidation of the preceding compound with potassium ferricyanide in alkaline solution, is deposited from benzene in prismatic crystals and melts at 180° ; on boiling with alcoholic potash, the thionaphthol is regenerated. No crystalline mercurchloride could be obtained.

The *methyl ether*, $C_{10}H_8 \begin{smallmatrix} \text{N} \\ \text{S} \end{smallmatrix} \text{C} \cdot \text{SMe}$, is formed by heating the thionaphthol with methyl iodide, and crystallises from dilute alcohol in colourless needles melting at $73.5-74^{\circ}$.

Carbanilamidothiophenol, $C_6H_4 \begin{smallmatrix} \text{N} \\ \text{S} \end{smallmatrix} \text{C} \cdot \text{NHPh}$, is prepared by heating azobenzene with two molecular proportions of phenylthiocarbimide for three hours at $260-270^{\circ}$; the product is most readily purified by solution in light petroleum or hydrochloric acid. The *picrate* crystallises from alcohol, and melts at 222° . The *aurochloride* forms brownish-red needles. The *acetyl derivative* is deposited from alcohol in colourless needles and melts at 167° . J. B. T.

Action of Sulphur on Benzaldehyde. By G. A. BARBAGLIA and A. MARQUARIT (*Ber.*, 24, 1881-1883).—When benzaldehyde (30 grams) is heated with sulphur (10 grams) in a sealed tube for 36 hours (compare Gazzarini, *Abstr.*, 1888, 950), a reddish-coloured, crystalline mass, consisting of small, lustrous plates and rectangular prisms, is obtained. On opening the tube, little or no hydrogen sulphide is given off. The product is treated with ether, whereby the crystals are dissolved, leaving the sulphur and another compound (see below) behind. The ethereal solution is shaken with an aqueous solution of sodium carbonate, and on acidifying the alkaline extract with hydrochloric acid, a copious precipitation of benzoic acid occurs, whilst, on evaporating the ethereal solution, a compound is obtained which, on repeated crystallisation from alcohol, forms lustrous, white plates, and melts at $121-122^{\circ}$; it is identified as stilbene by its melting point, and that of the dibromide obtained from it. The residue insoluble in ether yields, on treatment with benzene or chloroform, a compound containing sulphur, crystallising in white needles, and melting at $164-167^{\circ}$, which has all the properties of γ -thiobenzaldehyde (Baumann and Fromm, *Abstr.*, 1890, 25). It therefore appears probable that the initial action of sulphur on benzaldehyde is the formation of thiobenzaldehyde and benzoic acid, being in this stage analogous to the formation of thio-derivatives with aldehydes of the fatty series (see *Abstr.*, 1881, 34; 1885, 136), the thiobenzaldehyde then decomposing into stilbene and sulphur thus: $2\text{CHSPH} = \text{CHPh}:\text{CHPh} + \text{S}_2$. In this case, the formation of stilbene ought to be effected by very small quantities of sulphur, and experiment shows that a quantity of the latter equal in weight to $\frac{1}{16}$ of the benzaldehyde is sufficient. Klinger (*Abstr.*, 1877, 306; 1878,

132) obtained stilbene by heating amorphous thiobenzaldehyde with copper powder. A. R. L.

Thio-derivatives of Benzaldehyde. By E. BAUMANN and E. FROMM (*Ber.*, 24, 1431—1440).—The majority of thioaldehydes do not volatilise without decomposition, and are very sparingly soluble in benzene or glacial acetic acid; molecular weight determinations of them are therefore most conveniently made with naphthalene as solvent. The molecular depression for naphthalene is given by Raoult as 82, by Fabrizi as 85·6, whilst Eykmann found it to vary from 68·3 to 76·6, although for the greater number of his experiments the value is about 70. The theoretical number deduced from Van't Hoff's formula is 69·4. The authors have determined the molecular depression in the case of trithioformaldehyde, α - and β -trithiacetaldehyde, and trimethylene tetrasulphide, the vapour densities of which are known; the highest value was 72, the lowest 67·7, and the mean 69·6; the molecular weights thus obtained agree closely with those calculated from the depression in glacial acetic acid solution.

β -Thiobenzaldehyde (m. p. 225—226°) has the formula $3(C_7H_5S)$, and crystallises with 1 mol. benzene; on account of its analogy with β -thiacetaldehyde, its present name is correct (compare this vol., p. 1008). γ -Thiobenzaldehyde (m. p. 167°) also has a trimolecular formula; it is proposed in future to term it α -thiobenzaldehyde to show its relation to α -thiacetaldehyde.

The compound hitherto called α -thiobenzaldehyde, which is amorphous, melts at 83—85°, and is prepared by the action of ammonium sulphide, or hydrogen sulphide, on benzaldehyde, is not a trithiobenzaldehyde, but a complicated polymeride, or perhaps a mixture of several compounds of high molecular weight; its formula is probably $(C_7H_5S)_{12}$, and it is comparable with the polymeric thioformaldehyde of Wohl.

By repeated solution of this amorphous compound, a small quantity of β -thiobenzaldehyde is separated; the remainder, however, is quite unchanged in properties. The elementary analyses of several preparations give 0·3 to 1·0 per cent. more sulphur than is required by the formula $(C_7H_5S)_3$, the carbon being correspondingly low; this may be due to the presence of a little free sulphur.

Thiobenzaldine is obtained in small quantity during the preparation of polymeric benzaldehyde by the interaction of ammonium sulphide and benzaldehyde.

The formation of the polymeric compound is preceded by that of a hydroxymercaptan, $OH\cdot CHPh\cdot SH$, which is much less stable than the corresponding formic and acetic derivatives, and immediately undergoes condensation, the solvent alcohol probably acting as a dehydrating agent. The two trithiobenzaldehydes are odourless; the polymeric compound, when recently prepared, has a strong smell, which gradually disappears as purification proceeds. J. B. T.

Aromatic Thioaldehydes. By E. BAUMANN and E. FROMM (*Ber.*, 24, 1441—1456; compare this vol., p. 1008).— *α -Trithioparamethoxybenzaldehyde*, $C_{24}H_{24}S_3O_3$, is prepared by dissolving the aldehyde in

alcohol, adding 0.1 part of hydrochloric acid, and saturating the solution with hydrogen sulphide at a temperature of -5° to -10° ; it is readily soluble in benzene, sparingly in alcohol, and is deposited in small, needle-shaped crystals melting at 127° . The corresponding β -derivative is formed in a similar manner in presence of excess of hydrochloric acid and at ordinary temperatures; it crystallises with 1 mol. benzene in transparent plates, and melts at 183° .

By the action of hydrogen sulphide on paramethoxybenzaldehyde in alcoholic solution, a plastic compound is obtained which hardens after some time; it softens at $75-77^{\circ}$, and contains more sulphur than the thioaldehydes.

On treatment of the methoxybenzaldehyde, in alcoholic solution, with ammonium sulphide, a crystalline polymeric thio-derivative of the formula $(C_6H_5SO)_n$, is obtained, melting at $90-92^{\circ}$, together with *anisyl bisulphide*, $S_2(CH_2C_6H_4OMe)_2$; this crystallises from alcohol, on the addition of water, in large, thin plates. By the reduction of this compound, *anisylmercaptan* is formed; it is a yellow, oily liquid, volatile with steam. The *copper* and *silver salts* are yellow and amorphous.

α-Trithiorthomethoxybenzaldehyde is prepared in a similar manner to the above para-compound, which it closely resembles, and melts at 157° . The β -derivative crystallises from benzene in slender needles, and melts at 224° . From the mother liquors, an amorphous substance is deposited which softens at 60° , and melts at about 70° ; it is probably a mixture of oxysulphides. An impure product is obtained by the action of hydrogen sulphide on the methoxybenzaldehyde; the compound formed with ammonium sulphide is a mixture of various polymerides, and melts at $85-88^{\circ}$.

Orthisobutoxybenzaldehyde is a strongly refractive liquid which boils at 265° . The *α-trithioaldehyde*, $C_{13}H_{12}S_3O$, is readily soluble, crystallises from alcohol in slender needles, and melts at 142° . The β -modification is deposited from benzene in transparent plates or prisms, and melts at $162-163^{\circ}$. As in the preceding cases, the polymeric compounds are impure; that obtained with ammonium sulphide melts at $52-56^{\circ}$, and contains more sulphur than the thioaldehydes.

α-Trithiocinnamaldehyde, $C_{17}H_{14}S_3$, crystallises from alcohol and melts at 167° ; it is readily converted into the isomeric form by the action of ethyl iodide, but iodine does not cause this change. The β -compound is deposited in small, prismatic crystals, which do not contain benzene of crystallisation, and melt at 213° . On treatment of cinnamaldehyde in alcoholic solution with hydrogen sulphide, a yellow, viscid liquid is formed which contains oxygen, and consists of a mixture of several compounds. With ammonium sulphide and cinnamaldehyde, a colourless, flocculent precipitate is obtained which does not crystallise; it softens at 127° , and melts at 142° , and, on analysis, proves to be a mixture of at least two substances, one containing nitrogen, and the other more sulphur than the trithioaldehydes; the molecular weight is not less than 722° .

The molecular weights of all the above compounds were determined by Raoult's method in naphthalene solution.

These results show that in every case hitherto investigated aromatic aldehydes yield two isomeric trithio-derivatives, together with substances which are either mixtures or else complicated polymers; the stability of these tri-derivatives shows that the sulphur atoms are each linked to two carbon atoms, or, in other words, that the compounds are to be regarded as trithiomethylene substitution products.

The tri- and poly-thiobenzaldehydes yield cinnamene and thionessal on heating; lepiden, the corresponding oxygen compound, has been shown by Japp and Klingemann to be tetraphenylsulfuran. Thionessal is therefore tetraphenylthiophen, and its formation, by heating cinnamene or phenylacetic acid with sulphur is an additional proof of the correctness of this view. J. B. T.

Behaviour of Cinnamaldehyde towards Alkaline Hydrogen Sulphites. By F. HEUFLER (*Der.*, 24, 1805—1807).—The reaction which takes between cinnamaldehyde and alkaline hydrogen sulphites was first examined by Bertagnini (*Annalen*, 85, 271), and has been utilised by Bertram and Gildemeister for estimating the quantity of cinnamaldehyde in oil of cassia. The author finds that cold saturated solutions of potassium and sodium hydrogen sulphites combine with cinnamaldehyde in the normal manner, the last-named forming the compound $\text{CHPh}\cdot\text{CH}\cdot\text{CH}(\text{OH})\cdot\text{SO}_3\text{Na}$, which then, on heating, undergoes the following reaction:—

This compound may also be obtained directly, and in quantitative proportions, by adding cinnamaldehyde (1 mol.) to a hot concentrated solution of an alkaline hydrogen sulphite. The *potassium* salt crystallises from water in compact needles, having the composition $\text{C}_9\text{H}_{10}\text{O}(\text{SO}_3\text{K})_2 + 2\text{H}_2\text{O}$; and on dry distillation or boiling with soda is reconverted into cinnamaldehyde. Dilute sulphuric acid, on the other hand, converts it into cinnamaldehydesulphonic acid, $\text{C}_9\text{H}_9\text{Ph}(\text{SO}_3\text{H})\cdot\text{CHO}$, which readily combines with phenylhydrazine, forming the *phenylhydrazine salt of cinnamaldehydrazonesulphonic acid*; this compound crystallises in yellowish plates, melts with decomposition at $165\text{--}166^\circ$, and is decomposed by aqueous soda with formation of phenylhydrazine and cinnamaldehydrazone. H. G. C.

Some Ketones. By G. ERRERA (*Gazzetta*, 21, 94—103).—*Paratolyl ethyl ketone*, $\text{C}_6\text{H}_4\text{Me}\cdot\text{COEt}$, prepared by the dry distillation of a mixture of barium propionate and paratoluate, is a pale-yellow liquid with a characteristic odour, which boils at $237\text{--}239^\circ$, and is insoluble in water. It does not combine with sodium hydrogen sulphite, but it yields a liquid condensation product with phenylhydrazine; it also yields an *oxime*, which crystallises in large, colourless plates melting at $86\text{--}87^\circ$. On oxidation with nitric acid (sp. gr. = 1.38), dinitroethane and metanitroparatoluic acid are formed. *Metanitroparatolyl ethyl ketone*, $\text{NO}_2\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{COEt}$, prepared by dissolving paratolyl ethyl ketone in well cooled nitric acid (sp. gr. = 1.51) and precipitating with water, crystallises from alcohol in pale-yellow plates which

melt at 50—51°. On boiling with dilute nitric acid, it is converted into metanitroparatoluic acid. It yields a *phenylhydrazone*,

which crystallises from alcohol in orange-coloured needles melting at 147—149°. *Metadintrodiparatolyl ketone*, $\text{CO}(\text{C}_6\text{H}_4\text{Me} \cdot \text{NO}_2)_2$, is obtained by the action of nitric acid (sp. gr. 1.51) on diparatolyl ketone. It dissolves freely in warm alcohol, and crystallises, on cooling, in yellow, prismatic needles. It is not affected by prolonged boiling with ordinary nitric acid, and is only very slowly and partially decomposed by the strong acid (1.45). *Diparatolyl ketone*, $\text{CO}(\text{C}_6\text{H}_4\text{Me})_2$, is obtained as a bye-product in the preparation of ethyl paratolyl ketone, or by the action of aluminium chloride on a mixture of toluene and carbonyl chloride. It yields, with some difficulty, an *oxime*, $\text{NOH} \cdot \text{C}(\text{C}_6\text{H}_4\text{Me})_2$, which crystallises in colourless prisms melting at 161—162°.

Paraxylyl methyl ketone, $\text{C}_6\text{H}_4\text{Me} \cdot \text{CH}_2 \cdot \text{COMe}$, is prepared by distilling a mixture of the barium salts of acetic acid and homoparatoluic acid ($\text{C}_6\text{H}_4\text{Me} \cdot \text{CH}_2 \cdot \text{COOH}$, from synthetical paraxylene), and treating the fraction 220—250° with sodium hydrogen sulphite. It is a colourless, aromatic liquid, boiling at 232—233°. It yields an oily phenylhydrazone and an *oxime*, which crystallises in large, oblique prisms melting at 90—91°. The *metanitro-derivative* is obtained in an impure condition by the action of nitric acid (1.51) on the ketone; the *hydrazone*, $\text{NO}_2 \cdot \text{C}_6\text{H}_4\text{Me} \cdot \text{CH}_2 \cdot \text{CMe} \cdot \text{N}_2\text{HPh}$, crystallises from alcohol in long, brilliant-red needles melting at 212—213°.

Diparaxylyl ketone, $\text{CO}(\text{CH}_2 \cdot \text{C}_6\text{H}_4\text{Me})_2$, is obtained in the preparation of paraxylyl methyl ketone, occurring among the products which distil over above 300°. It forms colourless crystals melting at 54°. The *oxime*, $\text{NOH} \cdot \text{C}(\text{CH}_2 \cdot \text{C}_6\text{H}_4\text{Me})_2$, crystallises in colourless needles and melts at 106°.

S. B. A. A.

Hydrogenation of Benzoic Acid. By O. ASCHAN (*Ber.*, 24, 1864—1869).—On reduction of benzoic acid with sodium amalgam in acid solution, in addition to benzaldehyde and benzyl alcohol, about 8 per cent. of tetrahydrobenzoic acid is formed. Better results are obtained by dissolving 50 grams of benzoic acid in 250 c.c. of 10 per cent. soda solution in a reflux apparatus; 2.5 kilos. of sodium amalgam are added in portions of 300—400 grams, and the flask is heated on the water-bath for 20—25 hours, a slow, continuous stream of carbonic anhydride being passed into the liquid; sufficient water must be added from time to time in order to prevent the separation of any sodium salts. The yield is 60—70 per cent.; but to attain this it is needful that the amalgam should be quite pure. Tetrahydrobenzoic acid behaves in every respect like an unsaturated compound; on treatment with bromine in molecular proportions, two *dibromides* are formed; the one obtained in larger quantity crystallises from a mixture of benzene and light petroleum, melts at 163°, and on warming with soda is converted into a crystalline substance, which is probably a bromolactone. The second compound is soluble in light petroleum, crystallises in long needles, and yields a solid, unsaturated acid on

treatment with soda. Tetrahydrobenzoic acid combines directly with hydrogen iodide and hydrogen bromide; by the action of sodium amalgam on the latter product, hexahydrobenzoic acid is formed as a viscid liquid, together with a small quantity of a solid acid. The *calcium salt* crystallises in long prisms, with $4\text{H}_2\text{O}$; the *silver salt* is amorphous. On heating tetrahydrobenzoic acid with concentrated hydriodic acid at $220\text{--}240^\circ$, a solid acid, free from iodine, is formed, and is being further investigated. *Methyl tetrahydrobenzoate* boils at $185\text{--}187^\circ$, and gradually undergoes decomposition. On hydrolysis with alcoholic potash, the sparingly soluble salt of a new acid is formed, crystallising in large plates. The acid itself melts above 100° , and will be described later.

It appears probable that hexahydrobenzoic acid will prove to be identical with hexanaphthenecarboxylic acid. J. B. T.

Asymmetrical Phenylhydrazidoacetic Acid. By A. REISSERT and W. KAYNER (*Ber.*, **24**, 1519—1522; see also Abstr., 1884, 1152).—The *ethyl salt of asymmetrical phenylhydrazidoacetic acid*,

may be obtained by heating together phenylhydrazine (2 mols.) and ethyl chloracetate (1 mol.) at 100° for 2—3 hours, dissolving the product in dilute hydrochloric acid, and extracting the solution with ether. The mass remaining on evaporating off the latter, is spread on a porous plate, and the residue recrystallised from benzene. It forms white needles, melts at 127° , is readily soluble in alcohol, ether, and chloroform, more sparingly in benzene, and is almost insoluble in light petroleum and water. The yield is small, owing to secondary reactions.

The ethyl salt is readily decomposed by dilute aqueous soda, with formation of *asymmetrical phenylhydrazidoacetic acid*,

which separates, on addition of acids, as a yellow, woolly, unstable precipitate. It is purified by dissolving repeatedly in boiling water and cooling quickly, when it forms slender, yellowish needles; it becomes brown at 125° , and melts with decomposition at $130\text{--}131^\circ$. It is soluble in most of the usual solvents, and only reduces Fehling's solution on warming. It differs altogether from the symmetrical phenylhydrazidoacetic acid described by Elbers (*Abstr.*, 1885, 535), and must, therefore, be the asymmetrical compound. H. G. C.

Anilpyruvic Acid. By C. BÖTTINGER (*Annalen*, **263**, 125—128).—*Tribromodianilidopyruvic acid*, $\text{C}_{15}\text{H}_{13}\text{Br}_3\text{N}_2\text{O}_2$, is obtained when anilpyruvic acid (5 grams) is suspended in chloroform, treated with bromine (6 grams) at the ordinary temperature, the dry product shaken with dilute soda to free it from brominated aniline, and the filtered solution acidified with hydrochloric acid; it crystallises from boiling alcohol, in which it is moderately easily soluble, in slender, colourless needles, melts at 264° with decomposition, has an intensely bitter taste, and is not decomposed by boiling soda. It dissolves in

concentrated hydrochloric acid and in concentrated sulphuric acid with a yellow coloration, and it is slowly decomposed by concentrated hydrochloric acid at 225° with evolution of carbonic anhydride; when treated with sodium amalgam, it loses bromine, and is converted into substances which are readily soluble in dilute acids. The *silver* salt is a colourless compound, soluble in ammonia. F. S. K.

Action of an Alcoholic Solution of Silver Nitrate on Ethyl Phenyldibromopropionate. By L. P. KINNICUTT and G. D. MOORE (*Amer. Chem. J.*, 13, 204—205).—It has been already noticed (*Abstr.*, 1885, 1010) that an alcoholic solution of silver nitrate only removes 1 atom of bromine from an alcoholic solution of ethyl phenyldibromopropionate. If the alcoholic solution is poured off from the settled silver bromide into water, an oil separates; this is extracted by ether and dried over calcium chloride; analysis shows that it is ethyl phenyl- α -bromo- β -nitropropionate,

its orientation being settled by the facts that it yields benzaldehyde on oxidation, and bromocinnamic acid (m.p. 131°) on treatment with sodium hydroxide. It is a pale straw-coloured oil of sweetish odour, and soluble in alcohol and ether; it does not distil without decomposition. The subject is still being investigated.

A. G. B.

Derivatives of Cumic Acid. By M. FILETTI and F. CROSA (*Gazzetta*, 21, 28—40).—*Metabromocumic acid*, $\text{C}_6\text{H}_4\text{BrPr-COOH}$ [$\text{COOH} : \text{Br} : \text{Pr} = 1 : 3 : 4$], previously described by Naquet and Louguinine (*Compt. rend.*, 72, 1031), and by Gerichten (*Abstr.*, 1879, 230), may be prepared directly from cumic acid and bromine. It separates from dilute alcohol in large, white crystals, melts at 150 — 151° , and is identical with the acid obtained by the authors from bromocumene prepared from thymol. The *magnesium* salt, $(\text{C}_{10}\text{H}_9\text{BrO}_2)_2\text{Mg} + 8\text{H}_2\text{O}$, crystallises in long, silky needles which become anhydrous at 160° . It is soluble in hot water. The *methyl* salt is an oily liquid which decomposes on distillation. The *acid chloride* is also a liquid, and decomposes on heating. The *amide*, $\text{C}_6\text{H}_4\text{Br-CONH}_2$, crystallises from benzene in silky needles, melts at 103 — 104° , and dissolves freely in alcohol and ether.

Orthonitrobromocumic Acid,

—Bromocumic acid on nitration yields a mixture of three acids which may be separated by fractional crystallisation from benzene; they are probably the three isomeric nitrobromocumic acids theoretically possible. The acid [$\text{NO}_2 = 6$] crystallises from benzene in large, pale-yellow, rhombic prisms, melts at 138 — 139° , and dissolves in alcohol, ether, &c. The *ammonium* salt, $\text{C}_{10}\text{H}_5\text{BrNO}_4\text{-NH}_4$, forms large, yellow plates very soluble in alcohol. The *magnesium* salt,

crystallises in thin, pale-yellow, lustrous plates which become an-

hydrous at 200°. It is very soluble in hot water. On reducing the acid with sodium amalgam, Widman's orthamidocumic acid (Abstr., 1886, 466) is formed, thus indicating the ortho-position of the NO_2 group.

Orthumidometabromocumic acid, prepared by treating a mixture of the nitro-derivative and ammonia with ferrous sulphate, crystallises from dilute alcohol in long, shining, pale-brown needles, melts at 166–167°, and dissolves freely in alcohol and ether, but only sparingly in water.

Paradibromocumic Acid, $\text{C}_6\text{H}_2\text{Br}_2\text{Pr-COOH}$ [$\text{COOH} : \text{Br} : \text{Pr} : \text{Br} = 1 : 3 : 4 : 6$].—When the preceding amido-acid is diazotised, the product crystallises in minute, rhombic prisms, which melt at 134° if gently raised to that temperature, but explode if sharply heated. Paradibromocumic acid, prepared by dissolving this diazoamido-compound in a saturated solution of hydrobromic acid, crystallises from light petroleum in triclinic prisms, melts at 148–149° with previous softening, and dissolves in alcohol, ether, and benzene. On oxidation with dilute nitric acid (sp. gr. 1.06), it yields paradibromoterephthalic acid, a confirmation of the constitutional formulæ assigned to some of the preceding compounds.

Paradibromonitrocumic acid, $\text{NO}_2\cdot\text{C}_6\text{HBr}_2\text{Pr-COOH}$, prepared by nitrating dibromocumic acid, crystallises from very dilute alcohol in brilliant, yellow scales, melts at 199–200°, and dissolves very freely in benzene and alcohol.

Paradibromonitroterephthalic acid, $\text{NO}_2\cdot\text{C}_6\text{HBr}_2(\text{COOH})_2$, prepared by heating dibromocumic acid with nitric acid (sp. gr. 1.2) for eight hours at 180°, crystallises from its aqueous solution in thin, slightly yellowish plates, melts at 257–258°, and dissolves in alcohol and in boiling water.

Orthonitrometabromocumic acid [$\text{COOH} : \text{NO}_2 : \text{Br} : \text{Pr} = 1 : 2 : 3 : 4$] is obtained, together with the acid [$\text{NO}_2 = 6$], as mentioned above. It crystallises from benzene in white needles, melts at 238–239°, dissolves readily in benzene, alcohol, and ether, but is insoluble in water. The ammonium salt, $\text{C}_{10}\text{H}_5\text{BrNO}_4\cdot\text{NH}_4$, crystallises in long, anhydrous needles, and is very soluble in water. On reduction with sodium amalgam, it yields the same orthamidocumic acid as the acid [$\text{NO}_2 = 6$]; it is therefore an ortho-acid, and the constitution assigned to it is the only possible one.

Orthamidometabromocumic acid, prepared by reducing the preceding acid with ferrous sulphate, crystallises in colourless or pale pinkish, pyramidal prisms, melts at 173–174°, and dissolves in alcohol and ether, but only very sparingly in water.

Orthodibromocumic Acid.—By diazotising the preceding acid, a diazo-compound is formed, crystallising in colourless, ill-defined prisms which melt with decomposition if gradually warmed to 120° in a capillary tube, but explode on quickly heating. On treatment with hydrobromic acid, it yields the corresponding dibromocumic acid, which crystallises from light petroleum in pale, reddish-yellow, orthogonally prisms, melts at 128–129°, and dissolves freely in alcohol, ether, &c. It undergoes oxidation with great difficulty.

Orthodibromonitroterephthalic acid, $\text{NO}_2\cdot\text{C}_6\text{HBr}_2(\text{COOH})_2$, prepared

by oxidising the preceding acid with very dilute nitric acid (sp. gr. = 1.06 or 1.12), crystallises from boiling water in pale, yellowish plates, softens at 275°, and melts at 280—281°, decomposing as soon as it is liquified. It is soluble in alcohol.

Metanitronetabromocumic acid $[\text{COOH}:\text{Br}:\text{Pr}:\text{NO}_2 = 1:3:4:5]$ is the most soluble of the acids obtained by nitrating metabromocumic acid, and remains in the mother liquor after separation of the ortho-acids. It crystallises in white needles, melts at 159—160°, and dissolves very freely in benzene and alcohol. S. B. A. A.

Homocumic and Homoterephthalic Acids. By M. FILLET and G. BASSO (*Gazzetta*, 21, 52—64).—*Homocumic acid*,

obtained by Rossi (*Compt. rend.*, 52, 403) by the action of potash on cumyl cyanide, is more advantageously prepared by reducing phenylisopropylglycollic acid with tin and fuming hydrochloric acid. It crystallises from an aqueous solution in slender needles, melts at 51—52°, and dissolves readily in most solvents, but only very sparingly in water. The *barium salt*, $(\text{C}_{11}\text{H}_{13}\text{O}_2)_2\text{Ba}\cdot 4\text{H}_2\text{O}$, crystallises in vitreous, lamellar prisms; the *calcium salt* forms microscopic plates containing 3 mols. H_2O . The *magnesium salt* separates in nodules containing 4 mols. H_2O ; it is more soluble than the preceding salts. The *methyl salt* is a liquid boiling at 255—257°; the *ethyl salt* boils at 264—265°. The *chloride* is a heavy liquid readily decomposed by cold water; the *amide* crystallises from boiling benzene in thin, octagonal plates, melts at 170°, and dissolves readily in alcohol, moderately in benzene, but very sparingly in ether, and not at all in water. In the preparation of the amide, there was obtained a very small quantity of a compound crystallising in oblique, acicular prisms, and melting at 104—107°, but not further investigated. The *anilide* of homocumic acid crystallises from light petroleum in plates, melts at 104°, and dissolves readily in all solvents except water.

Paradibromohomocumic acid, $\text{C}_6\text{H}_2\text{PrBr}_2\cdot\text{CH}_2\cdot\text{COOH}$, prepared by the action of bromine on homocumic acid, crystallises from light petroleum in plates, melts at 92°, and dissolves freely in all solvents but water. The *barium salt* crystallises in acicular prisms containing 5 mols. H_2O ; the *magnesium salt* forms plates with 8 mols. H_2O ; it is more soluble than the barium salt. The *methyl salt* is a liquid boiling without decomposition at 325—326°; the *chloride* is a heavy, colourless liquid; the *amide* crystallises from dilute alcohol in brilliant plates melting at 153°. It is insoluble in water. On oxidation with potassium permanganate, paradibromohomocumic acid is converted into dibromocumic acid and into an acid which has a percentage composition corresponding with the formula $\text{C}_{10}\text{H}_{10}\text{Br}_2\text{O}_4$; this crystallises from dilute alcohol in oblique prisms, melts at 214—215°, and probably has the constitution of a hydroxypropyldibromobenzoic acid,

Homoterephthalic acid, $\text{COOH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{COOH}$ [1:4], prepared by

oxidising homocumic acid with dilute nitric acid, crystallises from an aqueous solution in needles or plates, melts at 237° with partial sublimation, dissolves readily in boiling water or alcohol, but only very sparingly in other solvents. The substance described by Paterno and Spica (Abstr., 1878, 296) as homoterephthalic acid seems to have been nothing but impure terephthalic acid. The *barium* salt, $C_8H_4O_4Ba + H_2O$, becomes anhydrous at 150° ; it is soluble in water. The *methyl* salt boils at $300-302^{\circ}$, and the *ethyl* salt at $312-318^{\circ}$; both compounds are readily hydrolysed by dilute caustic soda. The *chloride* is immediately decomposed by cold water; the *amide* is a white, amorphous powder which melts at $236-237^{\circ}$, and dissolves in water and alcohol. S. B. A. A.

Thioxanthone. By C. GRAEBE and O. SCHULTZ (Annalen, 263, 1-15)—It has been shown by Ziegler (Abstr., 1890, 1292) that thioxanthone can be obtained from phenylthiosalicylic acid just as xanthone can be prepared from phenylsalicylic acid; the following paper gives a more complete account of the experiments on this subject.

The *diazo*-compound, $COOH \cdot C_6H_4 \cdot N_2 \cdot SPh$, is precipitated on gradually adding a solution of orthodiazobenzoic acid chloride to a well-cooled dilute solution of sodium thiophenate; it is a yellow, amorphous compound, melts at 60° with explosion, and dissolves unchanged in cold dilute soda or sodium carbonate.

Phenylthiosalicylic acid (diphenylsulphideorthocarboxylic acid),

is obtained when the preceding compound is warmed with soda; it separates from dilute alcohol in colourless plates, from glacial acetic acid in needles, melts at 166° , and sublimes readily. It is almost insoluble in cold water, but readily soluble in alcohol, benzene, and glacial acetic acid; it dissolves in warm concentrated sulphuric acid, being thereby converted into thioxanthone, yielding a solution which shows a green fluorescence; phosphorus pentachloride also converts it into thioxanthone. The *potassium* salt, $C_{13}H_9SO_3K$, crystallises in colourless needles, and is readily soluble in water, but only sparingly in alcohol; the *ammonium* salt, $C_{13}H_9SO_3NH_4$, crystallises in colourless needles, and is rather more sparingly soluble than the potassium salt. The *silver* salt is insoluble in water. The *ethyl* salt, $C_{13}H_{11}SO_3$, prepared from the silver salt, crystallises from hot light petroleum in colourless needles, and melts at 151° .

Sulphobenzilorthocarboxylic acid, $SO_2Ph \cdot C_6H_4 \cdot COOH$, is formed when the preceding compound is warmed with moderately concentrated (1 : 2) nitric acid; it crystallises from alcohol in colourless needles containing 1 mol. H_2O , and melting at 99° ; it loses its water at $100-105^{\circ}$, the anhydrous substance melting at 152° . It is very readily soluble in chloroform, and dissolves freely in alcohol and ether.

Thioxanthone, $C_6H_4 \cdot \overset{\text{S}}{\underset{\text{CO}}{\text{<}}}$ C_6H_4 , is obtained when phenylthiosalicylic acid is heated at 100° with concentrated sulphuric acid; it

crystallises from chloroform in long, yellow needles, melts at 209°, sublimes readily, and is insoluble in alkalis. When heated with potash at 230°, it is reconverted into phenylthiosalicylic acid.

Benzophenonesulphone, $C_6H_4<\begin{smallmatrix} SO_2 \\ CO \end{smallmatrix}>C_6H_4$, is easily prepared by oxidising thioxanthone with chromic acid in glacial acetic acid solution; it crystallises from alcohol or chloroform in yellowish needles, melts at 185°, and is readily soluble in ether, but only very sparingly in boiling water. It is identical with the compound obtained by Beckmann by heating benzophenone with fuming sulphuric acid. When warmed with zinc-dust and dilute soda, it gives first a violet and then a blue solution, but the colour disappears on exposing the filtered solution to the air, and also if the treatment with zinc-dust is continued for some time; with alcoholic potash it gives the same blue coloration.

Diphenylenemethane sulphide, $C_6H_4<\begin{smallmatrix} -S- \\ CH_2 \end{smallmatrix}>C_6H_4$, prepared by reducing thioxanthone with hydriodic acid and amorphous phosphorus, or by passing orthophenyltolyl sulphide through a red-hot tube, crystallises from chloroform in large needles or prisms, melts at 128°, boils at 340° (730 mm.), and sublimes very readily; it is only sparingly soluble in cold alcohol and ether, but very readily in chloroform, and it dissolves in warm concentrated sulphuric acid with a yellow or yellowish-red coloration, the solution showing a yellow fluorescence; it is readily converted into benzophenonesulphone by oxidising agents.

Diphenylenemethanesulphone, $C_6H_4<\begin{smallmatrix} SO_2 \\ CH_2 \end{smallmatrix}>C_6H_4$, is obtained when benzophenonesulphone is reduced with hydriodic acid and amorphous phosphorus; it crystallises from alcohol in colourless needles, melts at 170°, and is readily soluble in hot alcohol and ether.

F. S. K.

Isopropylphenylglycollic Acid and its Derivatives. By M. FILETI and G. AMORETTI (*Gazzetta*, 21, 41—52).—Isopropylphenylglycollic acid, $C_6H_4Pr^i\cdot CH(OH)\cdot COOH$, has been described by Raab (*Abstr.*, 1876, 398), and by Plöschl (*Abstr.*, 1882, 515). The *magnesium salt*, $(C_{11}H_{13}O_3)_2Mg + 4H_2O$, is a crystalline powder very sparingly soluble in water; the *calcium salt*, $(C_{11}H_{13}O_3)_2Ca + 1\frac{1}{2}H_2O$, crystallises in plates which become anhydrous at 150°; it is also very sparingly soluble in water. The *methyl salt*, $C_{12}H_{16}O_3$, crystallises from light petroleum in needles, melts at 80°, and dissolves in most ordinary solvents, but not in water. The *ethyl salt*, $C_{13}H_{18}O_3$, melts at 40—41° and is very freely soluble in all solvents except water. The *amide* crystallises from benzene in needles, melts at 116°, dissolves readily in alcohol, ether, chloroform, &c., but only sparingly in water. On treating the acid with phosphorus pentachloride, an unstable chloride is obtained which is decomposed by cold water and converted into phenylisopropylchloroacetic acid.

Isopropylphenylmethyleglycollic acid, $C_6H_4Pr^i\cdot CH(OMe)\cdot COOH$, prepared by the action of sodium methoxide on isopropylphenylchloroacetic acid, crystallises in plates and melts at 52—53°. The *sodium*

salt crystallises in brilliant plates containing 2 mols. H_2O , and is very soluble in hot water. *Isopropylphenylethylglycollic acid*,

prepared in the same way as the preceding compound, is a viscous, uncrystallisable liquid. *Isopropylphenylacetylgllycollic acid*, $\text{C}_6\text{H}_4\text{Pr}^\beta\text{-CH}(\text{OAc})\cdot\text{COOH} + \text{H}_2\text{O}$, crystallises from light petroleum in large prisms, and melts at $60-61^\circ$; it becomes anhydrous in a vacuum or when heated to near its melting point. It dissolves in the ordinary solvents. It is hydrolysed by boiling with water or dilute sodium carbonate. *Isopropylphenylchloroacetic acid*, $\text{C}_6\text{H}_4\text{Pr}^\beta\text{-CHCl}\cdot\text{COOH}$, (Abstr., 1886, 769), prepared by heating isopropylphenylglycollic acid with fuming hydrochloric acid, crystallises from light petroleum in oblique, lamellar prisms and melts at 82° . It is decomposed by water and by alcohol containing traces of water on heating, and by alkaline hydrates and carbonates at the ordinary temperature. The aqueous solution has a strong and persistent sweetish taste. *Isopropylphenylbromoacetic acid*, $\text{C}_6\text{H}_4\text{Pr}^\beta\text{-CHBr}\cdot\text{COOH}$, resembles the chlorinated derivative. It crystallises in plates melting at $94-95^\circ$. *Isopropylphenylanilidoacetic acid*, $\text{C}_6\text{H}_4\text{Pr}^\beta\text{-CH}(\text{NHPh})\cdot\text{COOH}$, prepared by treating the chlorinated acid with an excess of aniline, forms a crystalline powder, melts at $145-146^\circ$ with partial decomposition, and dissolves in alcohol and benzene, but not in water, &c. It is not attacked by dilute alkalis.

Isopropylbenzoylformic acid, $\text{C}_6\text{H}_4\text{Pr}^\beta\text{-CO}\cdot\text{COOH}$, prepared by oxidising isopropylphenylglycollic acid with potassium permanganate, crystallises from light petroleum in colourless, rhomboidal plates, melts at $106-107^\circ$, dissolves in alcohol and ether and sparingly in water. It is tinged yellow by exposure to light. The calcium salt, $(\text{C}_{11}\text{H}_{11}\text{O}_3)_2\text{Ca} + 2\text{H}_2\text{O}$, forms acicular prisms very soluble in water. The barium, zinc, and magnesium salts are equally soluble; the last crystallises in needles. The ethyl salt is a liquid with a pleasant odour. The amide, $\text{C}_{11}\text{H}_{13}\text{O}_3\text{N}$, is obtained as a crystalline powder melting at 189° and soluble in alcohol and chloroform.

Isopropylphenylisonitrosoacetic acid, $\text{C}_6\text{H}_4\text{Pr}^\beta\text{-C}(\text{N}\cdot\text{OH})\cdot\text{COOH}$, prepared by treating sodium isopropylbenzoylformate with hydroxylamine, crystallises from its ethereal solution in colourless, lamellar prisms, melts with decomposition at 124° , and dissolves in water, alcohol, and ether.

S. B. A. A.

Synthesis of Hydroxyzanthenes. By S. v. KOSTANECKI and B. NESSLER (*Ber.*, 24, 1894—1897).—Orsellenic acid and paraorsellenic acid both yield the same hydroxymethylxanthone, and this is identical with the salicylresorcinol ether described by Michael (Abstr., 1884, 311). When orcinol is distilled with salicylic acid, besides the above-mentioned hydroxymethylxanthone, which the authors denominate the α -derivative, an isomeride, β -hydroxymethylxanthone, is simultaneously formed; this crystallises from dilute alcohol in colourless needles and melts at 285° . The two hydroxymethylxanthenes have the constitutions $\text{C}_6\text{H}_4\text{<}\overset{\text{O}}{\underset{\text{CO}}{\text{C}}}\text{>C}_6\text{H}_4\text{Me}\cdot\text{OH}$ [$\text{O} : \text{OH} : \text{Me} = 1 : 3 : 5$ and

1 : 5 : 3], although which represents the α - and which the β -compound cannot at present be decided. The β -compound appears also to be formed when the orsellenic acids are distilled with salicylic acid. When resorcinol is distilled with salicylic acid and acetic anhydride, the hydroxyxanthone described by Michael (*loc. cit.*) is obtained as chief product, whilst an *isomeride* which melts at a high temperature, and was not obtained thoroughly pure, is also formed. As Michael's hydroxyxanthone is obtained from resorcinolcarboxylic acid $[(\text{OH})_2 : \text{COOH} = 1 : 3 : 4]$, it must have the constitution $[\text{OH} = 3]$.

1 : 3-*Isoeuzanthone*, $\text{C}_{13}\text{H}_8\text{O}_2(\text{OH})_2$, is formed, together with other products which were not purified, from phloroglucinol and salicylic acid; it is separated from the other compounds by treating the crude product with alkali, and on acidifying the alkaline extract, it is precipitated. It crystallises from dilute alcohol in yellowish needles, and melts at 247° . Experiments are in progress on the action of other phenolic compounds on salicylic acid. A. R. L

The Tannic Acid of Oak-wood. By C. BÖTTINGER (*Annalen*, 263, 108—125).—When the acetyl derivative of oak-wood tannic acid is reduced with sodium amalgam in boiling, dilute alkaline solution, it yields a compound of the composition $\text{C}_{15}\text{H}_{18}\text{O}_7$ or $\text{C}_{15}\text{H}_{16}\text{O}_8$ (*hydroquercic acid*), a compound of the composition $\text{C}_7\text{H}_6\text{O}_2$ (*querlactone*), an acid, which is in all probability trihydroxybutyric acid, traces of gallic acid, oxalic acid, acetic acid, and oak-wood tannic acid, and a substance of unknown composition, which very readily undergoes oxidation. On acidifying the solution with sulphuric acid, the hydroquercic acid is obtained as a dirty-brown precipitate; the solution is then repeatedly extracted with ethyl acetate, the extract evaporated, and the residue mixed with water. The portion insoluble in water is dissolved in a little alcohol, and the solution treated with a large volume of ether, when hydroquercic acid and another compound, which is readily soluble in acetic anhydride, are precipitated; the filtered solution is evaporated, the residue dissolved in ether, with the addition of a few drops of light petroleum, and the filtrate evaporated. The residual querlactone is separated from a trace of gallic acid by treating with a little water, and is then freed from the readily oxidisable substance referred to above by dissolving it in ether and shaking the solution with ammonia; the oxidisable substance remains in the ethereal solution in combination with some of the querlactone, and on acidifying the ammoniacal solution, the rest of the lactone is liberated as an oil and can be extracted with ether.

Hydroquercic acid, purified by washing with ether, water, and ethyl acetate consecutively, and then dried for two hours in a desiccator, has the composition $\text{C}_{15}\text{H}_{18}\text{O}_7$, but when completely dried in a desiccator, it has the composition $\text{C}_{15}\text{H}_{16}\text{O}_8$; it is precipitated from its solution in acetic acid on the addition of water in a dirty-brown, flocculent condition, has a bitter taste, and is only sparingly soluble in cold water, but moderately easily in boiling water, and readily in alcohol. It dissolves in 20 per cent. nitric acid with evolution of carbonic anhydride, yielding a reddish-yellow solution, and it dissolves

slowly in cold concentrated sulphuric acid with a reddish-brown coloration; in its aqueous or acetic acid solution, bromine produces an intensely yellow precipitate. When heated with 20 per cent. hydrochloric acid at 150° , it gives off carbonic anhydride and methyl chloride yielding a dark substance which dissolves only slowly in alkalis; hydriodic acid at 220 — 225° decomposes it with liberation of carbonic anhydride and methyl iodide, and formation of iodoform and other products. It is hygroscopic, and when heated at 100° , it loses water, which it absorbs again on cooling; heated at 170° , it is converted into a substance which is insoluble in alcohol and dilute acetic acid. The *acetyl* derivative, $C_{15}H_{14}O_6Ac_2$, is a dirty-brown powder. In neutral solutions of the ammonium salt, barium chloride produces a voluminous, amorphous precipitate, which, when dried at 100° , has the composition $(C_{15}H_{15}O_6)_2Ba$; the *lead* salt has the composition $(C_{15}H_{15}O_6)_2Pb$. In neutral solutions of the acid, silver nitrate gives a reddish-brown coloration, and on adding acetic acid to the solution, an acid silver salt is precipitated.

Querlactone, $C_5H_6O_2$, melts at a low temperature and separates from water as an oil; it is very readily soluble in acetic acid, alcohol, ether, and ethyl acetate, but insoluble in benzene and light petroleum. When boiled with barium hydroxide, it is converted into a barium salt which is insoluble in water, but soluble in acetic acid. It reduces ammoniacal silver nitrate in the cold, and is only very slowly decomposed by 20 per cent. hydrochloric acid at 150° ; the *lead* salt has the composition $(C_5H_7O_2)_2Pb$. A compound analogous to querlactone can also be obtained from the acetyl derivatives of oak-bark and pine-bark tannic acids.

The oxidisable substance mentioned above dissolves freely in ether and alcohol, but is only sparingly soluble in benzene and light petroleum; when its ethereal solution is filtered through paper, the latter is coloured intensely red. When the freshly prepared substance is agitated with a drop of concentrated ammonia in the dark, it yields a colourless, seemingly crystalline mass which immediately turns red on exposure to light; it loses this property on keeping. The freshly prepared substance gives an intense rose-red coloration on boiling with silver nitrate, ferric chloride, or copper sulphate, but when it has been kept for some time, it reduces silver nitrate in the cold, and ferric chloride on boiling, without any coloration being produced.

When the acetyl derivative of oak-bark tannic acid is reduced with sodium amalgam as described above, it yields hydroquercic acid, hydroquergalic acid, lagic acid, $C_6H_4O_3$, identical with the compound obtained by the oxidation of gallic acid, trihydroxybutyric acid, a little gallic acid, and other compounds; the hydroquergalic acid can be separated from the hydroquercic acid by treating the mixture of the two compounds with 20 per cent. acetic acid, in which the latter is the more readily soluble.

Hydroquergalic acid is a brownish-red, amorphous compound, readily soluble in boiling water, but only sparingly in cold water and insoluble in boiling alcohol, ether, ethyl acetate, acetic anhydride, and acetic acid; in neutral solutions of the ammonium salt, many

metallic salts produce brown, amorphous precipitates. The acid, dried over sulphuric acid, has the composition $C_{14}H_{14}O_6$, and loses approximately 1 mol. H_2O at 100° ; when heated with alcoholic potash and ethyl iodide, it is partially converted into an ethyl salt, which is readily soluble in alcohol, ethyl acetate, and acetic acid.

F. S. K.

Some Derivatives of Phthalic Sulphinide. By C. W. MOULTON (*Amer. Chem. J.*, 13, 193—203).—Phthalic sulphinide (Abstr., 1885, §39) is best prepared as follows:—Finely powdered naphthalene (1 kilo.) is rubbed up with sulphuric acid (750 grams) in the cold; it is then heated on the water-bath until the naphthalene melts, and kept at this temperature with constant stirring for two hours; the whole is poured into 12 litres of water at 85° , cooled to 50° , filtered through cloth, neutralised with chalk, again filtered, and precipitated with sodium carbonate. It is once more filtered and evaporated to 2 litres, when sodium α -naphthalenesulphonate crystallises on cooling; this is filtered, dried (finally at 185°), powdered, and treated with 80 per cent. of its weight of phosphoric chloride; after driving off the oxychloride on the water-bath, the mass is cooled and washed once with cold water. The chloride is added by degrees to an excess of strong ammonia, kept cool; the excess of ammonia is expelled on the water-bath, and the sulphonamide (450 grams) washed by boiling in 2 or 3 litres of water, cooled, filtered, and dried. To oxidise the sulphonamide, potassium hydroxide (180 grams) and potassium permanganate (900 grams) are dissolved in 12 litres of water at 40° and 200 grams of the amide stirred in; the mixture is kept at 60 – 100° until the permanganate is reduced; after filtering and washing the manganese dioxide by boiling it in water, hydrochloric acid is added to the mixed filtrate and washings, until they are nearly neutral; the whole is evaporated to 1 litre, and excess of hydrochloric acid added, when the acid potassium salt of the sulphinide crystallises; it is recrystallised from water and boiled (25 grams) with water (450 c.c.) and hydrochloric acid (50 c.c. of sp. gr. 1.175) for 15 minutes and slowly evaporated to obtain the phthalic sulphinide. The yield of the acid potassium salt is 40–45 grams.

When phthalic sulphinide is heated for some time with hydrochloric acid, it is converted into acid ammonium sulphophthalate (Compare Remsen and Burton, Abstr., 1890, 94.)

When phthalic sulphinide is dissolved in an alcohol and the solution saturated with hydrogen chloride and boiled, the corresponding alkyl salt of sulphaminephthalic acid is obtained.

Dimethyl α -sulphaminephthalate, $SO_2NH_2 \cdot C_6H_3(COOMe)_2$, crystallises in long, narrow, very thin plates, which have a characteristic nacreous lustre when dried on the filter; it melts at 135° and dissolves in hot water.

Diethyl α -sulphaminephthalate forms long, needle-shaped crystals arranged in bundles; it melts at 101.5 – 102° , and is less soluble in water and less stable than the dimethyl derivative.

Dipropyl α -sulphaminephthalate is difficult to crystallise; those crystals which were obtained, melted between 64° and 68° , the latter temperature being more probably correct.

Crystals of $\text{SO}_2\text{NH}_2\cdot\text{C}_6\text{H}_4(\text{CONH}_2)_2$ were obtained when the diethyl salt was treated with excess of ammonia in the cold for 24 hours, and then heated and concentrated on the water-bath. When these crystals were dissolved in water and acidified, *carbamine sulphinide*, $\text{CONH}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_2\text{NH}$, was precipitated; this compound forms tabular crystals, melts at 275° (uncorr.), and dissolves in water somewhat sparingly, and in boiling alcohol slightly, but not in ether; the *ammonium*, *barium*, and *silver* salts are described.

α -Sulphophthalic acid was prepared by converting the acid ammonium salt, obtained from phthalic sulphinide (see above), into chloride by phosphoric chloride, and boiling this with water; it is very soluble in water and in absolute alcohol, but not in ether; it is difficult to crystallise; some crystals which were obtained melted at $62\text{--}64^\circ$. Attempts to obtain an anhydride of sulphophthalic acid failed.

A. G. B.

Symmetrical Alkylisophthalic Acids. By O. DOEBNER (*Ber.*, 24, 1746—1753).—Attempts to isolate the intermediate product of the reaction between pyruvic acid and an aldehyde in the presence of barium hydroxide have led to negative results; its formation is, however, indicated by the fact that a purer ultimate product is obtained when the mixture is boiled for a longer period than that previously given (*Abstr.*, 1890, 1283). Ethylisophthalic acid is prepared by boiling together a mixture of pyruvic acid (50 grams), propaldehyde (16 grams), and barium hydroxide (120 grams) dissolved in water (1 litre) for 15—20 hours in a reflux apparatus; it is isolated as already described (*loc. cit.*), and is best purified by crystallisation from a mixture of acetone and water (equal parts); it melts at 263° . The *barium salt* separates from concentrated aqueous solutions in needle-shaped crystals containing 5 mols. H_2O ; it loses $3\frac{1}{2}$ mols. H_2O at 140° , but the remainder is not expelled by heating at 200° ; whilst the *calcium salt* forms prismatic crystals containing 3 mols. H_2O , and is easily soluble in water.

Isopropylisophthalic acid is produced from pyruvic acid (50 grams) and isobutaldehyde (20 grams); the yield is 10 grams, or about double that previously obtained. It is best purified by repeated crystallisation from dilute acetone, and then melts at 285° . The *barium salt* forms small, hygroscopic, prismatic crystals which contain $2\frac{1}{2}$ mols. H_2O , and retain $\frac{1}{2}$ mol. H_2O when heated at 200° ; the *calcium salt* forms small crystals containing $2\frac{1}{2}$ mols. H_2O , easily soluble in water; the *silver salt* is a white powder containing 1 mol. H_2O , insoluble in water; whilst the *lead*, *copper*, and *mercury salts* are amorphous precipitates sparingly soluble in water. Isopropylbenzene and carbonic anhydride are obtained when the calcium and other salts are heated.

Isobutylisophthalic acid is prepared from pyruvic acid (50 grams) and isovaleraldehyde (25 grams); the yield of pure acid is 8 grams. It separates from dilute acetone in small, colourless plates, and melts at 269° . The *barium salt* forms hygroscopic, prismatic crystals containing 3 mols. H_2O , and is easily soluble in water; it loses $2\frac{1}{2}$ mols.

H_2O at 140° . The *calcium salt* crystallises from a small quantity of water with 2 mols. H_2O ; whilst the *silver salt* is a white, anhydrous precipitate, sparingly soluble in water.

Phenylisophthalic acid is obtained by boiling pyruvic acid (50 grams) and benzaldehyde (30 grams) with the above-mentioned quantity of barium hydroxide solution for 15 hours. As the barium salt is sparingly soluble in hot water, the chief portion occurs in admixture with the precipitate of barium oxalate and carbonate; the yield of pure acid is 8 grams. The *barium salt* crystallises in small needles containing $4\frac{1}{2}$ mols. H_2O ; it loses $3\frac{1}{2}$ mols. H_2O at 140° ; the *calcium salt* forms small, anhydrous crystals, and is sparingly soluble in water; whilst the copper salt is a bluish-green, and the *silver* and *lead* salts are white precipitates which are sparingly soluble in water. Phenylisophthalic acid is the only known dicarboxyl-derivative of diphenyl which contains both the carboxyl groups in one nucleus.

Furfurisophthalic acid, $\text{C}_4\text{OH}_3\cdot\text{C}_6\text{H}_3(\text{COOH})_2$, is produced by the action of barium hydroxide solution on a mixture of pyruvic acid (50 grams) and furfuraldehyde (28 grams); the yield is only 1 gram; it crystallises from dilute acetone in dense, glistening needles, melts at 290° with decomposition, and is sparingly soluble in water, readily in alcohol, ether, acetone, and benzene. The *barium salt* is soluble in hot water; whilst the lead, silver, and copper salts are sparingly soluble precipitates.

A. R. L.

Stereo-isomeric Methylphenylsuccinic Acids. By N. ZELINSKY and L. BUCHSTAB (*Ber.*, 24, 1876—1880).—*Ethyl α -bromophenylacetate* boils at 150 — 151° under a pressure of 10—15 mm.

Ethyl methylphenylcyanosuccinate, $\text{COOEt}\cdot\text{CMe}(\text{CN})\cdot\text{CHPh}\cdot\text{COOEt}$, is prepared by dissolving ethyl α -cyanopropionate (b. p. 195 — 200°) and sodium in equivalent proportion in alcohol, and gradually adding ethyl α -bromophenylacetate (1 mol.). Much heat is developed, causing the mixture to boil; the reaction is completed by heating on the water-bath for 2—3 hours, water is then added, and the heavy oil which separates extracted with ether. On distilling the ethereal solution, the compound is obtained as an oil boiling at 320 — 330° . When heated with aqueous potash, and the alkaline liquid washed with ether, acidified with hydrochloric acid, and then extracted with ether, an oily product, probably a tricarboxylic acid, is obtained; when the latter is dissolved in concentrated sulphuric acid, water added to incipient turbidity, and the mixture boiled for some time, *methylphenylsuccinic acid* separates in crystals.

Methylphenylsuccinic acid may be separated into two isomerides by fractional crystallisation from water; the less soluble modification, which is formed in the larger quantity, melts at 192 — 193° , at the same time losing water and forming the anhydride, whilst the more soluble modification melts at 170 — 171° .

When methylphenylsuccinic acid (m. p. 192 — 193°) is slowly brought to a temperature of 120 — 130° , water is eliminated, and on quickly raising the temperature to 310 — 320° the anhydride passes over as an oil. When the latter is boiled with water, it dissolves and methylphenylsuccinic acid (m. p. 192 — 193°) separates on cooling, whilst the

acid (m. p. 170—171°) is obtained from the filtrate. On the other hand, the acid (m. p. 170—171°) is exclusively formed when the anhydride is exposed to the air. The electrical conductivities are as follows:—

Methylphenylsuccinic acid (m. p. 170—171°) k 0.0233.

„ „ (m. p. 192—193°) k 0.0372.

The strongly negative character of the phenyl group is exemplified in the much higher values obtained in the case of the above-described acids, compared with those obtained with the two dimethylsuccinic acids (*Zeit. physikal. Chem.*, 5, 405). The question whether the anhydride exists in two stereo-isomeric modifications is still open.

A. R. L.

Action of Urea on Sulphanilic Acid. By J. VILLE (*Compt. rend.*, 112, 868—870).—An intimate mixture of finely-powdered urea (1.5 mols.) and sulphanilic acid (1 mol.) becomes pasty at 105°, begins to melt at about 110°, but becomes solid again at 115—120°. If heated for three or four hours at 125°, ammonia is evolved; the product, after cooling, is dissolved in water, mixed with barium hydroxide, and allowed to remain in a vacuum over sulphuric acid for 48 hours, in order to decompose the ammonium salt that has been formed. Excess of barium is removed by means of carbonic anhydride, and the concentrated filtrate, when mixed with alcohol, yields a precipitate of the barium salt which can be purified by repeated solution in water and precipitation by alcohol, and from which the acid is obtained by treatment with the calculated quantity of sulphuric acid. The filtered liquid is evaporated on a water-bath, and afterwards in a dry vacuum, when *sulphanilicocarbamic acid*, $C_7H_5N_2SO_4$, separates in feathery, microscopic lamellæ, very soluble in water, somewhat easily soluble in acids, but quite insoluble in ether, chloroform, and benzene. It is strongly acid, decomposes carbonates, and forms crystallisable salts. The barium salt crystallises with 3 mols. H_2O in monoclinic prisms, soluble in water, but insoluble in alcohol; it becomes anhydrous at 95°, and then has the composition

When the acid is heated in sealed tubes at 100° with excess of barium hydroxide solution, it yields ammonia, carbonic anhydride, and sulphanilic acid in equal molecular proportions. This decomposition and its mode of formation show that the acid has the constitution $SO_3H \cdot C_6H_4 \cdot NH \cdot CO \cdot NH_2$.

C. H. B.

Nitrocymenesulphonic Acids. By G. FERRERA (*Gazzetta*, 21, 65—76).—*Nitro- α -cymenesulphonic acid* (compare Abstr., 1890, 1287), when perfectly pure, crystallises in pale-yellow needles free from any reddish tinge, and its aqueous solution is not reddened by light. The pure barium salt crystallises in slender, silky, yellow needles containing 1 mol. H_2O ; the pure magnesium salt crystallises in bright-yellow tables containing 5 mols. H_2O ; the lead salt in bright-yellow needles containing 1 mol. H_2O ; the zinc salt in large, pale-yellow,

rhombic tables containing 6 mols. H_2O , and the *calcium* salt in yellow plates with 1 mol. H_2O .

The *lead* salt of amido- α -cymenesulphonic acid crystallises in red nodules with 4 mols. H_2O . On diazotising this acid, *diazo- α -cymenesulphonic acid* is formed, and separates in very slender needles. It is decomposed by treatment with absolute alcohol with the formation of Widman's ethoxy- α -cymenesulphonic acid. The *barium* salt of this acid is soluble in water, and crystallises in silvery plates containing $3\frac{1}{2}$ mols. H_2O . The *barium* salt of chloro- α -cymenesulphonic acid (Abstr., 1890, 1287) crystallises in colourless, lustrous plates containing 3 mols. H_2O .

The authors previously isolated (*loc. cit.*) from the mother liquors obtained in the preparation of barium nitrocymenesulphonate an abnormal magnesium salt crystallising with 6 mols. H_2O , but otherwise identical in composition with the normal salt. The *barium* salt corresponding to this modification crystallises with 5 mols. H_2O ; the *lead* salt, $(\text{NO}_2 \cdot \text{C}_6\text{H}_4\text{PrMe} \cdot \text{SO}_3)_2\text{Pb} \cdot 5\text{H}_2\text{O}$, crystallises in small, pale, yellowish needles; the *zinc* salt forms small needles containing 6 mols. H_2O ; and the *calcium* salt almost colourless needles with 9 mols. H_2O . These salts cannot be converted into the corresponding normal nitrocymenesulphonates, with which they are probably isomeric. The acids derived from both series of salts, however, seem to yield the same amido-derivative.

S. B. A. A.

Unsaturated Sulphones. By R. OTTO (*Ber.*, 24, 1510).—Unsaturated sulphones are readily obtained by the action of sodium benzenesulphinate or paratolylsulphinate on allyl chloride. *Phenylallylsulphone* is an oil, but *paratolylallylsulphone* crystallises in splendid monosymmetric prisms or tablets, and melts at $52-53^\circ$. Both compounds readily combine with bromine, forming additive compounds.

H. G. C.

Certain Sulphone Derivatives and their Hydrolysis in Alkaline Solution. By W. AUENRIETH (*Ber.*, 24, 1512-1519).—In continuation of the work done by Stuffer (this vol., p. 180) and by himself (this vol., p. 567), the author has prepared some new sulphone derivatives and examined their behaviour towards alkalis, and has also been able to confirm the statement of Stuffer that in hydrolysing ethylsulphonesulphonal all the sulphone groups are eliminated as ethylsulphinic acid, no methylphenylsulphone being formed.

Ethylsulphonephenylsulphonal, $\text{CMe}(\text{SO}_2\text{Ph})_2\text{CH}_2\text{SO}_2\text{Et}$, is obtained by carefully oxidising the phenylmercaptale of thiethylacetone (this vol., p. 567), and crystallises from alcohol or ether in small, lustrous needles, melts at $138-139^\circ$, is sparingly soluble in boiling water and in cold alcohol and ether, readily in chloroform. It is readily hydrolysed by decinormal potash solution, 2 mols. of benzenesulphinic acid and 1 mol. of ethylsulphinic acid being formed.

In the author's previous paper, the preparation of the phenylmercaptale of thiophenylacetone was described. A much better yield of this compound is obtained by passing a slow current of hydrogen chloride into an ice-cold mixture of thiophenylacetone and phenylmercaptan, pouring the product after some hours into water, and re-

crystallising the precipitated compound from alcohol. No reaction takes place between this compound and potassium permanganate in aqueous solution, but on addition of benzene, oxidation slowly takes place, $\alpha\beta$ -diphenylsulphone- β -thiophenylpropane,

being formed. The latter crystallises from alcohol in slender needles, melts at 156 — 157° , and is sparingly soluble in other and cold alcohol, readily in chloroform. On treatment with potash, it yields methylphenylsulphone, phenylmercaptan, and benzenesulphinic acid. All attempts to convert the remaining thiophenyl group into a sulphone group were without success. The compound is also probably identical with that obtained by Otto and Rössing by the oxidation of phenylsulphoneacetone- α -mercaptol (this vol., p. 368).

From the results described in this and in previous papers, it appears that whilst the sulphones of the general formula $\text{CR}_2(\text{SO}_2\text{R})_2$ are stable towards alkalis, the addition of the groups SO_2Ph , SO_2Et , or of chlorine, has such an effect on the molecule that all three sulphone groups are eliminated by an alkali in the form of a sulphinic acid. Further, disulphonesulphides of the formula

behave towards alkalis in a similar manner to alkylene sulphones with adjacent sulphone groups, only one of these being eliminated as a sulphinic acid.

H. G. C.

Action of Phenylhydrazine on Ethyl Chloromalonate. By R. BURMEISTER and A. MICHAELIS (*Ber.*, 24, 1800—1802).—When ethyl chloromalonate (1 mol.) and phenylhydrazine (3 mols.) are mixed together, separation of phenylhydrazine hydrochloride and slow evolution of nitrogen take place. After two days, the former is filtered off, the filtrate extracted repeatedly with ether, and the ethereal solution washed several times with dilute hydrochloric acid. On evaporation, an oil is obtained which quickly solidifies, and after recrystallisation from hot ether forms colourless needles, melts at 90° , and reduces Fehling's solution on boiling. It has the composition $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O}_4$, and combines directly with phenyl cyanate and phenylthiocarbimide, forming the crystalline additive compounds $\text{C}_{18}\text{H}_{16}\text{N}_2\text{O}_4$ and $\text{C}_{18}\text{H}_{14}\text{N}_2\text{O}_3\text{S}$. The former crystallises in colourless needles and melts at 158° , whilst the latter forms transparent prisms and melts at 141° .

The original product of the reaction dissolves readily in aqueous or alcoholic potash, and the former solution on addition of hydrochloric acid at once yields a compound crystallising in glistening plates, which, after recrystallising from alcohol, melts at 192° , and has the composition $\text{C}_9\text{H}_8\text{N}_2\text{O}_2$. It differs, therefore, from the first compound by containing the elements of alcohol less.

The constitution of these substances is not yet finally settled, but the authors believe they are probably derivatives of an amido-dihydroindoxyle, $\text{C}_6\text{H}_4 \cdot \text{N}(\text{NH}_2) \cdot \text{CH}(\text{OH}) \cdot \text{CH}_3$. The compound melting

at 90° is probably $C_6H_4<\frac{N(NH_2)}{CH(OH)}>CH\cdot COOEt$, and is formed in the following manner:—

The carbonyl group of this compound is then reduced by the action of the third mol. of phenylhydrazine, nitrogen being simultaneously evolved.
H. G. C.

Synthesis of Indigotindisulphonic Acid (Indigocarmine). by B. HEYMANN (*Ber.*, 24, 1476—1478).—It has already been shown by Heymann (this vol., p. 75) that phenylglycocine may be converted into indigotin by fusion with caustic potash and oxidation of the resulting leuco-compound. Other dehydrating agents, such as sulphuric acid and zinc chloride, do not have the same effect. The author finds, however, that if, instead of concentrated sulphuric acid, fuming acid be employed, indigotindisulphonic acid is readily obtained. This may be shown on the small scale by gently warming phenylglycocine with fuming sulphuric acid in a test-tube, a yellow solution being obtained which when poured on to ice shows the characteristic colour of indigocarmine solution.

On the large scale, the following method is adopted:—1 part of phenylglycocine is mixed with 10—20 parts of sand, and 20 times the quantity of sulphuric acid containing 80 per cent. of anhydride gradually added, the temperature not being allowed to rise above 30°. The yellow solution, on addition of ordinary concentrated sulphuric acid, evolves sulphurous anhydride, and assumes the deep blue colour of indigo; ice is then added, and the colouring matter precipitated by addition of common salt. The yield of pure indigocarmine thus obtained is about 60 per cent. of the phenylglycocine employed.

The mechanism of the reaction is not yet clear; possibly the sulphonic acid of indoxyle sulphate is first formed, and on addition of sulphuric acid undergoes the following reaction:—

Hydrobenzoïns and their Anhydrides. By K. AUWERS (*Ber.*, 24, 1776—1783).—The author has repeated the experiments of Zincke (*Abstr.*, 1880, 114), in the hope of obtaining again the substances prepared in small quantity by him, as these might possibly be isomerides of benzoïn and benzile. This expectation has, however, not been fulfilled, but a number of other observations have been made in the hydrobenzoïn group, and are given in this paper.

Concentrated nitric acid of sp. gr. 1·4 acts on both hydrobenzoïns at the ordinary temperature or even at 0°, with formation of benzoïn.

The oxidation takes place more slowly with the iso-compound, and the product is also frequently oily for a short time, but crystallises eventually to a magma of needles. If the mixture be slightly warmed, the oxidation product of isohydrobenzoin cannot be obtained crystalline. The anhydrides are attacked in a similar manner at the ordinary temperature. A mixture of equal volumes of fuming nitric acid and acetic acid has the same effect as nitric acid alone, but a cold acetic acid solution of potassium dichromate or dilute potassium permanganate solution, like chromic anhydride, converts both compounds into benzaldehyde.

Bromine acts on both hydrobenzoins in acetic acid solution at 100° with formation of benzile and smaller quantities of stilbene bromide. A somewhat similar reaction has been observed by Pechmann (*Abstr.*, 1890, 1222). Both compounds also unite directly with orthotolyl cyanate on heating at 100° under pressure, yielding additive compounds having the formula $(\text{CHPh}\cdot\text{O}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{Me})_2$. That obtained from hydrobenzoin crystallises in colourless needles melting at 233–234°, and that from the iso-compound in small needles melting at 163°.

When stilbene bromide is heated with alcoholic potassium hydro-sulphide, the oily product obtained is stilbene, and not, as would be expected, bromostilbene or tolane (see also Forst and Zincke, this *Journal*, 1876, ii, 634).

In the preparation of the anhydrides by Zincke's method, diphenyl-acetaldehyde, $\text{CHPh}_2\cdot\text{CHO}$, is always obtained as a bye-product. On treatment with hydroxylamine, it yields *diphenylucetaldoxime*, $\text{CHPh}_2\cdot\text{CH}\cdot\text{NOH}$, which forms slender, white needles and melts at 120°. A small quantity of another substance containing nitrogen is also formed in the reaction, but the amount was insufficient to determine whether it was an isomeric oxime.

The molecular weights of the anhydrides as determined by Raoult's method agree with the double formula $\text{C}_{28}\text{H}_{24}\text{O}_3$, and these are, therefore, in all probability ether-like compounds having the constitution $\text{CHPh}\cdot\text{O}\cdot\text{CHPh}$
 $\text{CHPh}\cdot\text{O}\cdot\text{CHPh}$. The hydrobenzoin anhydride is best prepared by gently warming hydrobenzoin with half its weight of phosphoric anhydride, adding water, and recrystallising the insoluble portion from alcohol.

In order to obtain comparative molecular weights of other anhydrides, those of the dimethylsuccinic acids were examined by Raoult's method. In both cases the results agreed with the simple formula $\text{C}_8\text{H}_8\text{O}_3$.
 H. G. C.

Aldehyde-green. By W. v. MILLER and J. PLÖCKL (*Ber.*, 24, 1700–1715).—Aldehyde-green was discovered by Cherpín in 1862, and was shown to contain sulphur by Hofmann (*Ber.*, 3, 761), who ascribed to it a provisional formula. Lucius, however (*Würtz Dict.*, 1, 234), states that it does not contain sulphur, as it is produced by the action of aldehyde on an acid solution of rosaniline, the function of the sodium thiosulphate subsequently used being merely to precipitate the blue and violet dyes which are formed simultaneously.

Aldehyde-blue, prepared by Gattermann and Weichmann's method (Abstr., 1890, 503), is precipitated from its aqueous solution by sodium chloride, and when the filtrate has a blue colour this is due to the use of too little precipitant and not to the presence of a second blue dye, as stated by Gattermann and Weichmann; the green dye, however, which these chemists obtained from the same filtrate, exists ready formed, and separates, after a time, or more quickly when it is heated; it is probably identical with the non-sulphuretted aldehyde-green (see below). Aldehyde-blue has the composition $C_{31}H_{37}N_3O_2Cl$; it is not a quinaldine derivative, as stated by Gattermann and Weichmann (*loc. cit.*), but the hydrochloride of an anhydroaldolpararosaniline, $OH \cdot C(C_6H_4 \cdot N \cdot CH \cdot CH_2 \cdot CHMe \cdot OH)_3$; a similar blue dye is formed from isobutaldehyde and pararosaniline.

When pararosaniline (50 grams), concentrated hydrochloric acid (200 grams), and paraldehyde (100 grams) are heated together on the water-bath for three hours, a brownish solution is formed; this is diluted to 4 litres, saturated with hydrogen sulphide, and an excess of sulphurous acid added, when a resinous mass, together with sulphur, separates out. It is filtered, and the operation repeated; on adding ammonia to the filtrate, a colourless base separates, which is spread on a porous tile, and then dried at 65° in a current of hydrogen; it is soluble in acids, ether, alcohol, and benzene, and has the composition $C_{31}H_{35}N_3 + \frac{1}{2}H_2O$; the yield is 35—45 grams. The compound is the leuco-base of a green dye, which latter is produced on treating it with lead peroxide in an acid solution, or with chloranil in an alcoholic solution; it has the constitution $C_6NH_5Me \cdot CH(C_6NH_5Me)_2$, and thus contains one quinaldine and two dihydroquinaldine residues. When the base is dissolved in dilute hydrochloric acid and treated with nitrous acid, a resinous substance is formed, which is soluble in ether, but does not yield the dye on oxidation. The *monobenzoyle derivative* is prepared by dissolving the base in benzene, gradually adding benzoic chloride, and shaking the mixture with aqueous soda; it is hydrolysed when heated at 120° with concentrated hydrochloric acid. When the base is dissolved in glacial acetic acid, and treated with bromine, a brown, amorphous substance is obtained; this does not yield a dye on oxidation; when, however, it is treated with tin and hydrochloric acid, a base giving a green dye on oxidation is formed, and when boiled with tin and hydrochloric acid, a base giving a blue dye on oxidation is obtained. That the above-described leuco-base is not quite a homogeneous substance, is seen by the following:—When an ethereal solution of it is mixed with one of chloranil, a deep-blue colour is produced, and, later, flocks of a coppery lustre separate, whilst the green dye is obtained from the filtrate by evaporation; the composition of these dyes could not be determined with certainty. When aldehyde-blue is heated at 70° with concentrated hydrochloric acid, and alcohol added, a green coloration is produced; isobutaldehyde-blue gives no such coloration. The directions given by Lucius for the preparation of aldehyde-green are as follows:—Pararosaniline (8 grams) is dissolved in dilute sulphuric acid (20 grams of acid to 30 grams of water), and heated at 50° with aldehyde (40 grams) until a drop of the mixture yields a greenish-blue colour with alcohol.

If instead of treating this solution, diluted to $1\frac{1}{2}$ litres, with hydrogen sulphide and sulphurous anhydride, as Lucius directs, sodium chloride is added, a blue dye is precipitated, and on adding sodium acetate to the filtrate from this, a green dye separates. The latter is air-dried, washed with water, and twice dissolved in alcohol and reprecipitated with ether; it is then shaken with dilute ammonia, collected and washed, and after again dissolving in alcohol and reprecipitating with ether, it is dried in a current of hydrogen at 55° . It has the composition represented by the formula

and is the parent compound of ordinary aldehyde-green (see below), which it resembles, but is more fugitive towards light; its production, therefore, explains Lucius' observation that aldehyde-green does not contain sulphur. Aldol reacts with diamidotriphenylmethane, and a leuco-base, $\text{CHPh}(\text{C}_6\text{H}_4\cdot\text{N}\cdot\text{CH}\cdot\text{CH}_2\cdot\text{CHMe}\cdot\text{OH})_2$, is formed; this, on oxidation, yields a green dye closely resembling that obtained by the preceding method.

When pararosaniline is dissolved in dilute sulphuric acid and heated with aldehyde (as above) at 50° for three hours, and the product is poured into hydrogen sulphide solution (3 litres) heated to 90° , and sulphurous acid (200 grams) added, the mixture being then boiled for some time, a blue dye separates on adding sodium chloride (300 grams); sodium acetate then precipitates aldehyde-green from the filtrate; the latter has the constitution

When the non-sulphuretted green, prepared from ordinary rosaniline and aldehyde, is boiled with a solution of sodium thiosulphate (Cherpin's method), Usèbe's aldehyde-green is formed, and is isolated in the same manner as the last-described colouring matter; it has the

A. R. L.

A Closed Chain Analogue of Ethylene. By E. BAMBERGER and W. LÖTHER (*Ber.*, 24, 1887—1888).—The authors come to the conclusion that dihydronaphthylene is an analogue of ethylene. It combines with hypochlorous acid forming *tetrahydronaphthylene chlorhydrin*, $\text{C}_6\text{H}_4 \begin{smallmatrix} \text{CH}_2 & \text{---} & \text{CH}_2 \\ | & & | \\ \text{CH}(\text{OH}) & \cdot & \text{CHCl} \end{smallmatrix}$; this yields a crystalline *ammonium derivative*, $\text{C}_6\text{H}_4 \begin{smallmatrix} \text{CH}_2 & \text{---} & \text{CH}_2 \\ | & & | \\ \text{CH}(\text{OH}) & \cdot & \text{CH}\cdot\text{NMe}_3\text{Cl} \end{smallmatrix}$ corresponding with choline hydrochloride.

When tetrahydronaphthylene chlorhydrin is treated with alkalis, three *isomerides* of the formula $\text{C}_{10}\text{H}_{10}\text{O}$, a *dihydric alcohol*, $\text{C}_{10}\text{H}_{12}\text{O}_2$, and naphthalene are formed according to the conditions of the experi-

ment. The initial product, *tetrahydronaphthylene oxide*, $C_{10}H_{10}O$, is a crystalline, comparatively easily volatile compound, and is of especial interest as the first representative of closed ring oxides. The strain which prevails within the molecule, and thereby the tendency to disrupt the union by means of oxygen of the two carbon atoms, causes it to combine with other radicles; thus, when added to a solution of ferric chloride, a precipitate of ferric oxide is produced, whilst the compound unites with the elements of hydrogen chloride. Further details will be given later.

A. R. L.

Decomposition of some Diazo-compounds of Naphthalene with Alcohol. By W. R. ORNDORFF and F. L. KORTRIGHT (*Amer. Chem. J.*, 13, 153–164).—*α*-Diazonaphthalene sulphate was prepared by mixing *α*-naphthylamine (10 grams) with water and sulphuric acid (40 grams), and passing nitrous fumes into the cooled mixture as long as they were absorbed; the liquid was filtered quickly, alcohol and ether added, and the mixture cooled in ice and salt until the sulphate crystallised. The yield was 79 per cent. of the theoretical. The sulphate crystallises in light-yellow, flat needles, and explodes feebly at 115° ; it dissolves easily in water, slightly in alcohol, and not at all in ether; it becomes green on exposure to light. When it was heated at 70 – 75° with alcohol, nitrogen was evolved, together with some aldehyde; by subsequently distilling off the alcohol, then distilling the residue with steam, and further treating this distillate, naphthalene (40 per cent. of the diazonaphthalene sulphate taken) and *α*-ethoxynaphthalene (b. p. 277° at 748 mm.; sp. gr. 1.0746 at $0^{\circ}/4^{\circ}$; 23 per cent. of the sulphate taken) were obtained. The identity of the latter compound was confirmed by preparing it from *α*-naphthol, after Henriques' method (*Annalen*, 244, 72). When *α*-diazonaphthalene sulphate is heated with water at 80 – 90° , nitrogen is evolved, whilst a colouring matter, some tar, and *α*-naphthol are formed.

β-Diazonaphthalene sulphate is prepared similarly to the *α*-salt, but a large excess of sulphuric acid is necessary; the yield is 74 per cent. of the theoretical. It forms flat, needle-shaped, yellow, biaxial crystals, which can be obtained nearly white by recrystallisation, but become green, and finally brown on exposure to light; it explodes feebly at 115° . When decomposed by alcohol, it yields about 30 per cent. in the form of *β*-ethoxynaphthalene and 7 per cent. in the form of naphthalene, a small quantity of *β*-naphthol being formed at the same time. When it is heated with water, the same reaction takes place as in the case of the *α*-salt. The action of hydrochloric acid (40 per cent.) on *β*-diazonaphthalene sulphate at the ordinary temperature converts about 50 per cent. of the salt into *β*-chloronaphthalene, a considerable quantity of *β*-naphthol being also formed.

β-Diazonaphthalene nitrate, obtained (53 per cent. of theoretical yield) by diazotising a well-cooled mixture of *β*-naphthylamine (10 grams), water, and nitric acid of sp. gr. 1.426 (10 grams), crystallises in flat, yellow needles, from a mixture of water, alcohol, and ether; it dissolves in water, but not in absolute alcohol or ether; it

becomes red in light, and explodes at 100° or by percussion. When decomposed by alcohol, about 26 per cent. of it is converted into β -ethoxynaphthalene, and 7 per cent. into naphthalene, a small quantity of nitro- and dinitro-naphthol being formed at the same time.

β -Ethoxynaphthalene melts at 37° , not 33° (Schaeffer, *Annalen*, 152, 287).

The above results indicate that with the diazonaphthalene compounds, when the diazo-group is in the α -position, the tendency is towards the introduction of hydrogen, resulting in the formation of naphthalene, when they are decomposed by alcohol; but when the diazo-group is in the β -position, the tendency is towards the introduction of the ethoxy-group, in place of the diazo-group, resulting in the formation of an ethoxynaphthalene (compare Remsen and others, *Abstr.*, 1888, 268; 1889, 975). A. G. B.

Orthoazo-compounds of α -Naphthol (β -Naphthaquinone Hydrazones). By E. NOELTING and E. GRANDMOUGIN (*Ber.*, 24, 1597—1600).—These compounds were prepared to compare their colours with those of the compounds of the para-series.

Parasulphophenylazo- α -naphthol, $\text{OH}\cdot\text{C}_{10}\text{H}_7\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_3\text{H}$ [$\text{OH}:\text{N}_2 = 1:2$; $\text{SO}_3\text{H}:\text{N}_2 = 1:4$], is obtained by shaking β -naphthaquinone (1 mol.) suspended in acetic acid with a cold concentrated aqueous solution of sodium paraphenylhydrazinesulphonate (1 mol.). A red precipitate of the sodium salt is obtained. The sodium salt is sparingly soluble in alcohol and cold water, easily in boiling water, and crystallises in beautiful red prisms. The free acid is obtained by adding hydrochloric acid to a solution of the sodium salt. In an acid bath, the azo-compound dyes silk and wool a beautiful ponceau colour. It is a position isomeride of orange No. 1. In general the orthohydroxyazo-dyes of α -naphthol are red; the parazo-dyes are yellowish-brown.

$\text{OH}\cdot\text{C}_{10}\text{H}_7(\text{SO}_3\text{H})\cdot\text{N}_2\cdot\text{Ph}$ [1 : 4 : 2] is a ponceau colour,

$\text{OH}\cdot\text{C}_{10}\text{H}_7(\text{SO}_3\text{H})\cdot\overset{\text{a}}{\text{N}}_2\cdot\text{C}_{10}\text{H}_7^{\text{a}}$ [1 : 4 : 2]

is an orseille red, $\text{OH}\cdot\text{C}_{10}\text{H}_7(\text{SO}_3\text{H})\cdot\text{N}_2\cdot\text{C}_{10}\text{H}_7^{\text{b}}$ is a ponceau. $\text{OH}\cdot\text{C}_{10}\text{H}_7\cdot\text{N}_2\cdot\text{C}_{10}\text{H}_6\cdot\text{SO}_3\text{H}$ [1 : 2] (from β -naphthaquinone and the hydrazine of naphthionic acid) is a bluish orseille red, whilst the [1 : 4] compound (from diazonaphthionic acid and α -naphthol) is brown.

Orthophenylazo- α -naphtholmetacarboxylic acid,

$\text{OH}\cdot\text{C}_{10}\text{H}_7\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ [$\text{N}_2:\text{COOH} = 1:3$],

is obtained by shaking β -naphthaquinone suspended in 10—15 times its weight of acetic acid with metahydrazinebenzoic acid suspended in water. It is necessary to use the pure hydrazinebenzoic acid. It is insoluble in water, but soluble in alkaline hydroxides and barium hydroxide, and dissolves in concentrated sulphuric acid to a reddish-brown liquid, which turns red on addition of a little water, and then precipitates the compound unchanged. It is insoluble in most solvents in the cold, and is purified by crystallisation from aniline;

from alcohol, it crystallises in prisms, coagulates at 200° , and melts at 260° with evolution of gas. It dyes silk and wool a bluish-red, and fibre mordanted with chromic oxide can be dyed with it. The *acetate*, $\text{OAc} \cdot \text{C}_{10}\text{H}_7 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{COOH}$, is obtained by boiling the above compound with acetic anhydride and sodium acetate in a reflux apparatus. It is easily soluble in alcohol, sparingly in benzene and acetic acid, crystallises from benzene in yellowish-orange crystalline masses, melts at 210° , and gives a red solution with concentrated sulphuric acid.

The *isomeric para-compound* $[\text{OH} : \text{N}_2 = 1 : 4]$ is obtained by the action of diazotised amidobenzoic acid on α -naphthol. It is a black powder with a green, metallic lustre, dissolves easily with a brown colour in alcohol and aniline, and is insoluble in benzene. With concentrated sulphuric acid, it gives a bluish-violet coloration, which, on addition of water, changes to red. It imparts a brown colour to silk and wool in an acid bath and to cotton mordanted with chromic oxide in a neutral bath.

E. C. R.

Molecular Change in the Formation of Disazo-compounds of α -Naphthol. By E. NOELLING and E. GRANDMOUGIN (*Ber.*, 24, 1601—1605).—In attempting to compare the disazo-compounds formed from the naphthaquinone hydrazone of metamidobenzoic acid and paramidobenzenesulphonic acid with diazobenzene with those from phenylazo- α -naphthol and the diazo-compound of amidobenzoic acid and sulphanilic acid respectively, a curious intramolecular change was observed to take place in the case of the latter reaction, and instead of the normal products, there were obtained phenyldisazo- α -naphthol, $\text{OH} \cdot \text{C}_{10}\text{H}_7 \cdot (\text{N}_2\text{Ph})_2$, $[1 : 2 : 4]$, together with disazo- α -naphthol-metamidobenzoic acid, $\text{OH} \cdot \text{C}_{10}\text{H}_7 \cdot (\text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{COOH})_2$, $[1 : 2 : 4]$, and disazo- α -naphthol-sulphanilic acid, $\text{OH} \cdot \text{C}_{10}\text{H}_7 \cdot (\text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{H})_2$, $[1 : 2 : 4]$, respectively.

Diazobenzene Chloride and β -Naphthaquinonehydrazonebenzoic Acid.—Diazobenzene chloride (1 mol.) is added to an alkaline solution of β -naphthaquinonehydrazonebenzoic acid (1 mol.), and the combination completed by heating on the water-bath. The product is precipitated with acid and crystallised from aniline and then from alcohol. It is sparingly soluble in the ordinary solvents, crystallises in very minute needles, blackens at 200° , and decomposes at 245 — 246° . Analysis gave results corresponding with the formula

It is only a feeble acid, dissolves in warm alkalis and baryta-water, but precipitates on cooling, has only faint tinctorial powers, and yields a green solution with concentrated sulphuric acid. The *acetate* crystallises from benzene in slender, yellow needles, darkens at 200° , and decomposes at 229 — 230° .

Diazobenzene Chloride and β -Naphthaquinonehydrazonesulphanilic Acid.—The reaction takes place in the same way as the above. The sodium salt of the disazo-compound is obtained as a gelatinous precipitate. The free acid, $\text{N}_2\text{Ph} \cdot \text{C}_{10}\text{H}_7(\text{OH}) \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{H}$ $[= 4 : 1 : 2]$, is a brownish-red powder, sparingly soluble in cold water, easily in hot water. It dyes silk and wool in acid bath a garnet-brown shade.

Diazosulphanilic Acid and Phenylazo- α -naphthol.—Phenylazo- α -naphthol is obtained by the action of diazobenzene chloride (1 mol.) on a solution of α -naphthol (1 mol.) in sodium hydroxide (2 mols.). At the same time, an appreciable quantity of the disazo-compound is formed. The phenylazo- α -naphthol is precipitated from the alkaline solution, dissolved in barium hydroxide, again precipitated, and crystallised from alcohol or acetic acid. It melts at 206°. When diazosulphanilic acid (1 mol.) is mixed with benzenediazo- α -naphthol (1 mol.) and sodium hydroxide (2 mols.) and the combination completed on the water-bath, a large quantity of the substance remains undissolved, and the alkaline solution becomes dark reddish-brown. The undissolved compound was identified as benzenedisazo- α -naphthol. The alkaline liquid contained the disulphonic acid of benzenedisazo- α -naphthol. This latter is not precipitated by acids, so that it was not obtained in the pure state; but a preparation obtained by the action of 2 mols. of diazobenzenesulphonic acid on α -naphthol seemed to be identical with it.

Metadiazobenzoic Acid and Phenylazo- α -Naphthol.—The combination of the two compounds takes place easily; the product of the reaction is a mixture of phenyldisazonaphthol and disazonaphtholphenylcarboxylic acid. To separate these compounds, the mixture is acidified and the dry precipitate extracted with chloroform. Benzenedisazo- α -naphthol is dissolved. The undissolved residue dissolves easily in alcohol, but could not be obtained crystalline. It is purified by solution in soda and reprecipitation with acid, and is so obtained as a reddish-black powder which blackens at 250° and decomposes at 264°. It was similar in all respects to the compound obtained by the action of diazobenzoic acid (2 mols.) on α -naphthol.

E. C. K.

Constitution of the Hydrazone of β -Naphthaquinone. By E. NOELTING and E. GRANDMOUGIN (*Ber.*, 24, 1592—1597).—The authors have obtained results which tend to show that phenylazo- β -naphthol and the isomeric hydrazone of β -naphthaquinone are azo-compounds and not hydrazones.

β -Naphthaquinone phenylhydrazone is obtained as described by Zincke and Bindewald (*Ber.*, 17, 3026). The yield is small, owing to the oxidising action of the β -naphthaquinone on the hydrazone; which latter is converted into benzene, whilst the quinone is converted into dinaphthylidiquinol. The phenylhydrazone melts at 138°, sublimes, like phenylazo- β -naphthol, in beautiful, orange-red needles with a green, metallic lustre, and is insoluble in cold alkali, but dissolves in the hot solvent and separates out unchanged on cooling. The sodium salt is obtained by dissolving the hydrazone in a methyl or ethyl alcoholic solution containing the theoretical quantity of sodium. The formula of the sodium salt is $\text{ONa} \cdot \text{C}_{10}\text{H}_6\text{N}_2 \cdot \text{Ph}$, since, on reduction of the ethyl salt obtained from it, aniline is formed and not ethylaniline.

Phenyldisazo- α -naphthol is obtained by adding a solution of diazobenzene chloride to an ice-cold solution prepared by dissolving twice the theoretical quantity of sodium in alcohol and adding the hydrazone. The mixture is allowed to remain over night and the product

filtered, dissolved in hot chloroform, and the solution mixed with absolute alcohol. It crystallises on cooling in slender, brown needles with a green lustre, melts at 193° , dissolves very sparingly in hot alkalis, easily in alcoholic sodium ethoxide, but is precipitated on addition of water. It is identical with the product obtained by Krohn by the action of diazobenzene chloride (2 mols.) on α -naphthol (*Ber.*, 21, 3240). The *acetate*, $\text{OAc}\cdot\text{C}_{10}\text{H}_7(\text{N}_2\text{Ph})_2$, is obtained by heating the disazo-compound with acetic anhydride and sodium acetate in a reflux apparatus until the colour changes from red to yellow. It crystallises from alcohol in beautiful, brown, prismatic needles, melts at 159 – 160° , decomposes at 200° , and dissolves in concentrated sulphuric acid with a green coloration. The *ethyl salt*, $\text{OEt}\cdot\text{C}_{10}\text{H}_7(\text{N}_2\text{Ph})_2$, is obtained by adding an excess of ethyl iodide to a solution of the diazo-compound in the theoretical quantity of sodium ethoxide, and allowing the mixture to remain three weeks in the cold. It crystallises from alcohol in tufts of reddish-brown needles, and melts at 121° . The *methyl salt* crystallises in blue-black needles with a metallic lustre, and melts at 123° .

It was not possible to obtain a hydrazoneoxime by the action of hydroxylamine or its salts on the β -naphthaquinone hydrazone.

E. C. R.

Nitro-derivatives of Alizarin and Purpurin. By R. BRASCH (*Ber.*, 24, 1610–1619).—*Diacetyl- α -nitroalizarin* is obtained by cautiously adding diacetylalizarin (1 part) to colourless nitric acid (2 parts; sp. gr. = 1.5) cooled with ice and salt, so that the temperature does not rise above zero; 1 part more of nitric acid is then added, and as soon as the product no longer gives the alizarin spectrum, the mixture is poured into iced water. It crystallises from acetic acid in beautiful, bright-yellow needles, melts at 194 – 195.5° (uncorr.), and is easily hydrolysed by cold soda solution.

α -Nitroalizarin obtained by hydrolysis of the acetyl compound, crystallises from acetic acid in brownish-yellow, prismatic needles, and melts at 289° (uncorr.). The absorption spectra of α -nitroalizarin is very like that of alizarin.

α -Amidoalizarin is obtained by reducing the nitro-compound suspended in dilute ammonia with hydrogen sulphide. The amido-compound is precipitated with hydrochloric acid, dried, and freed from sulphur by extraction with carbon bisulphide. It is sparingly soluble in most solvents, and crystallises from acetic acid in dark-brown scales with a yellowish-green, metallic lustre. When treated with excess of nitrous acid, it is not completely converted into a diazo-compound, and on warming the diazotised mixture, purpurin is formed. If, however, the diazotised mixture be saturated with alkali and then warmed and extracted with ether, alizarin is obtained. β -Amidoalizarin on diazotisation did not yield a trace of purpurin, but only alizarin, which is contrary to the statement of Auerbach (*Das Anthracen*, 1880, p. 152).

Strecker (*Zeit. Chem.*, 4, 264) has shown that when alizarin is treated with fuming nitric acid, at first an unstable compound is formed, which, in the presence of water, is easily converted into nitroalizarin. This unstable compound is also obtained from pur-

purin by the action of fuming nitric acid, and has the same percentage composition as nitrohydroxylizarin. The author names this unstable compound pseudonitropurpurin and the nitrohydroxylizarin nitropurpurin.

Pseudonitropurpurin is obtained by mixing alizarin with fuming nitric acid so as to form a thin paste, and allowing the mixture to remain until no alizarin can be detected with the spectroscopic. The mixture is poured on to ice, diluted with water, filtered, and washed with iced water. The yellow compound begins to dissolve as soon as all the acid is washed out, and decomposes into nitropurpurin.

It is purified by drying in thin layers in a vacuum and extracting the nitropurpurin with absolute ether. It is a bright-yellow mass, which is stable when pure and dry, is converted into nitropurpurin when heated with water, and dissolves in cold soda solution to a brownish-yellow solution, which goes red on warming, owing to the formation of nitropurpurin. In concentrated sodium hydroxide it is fairly stable, but turns red at once on the addition of water. The author gives two probable formulæ for this compound,

Nitropurpurin $[(\text{OH})_2 : \text{NO}_2 : \text{OH} = 1 : 2 : 3 : 4]$ is obtained from pseudonitropurpurin by boiling with water or alkali. It is very like purpurin, gives the same colours with chromium, iron, and alumina mordants, and dissolves in sulphuric acid with a yellowish-red; purpurin gives a carmine-red. If purpurin is cautiously added to a large quantity of well-cooled fuming nitric acid, a yellowish-brown compound is deposited which is identical with pseudonitropurpurin and is easily converted into nitropurpurin. β -Nitroalizarin $[(\text{OH})_2\text{NO}_2 = 1 : 2 : 3]$, when treated with 7 parts of nitric acid (1.5) at the ordinary temperature, yields the same intermediate compound and then nitropurpurin. The same nitropurpurin is also obtained by the action of nitric acid on α -nitropurpurin $[(\text{OH})_2\text{NO}_2 = 1 : 2 : 4]$.

Amidopurpurin is obtained by reduction of the nitro-compound with ammonium sulphide. It is very sparingly soluble in most solvents, dissolves in concentrated sulphuric acid with a reddish-yellow, and gives blackish colours with iron and chromium mordants, red with alumina mordants.

E. C. R.

Terpenes and Camphors. By O. WALLACH (*Ber.*, 24, 1525—1579).—The paper contains an account of the most important results obtained up to the present time.

The terpene-like hydrocarbons can be divided according to their empirical formulæ into three classes:—(1) Hemiterpenes or pentenes, C_5H_8 . (2) Terpenes, $\text{C}_{10}\text{H}_{16}$. (3) Polyterpenes, $(\text{C}_5\text{H}_8)_n$. The terpenes at higher temperatures split up into unsaturated hydrocarbons of the series C_5H_8 , whose best known representative is isoprene. Isoprene can undergo polymerisation into $\text{C}_{10}\text{H}_{16}$, and a further polymerisation into $\text{C}_{15}\text{H}_{24}$, $\text{C}_{20}\text{H}_{32}$, &c. Ordinary terpene is also polymerisable into such polyterpenes.

The present paper deals with the terpenes $\text{C}_{10}\text{H}_{16}$. At present the

following terpenes are known:—(1) Pinene, (2) camphene, (3) fenchene, (4) limonene, (5) dipentene, (6) sylvestrene, (7) phellandrene, (8) terpinene, (9) terpinolene. *Pinene* forms the main constituent of ordinary turpentine oil, occurs as an essential ingredient of the ethereal oils of most pines, and in greater or smaller quantity in many other ethereal oils. *Camphene* is important on account of its near relation to camphor. It is obtained from camphor through borneol or from pinene. It does not appear to occur in nature. *Fenchene* is closely related to camphene, and is obtained in a similar way from fenchone, a compound isomeric with camphor. *Limonene*, one of the most widely diffused terpenes, occurs in the ethereal oils of the *Aurantiacæ*, in orange-peel oil, in oil of lemons, bergamot, cummin, dill, oil of *Erigeron canadense*, and in the oil of fir needles. *Dipentene* is closely related to limonene. It is formed from limonene and pinene by the action of heat or of acids, and occurs in oil of camphor and elemi, in Russian and Swedish turpentine, and is formed together with isoprene by the dry distillation of caoutchouc, and as a byc-product in the formation of cineole, terpene hydrate, and terpineole. *Sylvestrene* occurs in Russian and Swedish turpentine. *Phellandrene* occurs in the oils of bitter fennel and water fennel, elemi, and eucalyptus. *Terpinene* is a product of the molecular change of other terpenes. It occurs naturally in oil of cardamom. *Terpinolene* is only slightly known.

The terpenes exist in physically different modifications. Thus the pinene from American turpentine is dextro-rotatory, that from French turpentine lævo-rotatory. By the action of mineral acids or by heat, the optically-active terpenes are rendered optically inactive. The inactive modifications are obtained by mixing equal proportions of the optical antipodes. Active terpenes as a rule give active derivatives. The inactive pinene, camphene, and phellandrene compounds are indistinguishable, except as regards optical properties, from the corresponding active compounds. The inactive modification of limonene is quite different from the active modification, and was taken for a distinct compound and called dipentene. Dipentene, however, stands in the same relation to dextro- and lævo-limonene as racemic acid does to dextro- and lævo-tartaric acids. Sylvestrene is only known in the dextro-modification; and fenchene, terpinene, and terpinolene in the inactive modifications. Camphene is the only terpene which is solid; it melts at 50°. Pinene, camphene, and fenchene boil at 160°, and have a high specific gravity (about 0.86). Limonene, dipentene, and sylvestrene boil at 175°, and have a low specific gravity (about 0.846 at 20°). Those terpenes which from chemical considerations are held to contain one ethylene bond, and those containing two ethylene bonds, show amongst one another a concordant molecular refraction.

The terpenes are unsaturated compounds, and differ in their capacity for combining with halogen hydrides. If dry hydrogen chloride be led into dry pinene, a molecule of the gas is added, and a saturated compound, pinene hydrochloride, is obtained, which melts at 125° and boils at 207–208°. Camphene in like manner unites with 1 mol. of hydrogen chloride to form camphene hydrochloride, which resembles pinene hydrochloride. It, however, easily loses

hydrogen chloride with formation of camphene, whereas pinene hydrochloride loses hydrogen chloride with difficulty, and then yields camphene and not pinene. Dry limonene, when treated with dry hydrogen chloride, yields a liquid hydrochloride, $C_{10}H_{16}, HCl$, which is not, however, saturated, and takes up moist hydrogen chloride to form the dihydrochloride $C_{10}H_{16}, 2HCl$. Dipentene and sylvestrene behave like limonene towards hydrogen chloride.

The bromo-additive compounds are also important as a means of characterising the terpenes. Pinene unites with 1 mol. of bromine, and yields a saturated dibromide, $C_{10}H_{16}Br_2$ (m. p. 169—170°). A bromine additive compound of camphene is not known. The compound $C_{10}H_{16}Br_2$, from fenchene, is liquid. Limonene, dipentene, sylvestrene, terpinolene unite with 4 atoms of bromine to form compounds of the formula $C_{10}H_{16}Br_4$. These bromides melt at 104—105°, 124—125°, 135°, and 116° respectively. From the above results, it is seen that two terpene groups exist. The members of one contain one ethylene bond, and give saturated compounds with 1 mol. of halogen and halogen hydride; the members of the second contain two ethylene bonds, and combine with 1 mol. of halogen hydride to form unsaturated compounds, and with 2 mols. of halogen or halogen hydride to form saturated compounds.

Well characterised compounds are obtained by the action of the oxides of nitrogen and their derivatives on the terpenes. Phellandrene combines with nitrogen trioxide, N_2O_3 , to yield phellandrene nitrite, $C_{10}H_{16}N_2O_3$ (m. p. 102°). Terpinene combines in a similar way with nitrous acid, and yields terpinene nitrosite, $C_{10}H_{16}N_2O_3$, which crystallises in transparent, monosymmetric prisms and melts at 155°. The other terpenes do not give crystalline compounds with N_2O_3 , but they yield important compounds with nitrosyl chloride, $NOCl$. These compounds are best prepared by adding ethyl nitrite or amyl nitrite to an acetic or alcoholic solution of the terpene, and passing hydrogen chloride into the well-cooled mixture. The compounds have the formula $C_{10}H_{16}Cl \cdot NO$, and correspond with terpinene nitrosite,

If the terpene be mixed with alkyl nitrite and nitric acid, instead of alkyl nitrite and hydrogen chloride, then an analogous nitrosate, $NO \cdot C_{10}H_{16} \cdot ONO_2$, is formed. The unsaturated hydrochlorides of the terpenes with two ethylene bonds easily form nitrochlorides and nitrosates of the composition $C_{10}H_{16} \cdot ClNO, HCl$ and $C_{10}H_{16} \cdot ClNO, HONO_2$. These compounds are not all very stable, and are decomposed when warmed. When treated with organic bases they are easily converted into nitrolamines, $NO \cdot C_{10}H_{16} \cdot NHR$. Such bases have been obtained from pinene, limonene, dipentene, sylvestrene, and terpinene; they are well crystallised and stable compounds, and give sharp melting points. When hydrochloric acid is withdrawn from the nitrochlorides, nitroso-compounds of the formula $C_{10}H_{16}NO$ are obtained which crystallise well. A table is given summarising the properties of the terpenes and their derivatives. The remainder of the paper deals with the constitution of the terpenes. The terpenes are convertible into one another, as is shown by the following table.

Pinene is distinguished by the readiness with which it is converted into other terpenes. The author puts forward the formula

for pinene, and maintains that it explains most of its reactions. The assumption of the existence of a diagonal bond is necessary, and obtains support from the fact that pinene hydrochloride by loss of hydrochloric acid yields a hydrocarbon, which by addition of hydrogen chloride is not again converted into pinene hydrochloride, and that pinene hydrochloride loses HCl with greater difficulty than its isomerides camphene, limonene, and dipentene hydrochlorides. When heated to a high temperature, pinene, which contains only one ethylene bond, is converted into dipentene, which contains two ethylene bonds. In the presence of dilute acids, it is converted into compounds which must be considered as derivatives of dipentene, and are obtainable from dipentene directly. Pinene, when treated with moist hydrogen chloride, does not yield pinene hydrochloride, but dipentene hydrochloride; with dilute nitric acid, it yields terpine. Dry reagents first break the ethylene bond in pinene, as is seen in the formation of pinene hydrochloride by the action of dry hydrogen chloride. When treated with moist acids, it not only yields dipentene derivatives but also terpinene, terpinolene, terpineole, and cineole. These compounds are, however, formed by a secondary reaction from terpine, $\text{C}_{10}\text{H}_{20}\text{O}_2$, or terpine hydrate, $\text{C}_{10}\text{H}_{20}\text{O}_2 + \text{H}_2\text{O}$. The formation of these compounds is then explained by giving to terpine the formula

Pinene.—The formula of pinene given above explains its most important reactions, its conversion into dipentene, terpineole, terpine hydrate, and cineole, and the splitting of the molecule to give isopsene. That pinene contains only one ethylene bond follows from the saturated nature of the hydrochloride, hydrobromide, and the dibromide. The molecular refraction also agrees with this supposition. Pinene nitroschloride is also a saturated compound. Two formulæ are possible, containing the groupings—

The author is inclined to consider formula I as most probable, from a consideration of its reactions. It is distinguished by its great stability, relatively to the other terpene nitrosochlorides. With fatty bases, it yields a nitrolamine; with aromatic bases, no such reaction takes place, but inactive pinene is produced with the formation of amidoazo-compounds. By this reaction it is possible to prepare chemically pure pinene. With inorganic bases, a different reaction takes place; thus alcoholic potash eliminates hydrogen chloride and nitrosopinene, $\text{C}_{10}\text{H}_{16}\text{NO}$, is formed. The latter differs from the analogous isomeric nitroso-compounds of other terpenes. Thus nitrosolimonene when warmed with dilute acid yields hydroxylamine and carvole, $\text{C}_{10}\text{H}_{14}\text{O}$, whilst nitrosopinene is not attacked by acids; it can even be warmed with concentrated sulphuric acid, and on addition of water is precipitated unchanged. This difference is explained if the isomeric compounds contain the group =NOH combined directly with a carbon atom, whilst nitrosopinene contains the group $\text{---N}\cdot\text{O}$. If the above formula be accepted for pinene nitrosochloride, one must assume that in the production of nitrosopinene the chlorine atom goes out with the para-hydrogen atom. Two formulæ are then possible for nitrosopinene, of which the author favours one with two diagonal bonds. When nitrosopinene is reduced with zinc and acetic acid, it yields pinylamine, $\text{C}_{10}\text{H}_{15}\cdot\text{NH}_2$. If pinylamine hydrochloride is heated above its melting point, it decomposes into ammonium chloride and cymene. A similar decomposition takes place in the case of pinene dibromide, which, on heating, also yields para-isopropylmethylbenzene. In the byc-products obtained in the formation of pinene nitrosochloride, pinole, $\text{C}_{10}\text{H}_{16}\text{O}$, is found. The latter yields a series of well-characterised derivatives of which the most important is pinole hydrate, $\text{C}_{10}\text{H}_{18}\text{O}\cdot\text{HOH}$ (m. p. 131°). Pinole hydrate is converted by dilute acids into pinole, and is identical with the compound obtained by the oxidation of moist turpentine under the influence of sunlight. Pinole, when oxidised with potassium permanganate, yields terebic acid, $\text{C}_8\text{H}_{10}\text{O}_4$; pinole hydrate and pinole glycol, however, yield terpenylic acid, $\text{C}_8\text{H}_{12}\text{O}_4$, that is, those two acids are obtained which are formed by the direct oxidation of pinene.

Camphene and Fenchene.—The constitution of camphene depends closely on that of camphor. Camphor is easily converted into camphene, either by reduction to borneol and elimination of the elements of water, or by converting the borneol into bornyl chloride and eliminating hydrogen chloride. The behaviour of camphor is best explained by the formula proposed by Bredt, and camphene would then have an analogous formula. This formula, although it explains the behaviour of camphene, does not so easily explain its formation from pinene hydrochloride.

In many fennel oils a liquid, camphor-like substance occurs. This compound is called fenchone, and is isomeric with camphor, and,

moreover, undergoes the same characteristic reactions (compare p. 1086). It yields a well-crystallised oxime, $C_{10}H_{16}NOH$, which behaves like camphoroxime towards dilute acids. It gives a nitrile-like compound, $C_9H_{15}CN$, an isoamide, $C_9H_{15}CONH_2$, a base, $C_9H_{15}CH_2NH_2$, and an acid, $C_9H_{15}COOH$, which are like the corresponding compounds from camphoroxime, and are isomeric with them. Fenchone, on reduction, yields fenchyl alcohol, and from this one obtains fenchyl chloride and fenchene, $C_{10}H_{16}$. These compounds are isomeric with borneol, bornyl chloride, and camphene. A table is given containing all the known compounds of camphene and fenchene. In general properties fenchene also resembles camphene, namely, in smell, high specific gravity, molecular refraction, and boiling point; it is, however, a liquid, whilst camphene is a solid. Fenchone, on oxidation with potassium permanganate, yields dimethylmalonic acid, $CH_3CH_2(COOH)_2$, and acetic acid, but not camphoric acid. The formation of dimethylmalonic acid points to the presence in fenchene of the grouping $CMe_2 < \overset{C}{\underset{\cdot}{C}}$, whilst camphor contains the isopropyl group and the grouping $CHMe_2 < \overset{C}{\underset{\cdot}{C}}$.

Limonene and Dipentene.—These two hydrocarbons probably have the same chemical structure, dipentene being the racemic modification of lævo- and dextro-limonene. Limonene combines easily with nitrosyl chloride; two compounds, α - and β -nitrosochlorides, are formed from both lævo- and dextro-limonene, so that four isomeric limonene nitrosochlorides exist. The β -compounds have a somewhat smaller rotatory power than the α -compounds. The author thinks these two modifications are identical as regards structure, and that the difference is due to polymerisation. Dextro- and lævo-limonene α -nitrosochlorides each yield two isomeric nitrolamines, of which two have the same melting point but are of opposite rotatory power. If two of these optical antipodes be recrystallised together in equal proportions, an inactive dipentene derivative is obtained. Limonene, from its behaviour towards halogens and halogen hydrides, has certainly two ethylene bonds. Goldschmidt has shown that carvoxime is identical with nitrosolimonene, and hence limonene may be considered to be hydrocymene. However, dipentene dihydrobromide (m. p. 64°) can be converted into a tribromide, $C_{10}H_{17}Br_3$ (m. p. 110°). The latter, when boiled with alcoholic potash, is converted into an unsaturated compound, $C_{10}H_{14}$, isomeric with cymene, which unites with bromine to form a well-characterised tetrabromide melting at 154° . Formulæ are given as far as possible in accordance with the above results. The three compounds terpeneole, terpene, and cineole show the relation between pinene and limonene and dipentene. Terpene, $C_{10}H_{20}O_2$, which crystallises with 1 mol. of water to form terpene hydrate, has already had a formula assigned to it which explains its reactions. Terpeneole and terpene hydrate are closely related to limonene and dipentene hydrochloride and to dipentene dihydrochloride, since when dipentene dihydrochloride is allowed to remain in contact with water, terpene hydrate is formed.

Cineole, $C_{10}H_{18}O$, occurs in many ethereal oils. It gives character-

istic additive compounds with bromine, iodine, hydrogen chloride, and hydrogen bromide. By the action of dehydrating agents, it is converted into dipentene. On oxidation with potassium permanganate, it is converted into cineolic acid, which easily passes into its anhydride. When the latter is distilled, it loses CO_2 and CO , and yields a compound $\text{C}_8\text{H}_{14}\text{O}$, which is easily converted into dihydro-metaxylene. Cineole can be obtained from terpene hydrate and terpineole. The following formulæ are given showing the relation of the above compounds:—

Nothing is known about the constitution of *sylvestrene*. In its physical and chemical properties it most closely resembles dextro-himonene. It contains two ethylene bonds. *Terpinolene* also contains two ethylene bonds, and probably only differs from dipentene in the relative position of these bonds.

Terpinene and *phellandrene* both combine with nitrogen trioxide to form compounds of the formula $\text{C}_{10}\text{H}_{16}\text{N}_2\text{O}_3$. The two compounds so obtained are, however, quite different. *Terpinene* nitrosite, when treated with fatty bases or ammonia, yields well-characterised nitrolamines. Both *terpinene* nitrosite and the nitrolamines behave in some cases as if they contained the group —NO ; in other reactions they behave as if they contained the group —NOH . *Phellandrene* nitrite is a somewhat unstable compound, and is not capable of yielding nitrolamines. On reduction, it yields a diamine which points to the constitution $\text{C}_{10}\text{H}_{16} < \begin{smallmatrix} \text{NO} \\ \text{NO}_2 \end{smallmatrix}$. The isomeric relation of *terpinene* and *phellandrene* to one another and to other terpenes has not been determined. *Terpinene* has probably an ethylene bond in the side chain. *Phellandrene*, which is easily convertible into cymene, is possibly a fatty compound.

The author draws attention to the similarity of some indene compounds to the terpenes.

E. C. R.

Presence of Ethylene Linkages in Terpenes. By G. WAGNER (*Ber.*, 24, 1682—1684).—The paper is a reply to Markovnikoff's criticism (*Ber.*, 24, 67) of a previous paper by the author.

Terebenthene. By R. VALET (*Compt. rend.*, 112, 732—734).—When anhydrous aluminium chloride is added to terebenthene, there is a slight development of heat, but no further change, even after several hours. If, however, the mixture is heated, or a few drops of benzene is added, there is a very violent reaction, with formation of

tarry products containing cymene and toluene. If the terebenthene is dissolved in 3 vols. of carbon bisulphide, and aluminium chloride is added gradually to the cooled liquid, the reaction is still energetic, and a blood-red solid is obtained, consisting chiefly of metaterebenthene and tetraterebenthene, with smaller quantities of cymene, colophene, and other hydrocarbons. It follows that the action of aluminium chloride on terebenthene is similar to that of antimony chloride.

When terebenthene is added gradually to a solution of bromine in 3 vols. of carbon bisulphide holding aluminium chloride in suspension and cooled below 0° , there is an energetic reaction with evolution of hydrogen bromide. After 136 parts of terebenthene have been added for every 800 parts of bromine, the liquid is allowed to remain until evolution of hydrogen bromide ceases, and is then treated with water and sodium hydroxide solution, and distilled. A small quantity of isopropyl bromide is obtained, but the product consists of heavy, tarry compounds, formed by the action of the bromine on the products of the polymerisation of the terebenthene. Terebenthene, when treated with bromine and aluminium chloride, does not, like cymene, split up into isopropyl bromide and a bromine derivative of toluene. The small quantity of isopropyl bromide obtained results from the action of the bromine on the cymene formed during the polymerisation of the terebenthene.

Terpene in the Oil from Compressed Gas. By A. ETARD and P. LAMBERT (*Compt. rend.*, 112, 945—947).—In the compression of the gas obtained by the pyrogenic decomposition of heavy paraffin oils, a quantity of volatile liquid condenses. If this liquid is fractionated, the fraction $140\text{--}190^{\circ}$ shows no constant boiling point. By rapid fractionation, however, a hydrocarbon, C_8H_8 , is obtained, which boils at 42.5° ; sp. gr. = 0.803; vapour density 2.45. This hydrocarbon, *pyropentylene*, polymerises at the ordinary temperature, and forms a solid compound, *dipyropentylene*, $C_{10}H_{12}$, which has all the principal properties of the terpenes. Polymerisation proceeds regularly, and can be followed by determining the sp. gr. When the dipyropentylene is heated, pyropentylene is again formed.

Pyropentylene has a very pungent taste and a peculiar odour. It is not affected by ammoniacal silver or cuprous solutions, but with a concentrated aqueous solution of silver nitrate, it yields a white, acicular precipitate, and it reduces an ammoniacal silver solution containing potash. With aqueous sulphurous acid, it yields a white, crystalline compound, $C_{10}H_{12} \cdot 2H_2SO_3$, almost insoluble in all reagents except alkalis, and with a remarkable tendency to retain any iron that was present in the reagents. With haloid acids, pyropentylene resinifies rapidly or explodes; oxidising agents destroy it completely; bromine alone yields liquid products.

Pyropentylene is not identical with valylene or perylene; it is isomeric with these hydrocarbons, and is more closely related to the terpenes.

C. H. B.

Action of Phthalic Anhydride on Amidoterebenthene. By L. PESCI (*Gazzetta*, 21, 1—4).—*Pinenephthalimide*,

—When amidoterebenthene (10 grams) is poured on to powdered phthalic anhydride (12 grams), a very energetic reaction ensues; the mass is then allowed to cool, and subsequently reheated at 170° , until the reaction is completed; the portion of the product insoluble in water consists of pinenephthalimide, which, after purification, crystallises from light petroleum in colourless nodules, composed of rectangular tables. It melts at $99\text{--}100^\circ$, and dissolves readily in alcohol, chloroform, and ether. It is laevorotatory, $[\alpha]_D = -35.38$.

Pinenephthalanic Acid, $\text{COOH}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_{10}\text{H}_{15}$.—The potassium salt of this acid is formed on dissolving pinenephthalimide in a hot solution of potash. It crystallises in thin, colourless needles, readily soluble in hot water. The acid obtained by decomposing this salt with hydrochloric acid, when pure, crystallises from chloroform on the addition of light petroleum in nodules composed of thin, colourless needles. It melts at first at $109\text{--}111^\circ$, but if kept for a few days the melting point falls to 101° . The silver salt,

is a white, amorphous compound.

New Compounds of the Camphor Series and a New Terpene. By O. WALLACH (*Annalen*, 263, 129—156).—A further investigation of the compound previously described as fenchole (this vol., p. 218), but which is, perhaps, better termed *fenchone*, has brought to light numerous additional points of resemblance between this substance and its isomeride, camphor; but what the relationship between the two compounds really is, remains at present unsolved.

Fenchone can be easily obtained in a state of purity by converting it into the crystalline alcohol described below, then warming the latter with nitric acid until oxidation is at an end, and distilling the regenerated fenchone with steam; an even simpler method is to warm the crude oil, obtained by fractional distillation, with concentrated nitric acid (3 parts), until all the impurities are destroyed. The pure compound boils at $192\text{--}193^\circ$, and gradually solidifies, when kept at a low temperature, to a mass of very hard crystals, which melt at $5\text{--}6^\circ$ to a liquid of sp. gr. 0.9465 at 19° ; its refraction is $[n]_D = 1.46306$ at 19° , from which the molecular refractive energy is found to be 44.23, the calculated value for a compound of the composition $\text{C}_{10}\text{H}_{16}\text{O}$, containing no double linking, being 44.11. The specific rotatory power of fenchone, purified by the methods given above, is $[\alpha]_D = 71.83^\circ$. It combines with bromine, yielding a crystalline, unstable additive compound, which is decomposed by alkalis with liberation of fenchone; iodine, phosphorus pentachloride, phosphoric anhydride, and phosphorus sulphide, have an action on fenchone similar to that on camphor, but the products have not yet been thoroughly investigated. Fenchone dissolves moderately easily

in cold concentrated hydrochloric acid, and with cold sulphuric acid it seems to give an unstable additive compound, which is decomposed by water; it is only very slowly destroyed by boiling fuming nitric acid, being thereby converted into organic acids and a heavy oil, which is insoluble in alkalis. It is slowly oxidised by a warm solution of potassium permanganate, yielding dimethylmalonic acid, acetic acid, and oxalic acid; its physiological action is very similar to that of camphor.

The melting point of fenchonoxime (*loc. cit.*) depends, to a very considerable extent, on the conditions of the experiment, and sometimes, when the oxime is heated quickly, the temperature rises to 164–165° before it is completely melted; fenchonoxime is volatile with steam, sublimes readily, and boils at about 240° with only slight decomposition when heated quickly; it is insoluble in soda, and its specific rotatory power in alcoholic solution is $[\alpha]_D = 65.94^\circ$.

The anhydride of the oxime (*loc. cit.*) has a sp. gr. of 0.898 at 20°; its specific rotatory power is $[\alpha]_D = 43.31^\circ$ and its refraction $n_D = 1.46108$ at 20°; it forms a crystalline compound with hydriodic acid.

A base of the composition $C_{10}H_{17}NH_2$, isomeric with fenchylamine (see below), is formed when the anhydride of the oxime is reduced with sodium and alcohol; when the product is treated with hydrogen chloride in ethereal solution, it behaves like an unsaturated compound, and forms a salt of the composition $C_{10}H_{15}N, 2HCl$; the *platinochloride* has the composition $(C_{10}H_{15}N)_2, H_2PtCl_6$.

Formylfenchylamine, $C_{10}H_{17}NH \cdot CHO$, is obtained when fenchone is heated with ammonium formate at 220–250° for three hours; it crystallises from water or dilute alcohol in lustrous plates, and seems to melt at 87°, but portions remain unliquefied until the temperature rises to 112°.

Fenchylamine, $C_{10}H_{17}NH_2$, prepared by boiling the formyl derivative with concentrated hydrochloric acid, and decomposing the salt thus produced with alkalis, is a colourless oil, of sp. gr. 0.9095 at 22°, and boiling at 195°; it has an odour recalling both that of piperidine and that of benzylamine, and it absorbs carbonic anhydride from the air, forming a solid carbonate; its specific rotatory power in alcoholic solution is $[\alpha]_D = -24.63^\circ$. The *hydrochloride*, $C_{10}H_{17}NH_2 \cdot HCl$, crystallises from water and alcohol in well-defined, transparent prisms. The *platinochloride*, $(C_{10}H_{17}NH_2)_2, H_2PtCl_6$, crystallises from water in long prisms, and effloresces when kept over sulphuric acid. The *sulphate* crystallises in needles or plates, and is not very readily soluble; the *nitrate*, the *benzoyl* derivative melting at 89.5°, and the *acetyl* derivative melting at 92° are easily obtained in crystals. When the hydrochloride of the base is treated with sodium nitrite, a neutral oil, which is neither fenchyl alcohol nor a diazo-compound, is obtained.

Benzylidenefenchylamine, $C_{10}H_{17}N \cdot CHPh$, is formed with development of heat when the base is treated with benzaldehyde; it melts at 41.5°.

Fenchyl alcohol, $C_{10}H_{17}OH$, is obtained when fenchone is reduced with sodium and alcohol; the yield is quantitative. It is a colourless,

crystalline compound, melts at 40—41°, boils at 201°, and has a sp. gr. of 0.933 at 50°; it is readily volatile with steam, and dissolves freely in alcohol, ether, light petroleum, and ethyl acetate, but is insoluble in water. Its specific rotatory power in alcoholic solution is $[\alpha]_D = -10.35^\circ$; on oxidation with nitric acid, it is reconverted into fenchone.

Fenchyl chloride, $C_{10}H_{17}Cl$, prepared by treating the alcohol with phosphorus pentachloride in light petroleum solution, boils at 84—86° under a pressure of 14 mm., and is readily volatile with steam; its sp. gr. is about 0.9830 at 21°.

Fenchene, $C_{10}H_{16}$, is obtained, together with phenylfenchylamine (see below), when fenchyl chloride is heated with aniline; when the reaction is at an end, the solution is mixed with acetic acid, and the fenchene isolated by distillation with steam. The hydrocarbon boils at 158—160°, is optically inactive, and its sp. gr. is 0.864 at 20°: its refraction is $[n]_D = 1.4690$ at 20°, from which the molecular refractive energy is found to be 43.84, the calculated value for $C_{10}H_{16}$ being 43.54. It combines readily with bromine in glacial acid solution, yielding, apparently, an unstable dibromide of the composition $C_{10}H_{16}Br_2$; it is moderately easily oxidised by potassium permanganate, yielding an acid of the composition $C_{10}H_{16}O_3$, which melts at 137—138°, and forms a sparingly soluble silver salt, $C_{10}H_{15}O_3Ag$. It differs from other terpenes in being comparatively stable towards concentrated nitric acid, oxidation taking place only on warming.

Phenylfenchylamine, $C_{10}H_{17}NHPh$, crystallises from alcohol in large, colourless needles, and melts at 93—94°. F. S. K.

Pyrogenic Conversion of Camphosulphophenols into Ordinary Phenols. By P. CAZENEUVE (*Compt. rend.*, 112, 730—732).—A mixture of the barium salts of the five camphosulphophenols previously described, when subjected to dry distillation, yields water; sulphur; gaseous products, consisting of hydrogen sulphide, sulphurous anhydride, carbonic anhydride, methane, with a small quantity of propane or propylene; a small quantity of hydrocarbons, probably chiefly paracymene; and homologues of ordinary phenol in quantity amounting to 25 per cent. of the camphosulphophenols.

The phenols boiling below 210° consist of orthocresol (m. p. 31°, b. p. 186°) and metacresol, without any trace of ordinary phenol. The first fractions of the portion boiling at 210—235° have the composition of mixtures of cresols with propylphenols, whilst the later fractions have the composition of mixtures of propylphenols with cymophenols. The products seem to contain neither thymol, carvacrol, nor carvol. When heated with hydrochloric acid at 130° for four hours, neither methyl chloride nor any other alkyl chloride is obtained, and hence alkyl ethers are absent. The composition of the products and their stability when exposed to air and light point to the absence of polymerides. C. H. B.

Morrenole. By P. ARATA and C. GELZER (*Ber.*, 24, 1851—1853).—The recently expressed juice of the fruit of *Morrenia brachystephana* is light yellow, and coagulates after remaining for 24 hours; the

liquid portion is separated, boiled, filtered, and evaporated to dryness, and the residue extracted with alcohol; the solution thus obtained contains considerable quantities of morrenine (compare this vol., p. 1122).
 * The coagulated portion of the juice is digested with alcohol; a yellow resin remains, which smells of caoutchouc, and is soluble in carbon bisulphide. From the alcoholic solution, colourless crystals are deposited on cooling, which melt at 168° , are insoluble in water, but readily dissolve in ether, light petroleum, and mineral acids. The compound is termed *morrenole*, has the formula $C_{14}H_{22}O$ or $C_{15}H_{24}O$, and is analogous to *cynanchole*, from *Cynanchum acutum*, and to *asclepion*, from *Asclepia Syriaca*.
 J. B. T.

Aspergillin, a Vegetable Hæmatin. By G. LINOSSIER (*Compt. rend.*, 112, 807—808).—Phipson's palmellin is rose-red, crystalline, and soluble in water, forming a dichroic solution which is rose-red by transmitted light, orange-yellow by reflected light. The solution is coagulated by heat, by ammonia, potash, or alcohol, but not by hydrochloric acid. When burnt, it leaves an ash containing calcium, chlorine, and iron.

The author's aspergillin is black, amorphous, and insoluble in water, but soluble in ammonia or potash, forming solutions which are not coagulated by heat or by alcohol. It is precipitated by hydrochloric acid. When burnt, it leaves a residue consisting of ferric oxide.

It is clear therefore that aspergillin is not identical with palmellin, and that the latter is not analogous to hæmatin (compare this vol., p. 845).
 C. H. B.

Humic Compounds. By BERTHELOT and G. ANDRÉ (*Compt. rend.*, 112, 916—922).—The results described in this paper were obtained with artificial humic compounds. 1500 grams of sugar, boiled for a long time with concentrated hydrochloric acid, gave 236 grams of humic matter insoluble in water; when dried at 100° , it had the composition C, 66.41; H, 4.57; O, 29.02 = 100, which agrees with the formula $C_{18}H_{14}O_6$. Another preparation contained C, 68.91; H, 4.58; O, 31.51 = 100, which agrees with the formula $C_{18}H_{16}O_7$; the product obtained by the action of hydrochloric acid on the alkali salts has the same composition. The first compound is *humic anhydride*; the second is the true *humic acid*. Both compounds when left in contact with water swell up and acquire a gelatinous consistence, in this respect resembling colloids. In presence of excess of potash, even in somewhat dilute solution, humic acid yields an insoluble colloidal salt, $C_{18}H_{15}K_3O_7 + nH_2O$, which is decomposed by prolonged washing with water, two-thirds of the alkali being removed, whilst a salt, $C_{18}H_{15}KO_7$, is left. This last salt is formed when humic acid or the anhydride is left in contact with even a very dilute solution of potash; it is but slightly decomposed by water, even after prolonged boiling. Carbonic acid is practically without effect in the cold, but dilute hydrochloric acid removes the whole of the potassium. On the other hand, the anhydride, or acid, slightly decomposes a solution of potassium chloride with liberation of a small quantity of hydrochloric acid.

With sodium hydroxide, humic anhydride forms a compound,

$C_{18}H_{18}NaO_7$, which is insoluble, and in presence of excess of soda another salt is formed, containing not quite three times as much sodium. The latter compound loses alkali when washed with water, and is converted into the first salt. Barium hydroxide and calcium hydroxide behave similarly, forming two salts, one of which is decomposed by water.

In contact with excess of dilute ammonia, humic anhydride forms an insoluble, gelatinous compound containing 4 mols. NH_3 . The product seems to be an acid amide; it does not lose ammonia at 40° in a current of hydrogen; at 100° , there is a distinct loss of nitrogen, and if the residue is boiled with magnesia and water, ammonia is evolved, but all the nitrogen is not expelled.

When heated with ammonia in sealed tubes at 100° , humic anhydride combines with about 9 per cent. of ammonia, and forms an insoluble product which can be dried at 100° , and does not lose all its nitrogen when boiled with magnesia. C. H. B.

Constitution of Rings containing Five Atoms. By E. BAMBERGER (*Ber.*, 24, 1758—1764).—Stohmann and Kleber have shown (this vol., p. 377) that when compounds containing the benzene and thiophen nuclei are hydrogenised, the first addition of H_2 has a different thermal value to that of the second and third additions, which latter have the same value. The author noticed a similar difference in the case of pyrroline and its hydrogenised derivatives when the alterations of basicity are compared instead of the thermal values, thus:—pyrroline has very feeble basic properties, whilst its di- and tetrahydro-derivatives are strong bases. This, he believes, may be explained by assigning to pyrroline a centric formula in which the nitrogen exists in the pentavalent condition, and to the di- and tetrahydro-derivatives a mixed formula and an alicyclic formula respectively, containing trivalent nitrogen. The same applies to indole. The paucity of facts precludes for the present the extension of the discussion to other ring compounds containing five atoms—thiophen, furfuran, &c. A. R. L.

Hantzsch's Pyridine Synthesis. By C. BEYER (*Ber.*, 24, 1662—1670).—The author brings forward a modified explanation of Hantzsch's pyridine synthesis, based on the results obtained by Claisen (*J. pr. Chem.* [2], 35, 413; *Annalen*, 218, 161), on the condensation of aldehydes with ethereal salts of ketonic acids. Claisen has stated that the group $\cdot CO \cdot CH_2 \cdot CO \cdot$ attacks a double bond between two carbon atoms in such a way that one hydrogen atom of the methylene combines with one carbon atom, and the residue, $\cdot CO \cdot \dot{C}H \cdot CO \cdot$, with the other carbon atom. Thus ethyl malonate and ethyl ethylidenemalonate combine according to the equation $MeCH:C(COOEt)_2 + CH_2(COOEt)_2 = CHMe[CH(COOEt)_2]_2$. The author has studied Hantzsch's synthesis from the point of view indicated by the above reaction. He considers that in the presence of ammonia, aldehyde ammonia, or ethyl paramidoacetoacetate, the condensation takes place in the following stages:—First, the aldehyde condenses with the ethyl acetoacetate to form ethyl ethylidinaacet-

ate, the latter then combines with a second molecule of the ethyl acetoacetate to form ethyl ethylidenediaceoacetate, and then the ammonia acts on the latter with formation of ethyl dihydrocollidinedicarboxylate. This is, however, contrary to the observation of Hantzsch, that ethyl benzylidenediaceoacetate, which has an analogous constitution to the above, does not yield a pyridine derivative with ammonia. It was therefore necessary to determine if a similar reaction took place between ethyl ethylidenaceoacetate and ethyl paramidoaceoacetate. If ethyl ethylidenaceoacetate is mixed in molecular proportion with ethyl paramidoaceoacetate, heat is evolved, a brisk reaction, with evolution of water, takes place, and almost pure ethyl dihydrocollidinedicarboxylate is obtained. The latter melts at 130° , and, when oxidised with nitrous acid, yields ethyl collidinedicarboxylate boiling at 308° . In a similar way, ethyl benzylidenaceoacetate and ethyl paramidoaceoacetate give ethyl dihydrophenyllutidinedicarboxylate. The intermediate additive compounds, which the author assumes are formed in the above reactions, cannot be separated.

The ammonia derivatives of benzoylacetone and of acetylacetone, corresponding with ethyl paramidoaceoacetate, were also examined in support of the above view. When benzoylacetoneimide and ethyl ethylidenaceoacetate are warmed together in molecular proportion, a brisk reaction takes place, water is eliminated, and, on cooling, a yellow, crystalline mass of *ethyl 3-benzoyldihydrocollidinedicarboxylate* is obtained. It crystallises from alcohol in yellow leaflets, melts at $186-187^{\circ}$, is an indifferent substance, dissolves, however, in concentrated mineral acids, but is precipitated unchanged on addition of water.

Ethyl 3-benzoylcollidinedicarboxylate is obtained by oxidising the foregoing compound, suspended in alcohol, with nitrous acid. The product is washed with ether, the nitrate decomposed with potash, and the free base extracted with ether. It forms a viscid, pale-yellow liquid which partially decomposes on boiling, and so gives no constant boiling point. It dissolves easily in dilute hydrochloric or sulphuric acid, and double salts are obtained on adding picric acid or platinic chloride to the solution. The *hydrochloride* crystallises in prisms and melts at 192° . The *platinochloride* crystallises from dilute hydrochloric acid in needles.

The methylimide of benzoylacetone, $\text{CPh}\cdot\text{CH}_2\cdot\text{CMe}\cdot\text{NMe}$, which is obtained by allowing a mixture of benzoylacetone and methylamine to remain some time, or by heating the mixture under pressure, and crystallises from light petroleum in beautiful leaflets melting at $74-75^{\circ}$, behaves in a similar way to benzoylacetoneimide.

Ethyl methylbenzoyldihydrocollidinedicarboxylate [$\text{Me} = 1$] is obtained by mixing the above methylimide with ethyl ethylidenaceoacetate; it crystallises from light petroleum in yellowish-white needles, and melts at 97° .

Ethyl 3-acetyldihydrocollidinedicarboxylate is obtained in a similar way from acetylacetoneimide. When the latter is mixed with ethyl ethylidenaceoacetate, a clear solution is obtained, heat is evolved, and on heating on the water-bath water is eliminated. Alcohol is then added, and the mixture cooled, when a crystalline mass is obtained. It

crystallises from dilute methyl alcohol in flat, yellowish-white needles, melts at 120° , and resembles the analogous compounds described above
E. C. R.

Oxidation of Aniluvitonic Acid. By C. BOTTINGER (*Annalen*, 263, 247—248).—Doebner and Miller (Abstr., 1886, 721) found that quinaldine, on oxidation, yields acetanthranilic acid and oxalic acid, and that α -alkyloinchonic acids give only anthranilic acid derivatives. The author has previously shown (*Ber.*, 15, 133) that aniluvitonic acid gives, on oxidation with potassium permanganate, the same pyridinetricarboxylic acid as is obtained from uvitonic acid under the same conditions; a repetition of these experiments, which seem to have been overlooked by Doebner and Miller, has confirmed the results previously published.
F. S. K.

β -Picoline. By P. SCHWARZ (*Ber.*, 24, 1676—1678).— β -Picoline is prepared by adding anhydrous glycerol (250 grams) to a mixture of phosphoric anhydride (200 grams) and dry ammonium phosphate (100 grams). The mixture is heated on the sand-bath in a reflux apparatus for about 50 hours, then diluted with water, and sodium hydroxide added to the well-cooled mixture. It is then distilled until the distillate reacts only faintly alkaline. The dilute solution of the base so obtained is mixed with solid soda and again distilled, when almost all the picoline is obtained in the first fractions, and is precipitated on addition of potash, and dried over potash. It boils at 140.5 — 143° , the greater part between 141 — 142° . When heated with benzaldehyde and a small quantity of zinc chloride at 230° , a small quantity of stilbazole, $C_{11}H_{11}N$, is obtained, identical with that obtained by Baurath from α -picoline (Abstr., 1888, 65, 608), and most of the β -picoline remains unchanged. Hence the author concludes that β -picoline prepared in the above way contains a small quantity of α -picoline, and that the former does not condense with benzaldehyde. All attempts to obtain a condensation product from β -picoline and benzaldehyde, or chloral, were unsuccessful.

The above results give a method of obtaining β -picoline free from α -picoline. β -Picoline, obtained as above, was converted into the mercuriochloride, the latter recrystallised and decomposed. The β -picoline obtained boiled at 141.5 — 142° . It was heated with benzaldehyde and zinc chloride at 225 — 230° . A small quantity of stilbazole was obtained. The unattacked base was recovered and converted into the mercuriochloride. The latter melts at 147 — 149° . The regenerated base boils at 141.5° (uncorr.; 143.5° , corr.), and has the sp. gr. 0.97256 at $0^{\circ}/4^{\circ}$. The platinochloride melts at 201 — 202° , the aurochloride at 186° , and the picrate at 149 — 150° .

E. C. R.

Synthesis of Oxypyridine and Piperidine Bases. By A. LADENBURG (*Ber.*, 24, 1619—1628; compare Abstr., 1890, 67).— α -Picolyalkaline, $C_6NH_4 \cdot CH_2 \cdot CH_2 \cdot OH$, boils at 114 — 116° under a pressure of 9 mm. The benzoyl derivative, $C_6NH_4 \cdot CH_2 \cdot CH_2 \cdot OBz$, is a viscid liquid; the platinochloride, $(C_{14}NH_{13}O_2)_2 \cdot H_2PtCl_6$, crystallises from water and melts at 164 — 168° ; the aurochloride is deposited in broad,

lustrous prisms. Picolinic acid is the sole oxidation product of picerylalkine; no pyridylacetic acid could be detected.

The corrected boiling point of α -pipecolylalkine,

is 234.5° . The *hydrochloride* and *mercurochloride* are both crystalline, and the former is very hygroscopic. The *benzoyl derivative* yields a *hydrochloride* which crystallises in small, colourless plates.

Methyl- α -pipecolylalkine, $C_5NH_9Me\cdot CH_2\cdot CH_2\cdot OH$, is prepared by heating α -pipecolylalkine with 5—6 parts of potassium methyl sulphate for 12—24 hours on the water-bath; the base is purified by means of the *mercurochloride*, and forms a colourless, viscid liquid boiling at 232.5° (corr.). The *platinochloride* is not crystalline; the *aurochloride* melts at $169—170^\circ$. The *mercurochloride*, $C_5NH_9OCl_2\cdot 5HgCl_2$, is deposited in well-developed crystals which melt at 214° without decomposition. On heating the base with methyl iodide in alcoholic solution, *methylpipecolylalkine methiodide*, $C_5NH_9Me\cdot CH_2\cdot CH_2\cdot OH\cdot MeI$, is deposited in colourless prisms. The *hydrochloride* does not crystallise; the *platinochloride* melts at 173° ; the *aurochloride* crystallises in lustrous, yellow needles, and melts at $211—212^\circ$. On treatment of the base with tropic acid and hydrochloric acid, a compound is obtained which affects the eyes in a similar manner to atropine; on this account, and from the general likeness of the other derivatives to those of tropine, the author regards the base as a dihydro-tropine. All attempts hitherto made to prepare tropine by the oxidation of this hydrotropine have failed; on treatment with potassium ferricyanide at the ordinary temperature, a compound is obtained which is isomeric with tropine, and is therefore termed *paratropine*; it is a colourless, strongly alkaline liquid boiling at $200—203^\circ$, and readily dissolves in ether. The *hydrochloride* is crystalline and readily soluble; the *aurochloride*, $C_5NH_9O\cdot HAuCl_4$, is deposited in small plates which melt at $181—182^\circ$; the *platinochloride* crystallises in transparent, orange-yellow prisms belonging to the monosymmetric system, and melts at $195—197^\circ$ with decomposition. The *mercurochloride*, $C_5NH_9O\cdot HCl_2\cdot 6HgCl_2$, is deposited from water in small crystals melting at 225° with decomposition.

By the action of hydriodic acid and phosphorus on paratropine at 150° , a compound is formed which crystallises from water in colourless needles, and is probably an iodide. J. B. T.

γ -Dipyridyl and γ -Dipiperidyl. By F. B. AHRENS (*Ber.*, 24, 1478—1480).—The γ -dipiperidyl previously described by the author (*Abstr.*, 1889, 59) is not a pure compound, but contains another substance which may be separated by converting the bases into their nitroso-compounds, that of γ -dipiperidyl being a solid and the other a liquid. γ -Dipyridyl is best prepared by allowing sodium to act on pyridine at the ordinary temperature in closed vessels until a homogeneous, black, pulverulent mass is obtained; this is exposed to the air until it becomes yellowish-white, then extracted with cold water, and the insoluble portion recrystallised from the hot liquid. It is reduced in amyl alcohol solution with a large excess of sodium, the

solution acidified with concentrated hydrochloric acid, and the aqueous layer treated with sodium nitrite. On cooling, slender, yellowish needles separate, which are extracted with chloroform, the extract evaporated, and the residue recrystallised from alcohol. The *nitroso- γ -dipiperidyl* thus obtained forms yellow crystals and melts at 141—143°. The free *γ -dipiperidyl* is prepared from the nitroso-compound by dissolving it in concentrated hydrochloric acid, passing in hydrogen chloride, then adding freshly prepared soda solution, and extracting at once with ether. The extract is dried with potash and evaporated, the dipiperidyl being obtained in broad, transparent needles, which are hygroscopic, absorb carbonic anhydride from the air, and melt at about 160°. The *hydrochloride* crystallises in needles; the *platinochloride*, $C_{10}H_{20}N_2 \cdot H_2PtCl_6$, in very stable plates; and the *aurochloride*, $C_{10}H_{20}N_2 \cdot 2HAuCl_4$, in long needles which gradually decompose when heated above 220°. The *mercuriochloride* forms stellate aggregates of slender needles, is readily soluble in hot water, and melts with blackening at 226—227°. The *picrate* forms sparingly soluble, jagged plates and blackens when heated above 200°.

H. G. C.

Oxidation of Quinoline Derivatives. By W. v. MILLER (*Ber.*, 24, 1900—1922; see also *Abstr.*, 1890, 1324).—The results obtained by various observers show that when alkyl halogen additive compounds of quinoline are oxidised with permanganate, the pyridine ring is destroyed, and derivatives of orthoamidobenzoic acid are obtained. The pyridine ring is also destroyed in the case of carbostyryl and cynurin, and generally in the case of hydrogen additive compounds. Both nuclei are destroyed in the oxidation of carbostyryl methyl ether and methylpseudocarbostyryl. The benzene nucleus is destroyed in aqueous or alkaline solution in the case of the following quinoline derivatives which contain substituents in the benzene nucleus:—Parabromoquinoline, parabromananitroquinoline, ortho- and para-nitroquinoline, α - and β -dinitroquinoline, ortho- and para-hydroxyquinolinecarboxylic acids, orthohydroxydithioquinolinecarboxylic acid, orthoquinoline-sulphonic acid, orthohydroxyquinoline, orthohydroxyparamidoquinoline, and α -hydroxyquinolinesulphonic acid. The benzene nucleus is destroyed in acid solution in the case of paramidophenylquinoline. Both the pyridine and benzene nuclei are destroyed on oxidation of γ -bromoquinoline in aqueous solution. Quinoline derivatives which contain substituents in both nuclei, generally undergo oxidation with destruction of the benzene ring.

From the above results, no general conclusion can be drawn unless it is assumed that the pyridine nucleus is destroyed in all cases where, according to v. Baeyer and Bamberger, the equality of the "central" or "potential" valence of the pyridine nucleus is destroyed, or where the pyridine nitrogen becomes pentavalent. The latter occurs in the oxidation of quinoline derivatives in acid solution; thus, on oxidation of aniluvitonic acid in alkaline solution, the benzene nucleus is destroyed, in acid solution the pyridine nucleus. In some other cases, where oxidation takes place with difficulty in alkaline liquids, it takes place easily in acid liquids. Paramidophenylquinoline is an exception, for in acid solution it yields α -hydroxynicotinic acid;

probably the presence of the amido-group has weakened the benzene nucleus.

When quinoline is oxidised in an aqueous solution with potassium permanganate, the benzene nucleus is destroyed, and pyridinedicarboxylic acid is obtained. Orthotoluquinoline and paratoluquinoline in like manner yield pyridinedicarboxylic acid.

The oxidation of methylquinolines, in which the methyl is in the pyridine nucleus, is influenced by the position of the methyl group. If the methyl group is in the γ -position, then the benzene nucleus is destroyed. If it is in the α -position, then the pyridine nucleus is destroyed. Substitution in the benzene nucleus does not appear to affect this rule. In the case of β -methylquinoline, both nuclei are destroyed, and oxalic acid, carbonic anhydride, and ammonia are formed. If, besides methyl in the α position, a second methyl group is present, then if the second methyl group is next the α -methyl, the pyridine nucleus is destroyed; if the second methyl group is in the γ -position, the benzene nucleus is destroyed.

If the pyridine nucleus contains carboxyl, then the benzene nucleus is always destroyed, and a pyridinecarboxylic acid is formed.

Orthotoluquinaldine.—The base (10 grams) is suspended in $1\frac{1}{2}$ litres of water and permanganate (42 grams) dissolved in water (500 c.c.) gradually added; the mixture is made neutral or faintly acid with sulphuric acid, and heated for 1—2 hours on the water-bath. The filtered solution is evaporated to dryness, and the product extracted with absolute alcohol; the alcoholic solution deposits a mixture of the acid and its potassium salt; it is dissolved in soda, and the acid precipitated with hydrochloric acid; it was identified as *acetyl-amidotoluic acid*. It crystallises from water or alcohol in shining, prismatic needles, melts at 193 — 194° , and is easily soluble in hot water and alcohol, sparingly in ether, and insoluble in dilute mineral acids; in concentrated mineral acids it dissolves with decomposition. The *silver* salt forms white needles, and quickly darkens on exposure to light. The *calcium* salt forms white, shining plates.

If the acid is heated above 200° , or if it is distilled with baryta, carbonic anhydride is split off, and orthotoluidine is obtained.

α - β -*Dimethylparatoluquinoline* was oxidised as described by Doebner and v. Miller for quinaldine; the acid obtained gave numbers corresponding with *methylacetanthranilic acid*; it crystallised from alcohol and water in white, asbestos-like needles, and melted at 193 — 194° .

Ethylquinoline [Et = 2'], when oxidised in alkaline solution, gives very bad results. In acid solution, however, oxidation takes place easily in the cold. The base is dissolved in dilute sulphuric acid, gradually mixed with a solution of permanganate, and the mixture kept acid by constant additions of sulphuric acid. The acid obtained was identified as propionylorthamidobenzoic acid. It crystallises best from high boiling petroleum in white, lustrous needles, and melts at 117° .

Methylquinoline [Me = 3'] is best prepared by saturating a mixture of formaldehyde (40 per cent., 100 grams) and propaldehyde (85 grams) with dry hydrogen chloride, adding to a mixture of

aniline (120 grams) and concentrated hydrochloric acid (240 grams), and heating in a reflux apparatus for some hours on the water-bath. The oxidation gave very bad results. The base (10 grams) was suspended in 5 per cent. caustic potash (1500 grams), and heated in a reflux apparatus on the water bath. The products were ammonia, carbonic anhydride, oxalic acid, the oxalate of the base, a brown, resinous mass, and some quantity of the base which remained unchanged.

Dimethylquinoline [$\text{Me}_2 = 2' : 4'$] is purified by conversion into the picrate, decomposing the latter with soda, distilling with steam, and finally by fractional distillation. It boils at $260-261^\circ$. For the oxidation, the base (10 grams) is suspended in 7 per cent. potassium carbonate solution (1500 c.c.), 4 per cent. permanganate solution gradually added, and the mixture heated on the water-bath. The product contains a considerable quantity of oxalic acid; it was neutralised, converted into the silver salt, then into the barium salt; the latter decomposed, and the acid crystallised from absolute alcohol. It was identified as picolinetricarboxylic acid; it crystallises in white, fibrous crusts, turns yellow at 189° , begins to sublime at 210° , turns brown at $210-230^\circ$, and melts at 235° with frothing and evolution of carbonic anhydride. Together with the above acid, a small quantity of the tetracarboxylic acid is formed. The same result is obtained by oxidation in the cold.

Quinaldinic acid is best prepared by oxidising benzylidenequinaldine with chromic acid. Benzylidenequinaldine is prepared by heating quinaldine (115 grams) with benzaldehyde (90 grams) for 4-5 hours in a sulphuric acid bath at $140-150^\circ$, and adding zinc chloride to the mixture from time to time until the further addition of zinc chloride causes no reaction. The mixture is then poured into a basin, and the crystalline mass extracted with concentrated hydrochloric acid and hot water; the filtered solution, on cooling, deposits crystals of benzylidenequinaldine hydrochloride. The latter was filtered off and decomposed with ammonia, and the benzylidenequinaldine dried on porcelain plates and crystallised from alcohol. It crystallises in colourless needles, melts at $99-100^\circ$, is insoluble in water, and easily soluble in chloroform and carbon bisulphide. The benzylidenequinaldine (10 grams) is dissolved in dilute sulphuric acid (200 c.c.), the solution gently boiled, and chromic acid (15 grams) in water (70 grams) and concentrated sulphuric acid (75 grams) gradually added. When the mixture has cooled somewhat, $\frac{3}{4}$ litre of water is added, and the mixture allowed to stand 48 hours. The solution is freed from benzoic acid by extraction with ether; the chromium precipitated with ammonia, filtered hot, and the filtrate evaporated to dryness and extracted with alcohol. The quinaldinic acid crystallises from water in asbestos-like needles, and melts at 156° .

The oxidation is carried out as follows:—The quinaldinic acid (10 grams) is dissolved in water (500 grams) containing a slight excess of potassium carbonate, and the cold solution gradually mixed with a cold saturated solution of permanganate (41 grams), and allowed to remain for a few days. It is then heated on the water-bath,

filtered, and the filtrate acidified with sulphuric acid, and dilute permanganate added as long as it is at once decolorised. The solution is then neutralised with ammonia and concentrated on the water-bath, again acidified with sulphuric acid, and the sulphate precipitated with alcohol; after being treated in this way once or twice to get rid of all the sulphate, the filtrate is concentrated and allowed to crystallise. After some days, a crystalline crust of pyridinetricarboxylic acid $[(\text{COOH})_3 = 2:5:6]$ is obtained. It is purified by conversion into the calcium salt, decomposing with sulphuric acid, converting into silver salt, and decomposing with hydrogen sulphide. It crystallises from water in thin leaflets, gives off carbonic anhydride at 130° , melts at $236-237^\circ$, and decomposes again above 237° , and is easily soluble in dilute alcohol and water, almost insoluble in ether, absolute alcohol, and acetic acid. The solution neutralised with ammonia gives white, insoluble precipitates with barium chloride, calcium chloride, lead nitrate, and silver nitrate; an olive-green precipitate with copper acetate, a yellowish-white with ferric chloride, and a carmine-red with ferrous sulphate.

α -Methylcinchoninic acid is obtained by gradually adding aniline (1 mol.) to a mixture of acetylcarboxylic acid (1 mol.) and acetaldehyde (1 mol.) diluted with absolute alcohol, and heating the mixture for 4-5 hours in a reflux apparatus on the water-bath.

For oxidation in alkaline solution, the acid (10 grams) is dissolved in warm water containing a slight excess of potassium carbonate, permanganate (56 grams in $1\frac{1}{2}$ litres of water) added, and the mixture warmed. The solution contained oxalic acid and an acid which, on analysis, gave numbers corresponding with picolinetricarboxylic acid. The latter was extremely difficult to purify, is easily soluble in water, insoluble in alcohol and ether, and decomposes at $210-225^\circ$. With iron sulphate it gives a red coloration.

In acid solution, the oxidation takes place in the cold, and acetyl-anthranilic acid (m. p. $179-180^\circ$) is obtained. E. C. R.

Alicyclic Homology. By E. BAMBERGER (*Ber.*, 24, 1697-1899).—In accordance with the views lately put forward by the author, dihydroindole and tetrahydroquinoline, although derived from distinctly different mother substances, ought both to behave like alkylated anilines. Dihydroindole itself is not known; the author has, therefore, compared the homologous dihydromethylketole with tetrahydroquinoline. These two bases are related to each other in the same way as propylaniline to isopropylaniline. The author finds that they behave alike. Thus hydromethylketole, when treated with a diazo-compound in the presence of sodium acetate, like hydroquinoline, yields a diazoamido-compound which crystallises in beautiful columns. In the presence of mineral acids, the reaction also takes place as with hydroquinoline, and the azo-group enters the benzene nucleus in the para-position. The azo-dye so obtained closely resembles the corresponding hydroquinoline dye, yields, on reduction, a diamine which gives the same characteristic colour reaction as paramidotetrahydroquinoline, and, like the latter, behaves as an alkyl-paraphenylenediamine. E. C. R.

Methoxydihydroxydihydroquinoline. By A. EICHENGRÜN and A. EINHOEN (*Annalen*, 262, 133—181).—*Metachlorobenzaldehyd-phenylhydrazone*, $C_6H_4Cl \cdot CH:N_2HPh$, crystallises from alcohol in colourless needles, melts at 134—135°, and is readily soluble in alcohol, ether, ethyl acetate, and chloroform, but more sparingly in light petroleum: its alcoholic solution decomposes on keeping.

Orthonitrometachlorobenzaldehyde, $NO_2 \cdot C_6H_4Cl \cdot CHO$, is obtained when metachlorobenzaldehyde (compare Erdmann and Schwechten, this vol., p. 448) is added drop by drop to a well-cooled mixture of concentrated sulphuric acid and potassium nitrate; it crystallises from alcohol in lustrous needles, melts at 77·5°, is readily soluble in hot water and most ordinary solvents, and is volatile with steam. On oxidation with potassium permanganate, it is converted into metachloronitrobenzoic acid (m. p. 137°). The *hydrazone*, $C_{13}H_{10}N_3O_2Cl$, crystallises from alcohol in needles, melts at 180—181° with decomposition, and is soluble in alcohol, ether, glacial acetic acid, chloroform, and benzene, but insoluble in light petroleum. The *oxime*, $C_7H_5N_3O_2Cl$, crystallises from alcohol in colourless, prismatic plates, and from hot water in needles, melts at 112°, and is readily soluble in the ordinary solvents.

Orthonitrometachlorophenylactic ketone,

is formed in small quantities (1—2 per cent.), together with a small quantity (2—3 per cent.) of orthonitrometachlorocinnamic ketone by the condensation of pure acetone with orthonitrometachlorobenzaldehyde at 0° in presence of dilute soda, but the principal product of the reaction is orthonitrometachlorophenylactic methyl ketone (compare Abstr., 1890. 1128); the three products are separated by taking advantage of their different solubilities in alcohol. Orthonitrometachlorophenylactic ketone separates from ethyl acetate in lustrous, dendritic forms, melts at 207·5—208·5° with decomposition, and is readily soluble in benzene, ethyl acetate, glacial acetic acid, and hot alcohol, but only sparingly in chloroform and ether, and insoluble in light petroleum; on prolonged boiling with concentrated soda, it yields small quantities of dichlorindigo. The *hydrazone*, $C_{23}H_{20}O_6N_4Cl_2$, crystallises from glacial acetic acid in small, deep red needles, melts at 193·5°, and is readily soluble in most ordinary solvents, except light petroleum.

Orthonitrometachlorocinnamic ketone, $CO(CH:CH \cdot C_6H_4Cl \cdot NO_2)_2$ (see above), is also formed when the preceding compound is boiled with acetic anhydride; it crystallises in golden needles, melts at 205—206°, and is soluble in hot benzene, glacial acetic acid, and ethyl acetate, but more sparingly in chloroform, and insoluble in alcohol, ether, and light petroleum. The *tetrabromide*, $C_{17}H_{10}O_2Cl_2N_2Br_4$, prepared by treating the ketone with bromine in glacial acetic acid solution, crystallises in colourless, lustrous needles, melts at 199—200° with decomposition, and is soluble in chloroform, benzene, and glacial acetic acid. The *hydrazone*, $C_{23}H_{16}N_4O_4Cl_2$, crystallises from glacial acetic acid in slender, carmine-red needles, melts at 194—195° with decomposition, and is readily soluble in hot glacial acetic acid, ethyl

acetate, and chloroform, but insoluble in alcohol, ether, and light petroleum.

Orthonitrometachlorophenyllactic methyl ketone,

(*loc. cit.*), crystallises in colourless, hexagonal plates, $a : b : c = 0.6412 : 1 : 1.4375$, $\beta = 76^\circ 4'$, belonging to the monoclinic system; it dissolves in concentrated sulphuric acid with a red coloration, and is immediately converted into dichlorindigo by alkalis. The *hydrazone*, $\text{C}_{18}\text{H}_{16}\text{N}_2\text{O}_3\text{Cl}$, crystallises from glacial acetic acid in wine-red needles, melts at 157 – 158° , and is soluble in most ordinary solvents, except light petroleum. The *oxime*, $\text{C}_{10}\text{H}_{11}\text{N}_2\text{O}_4\text{Cl}$, separates from alcohol in small plates, melts at 151° , and is soluble in ethyl acetate, but only sparingly soluble in benzene, chloroform, and light petroleum, and insoluble in ether.

Orthonitrometachlorobenzylideneacetone, $\text{NO}_2 \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{CH} : \text{CH} \cdot \text{COMe}$, is formed when the preceding compound is boiled with acetic anhydride; it crystallises from alcohol in colourless prisms, melts at 143° , and is soluble in glacial acetic acid, ethyl acetate, benzene, and chloroform, but more sparingly in ether and light petroleum. The *hydrazone*, $\text{C}_{16}\text{H}_{14}\text{N}_2\text{O}_3\text{Cl}$, crystallises from glacial acetic acid in slender needles, melts at 161° , and dissolves in glacial acetic acid, alcohol, and ethyl acetate with a red, and in ether, benzene, chloroform, and light petroleum with a yellow, coloration.

Orthonitrometachlorophenyl- β -lactic acid (*loc. cit.*) forms monoclinic crystals, $a : b : c = 0.8652 : 1 : 1.8184$, $\beta = 78^\circ 40'$ (m. p. 156° with decomposition), and is readily soluble in alcohol, ether, chloroform, benzene, acetone, ethyl acetate, and glacial acetic acid, but more sparingly in hot water, and insoluble in light petroleum; it dissolves in concentrated sulphuric acid with a red coloration, and, when heated with potash, it gives off an odour of nitrobenzene, yielding a red solution which becomes colourless on cooling. The *potassium* salt, $\text{C}_6\text{H}_7\text{NO}_5\text{ClK}$, crystallises from dilute alcohol in colourless, lustrous needles, turns brown on exposure to light, and is very readily soluble in water and ethyl acetate, but insoluble in absolute alcohol; the barium, calcium, silver, and copper salts are crystalline. The *ethyl* salt, $\text{C}_{11}\text{H}_{13}\text{ClNO}_5$, forms small, nodular crystals, melts at 110° , and is readily soluble in all ordinary solvents, except water. When the potassium salt of the acid is heated at 100° with a methyl alcoholic solution of potassium methoxide, a small quantity of an acid, probably methoxynitrophenyl acetic acid, which melts at 125 – 126° , is obtained.

Orthonitrometachlorobenzaldehyde, $\text{NO}_2 \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{CH} : \text{CH} \cdot \text{COOH}$, prepared by heating orthonitrometachlorobenzaldehyde with acetic anhydride and sodium acetate, crystallises from dilute alcohol in colourless needles, melts at 174 – 175° , turns reddish on exposure to light, and is readily soluble in glacial acetic acid, ethyl acetate, acetone, and chloroform, but only sparingly in benzene, and almost insoluble in light petroleum; it dissolves in concentrated sulphuric acid with a green coloration. The *silver* salt, $\text{C}_6\text{H}_5\text{NO}_4\text{ClAg}$, crystallises from dilute alcohol in colourless needles, and is soluble in hot water. The *barium* salt, $(\text{C}_6\text{H}_5\text{NO}_4\text{Cl})_2\text{Ba} + 3\text{H}_2\text{O}$, *calcium* salt $(+1\frac{1}{2}\text{H}_2\text{O})$ and

the *copper* salt ($+1\frac{1}{2}\text{H}_2\text{O}$) are crystalline. The *ethyl* salt, $\text{C}_{11}\text{H}_{13}\text{NO}_4\text{Cl}$, crystallises from alcohol in long, colourless needles, melts at 62° , and is very readily soluble in all ordinary solvents, except water, in which it is insoluble.

Orthonitrometachlorophenyl- β -lactic acid (m. p. 152°), prepared as previously described (*loc. cit.*) from the lactone,

(m. p. 147° with decomposition), or from the lactamide,

(m. p. 148°), is very readily soluble in alcohol, chloroform, ethyl acetate, and light petroleum, but rather more sparingly in ether, benzene, and warm water, and insoluble in light petroleum; it dissolves in sulphuric acid, yielding a bluish-green solution. The calcium salt and the salts of the alkalis are soluble in water, but the barium, copper, and lead salts are insoluble; the silver salt crystallises from ammonia in colourless needles, is soluble in hot water, and rapidly darkens on exposure to light. The *ethyl* salt, $\text{C}_{11}\text{H}_{13}\text{ClNO}_5$, crystallises from light petroleum in colourless, hexagonal plates, melts at 48° , and is readily soluble in alcohol, ether, ethyl acetate, benzene, and chloroform, but only sparingly in light petroleum.

A comparison of the properties of the two orthonitrometachlorophenyl- β -lactic acids (m. p. 152° and 156° respectively) and of those of their derivatives shows, beyond doubt, that the two acids are not identical.

Chlorodihydroxydihydroquinoline [$\text{H}_2 : (\text{OH})_2 : \text{Cl} = 3' : 4' : 2' : 4' : 3$], prepared by reducing orthonitrometachlorophenylactic acid (m. p. 152°) with ferrous sulphate and ammonia, crystallises from ethyl acetate in slender needles, melts at 172° , and is readily soluble in alcohol and warm water, but more sparingly in chloroform, benzene, and ether, and insoluble in light petroleum; when its aqueous solution is warmed with ferric chloride, there is produced a bright red coloration which disappears on cooling, and, when boiled with water, it is converted into chlorocarbostyryl (m. p. $262-263^\circ$), identical with the compound prepared by Einhorn and Launch from parachloroquinoline.

Orthonitrometachlorophenyl- β -lactaldehyde,

(*loc. cit.*), is a colourless oil, readily soluble in most ordinary solvents, except light petroleum; its *hydrazone*, $\text{C}_{10}\text{H}_{11}\text{N}_2\text{O}_2\text{Cl}$, crystallises in long, orange-red needles, melts at 182° , and is readily soluble in benzene and chloroform, but more sparingly in alcohol and glacial acetic acid, and very sparingly in ether and light petroleum.

Orthonitrometamethoxyphenyllactic acid (m. p. 106°) is readily soluble in warm water, alcohol, chloroform, and ethyl acetate, but more sparingly in ether, and very sparingly in light petroleum and benzene; when heated with concentrated sulphuric acid, it gives a green solution, the colour of which changes first to violet, and then to a brownish-red on boiling. The potassium salt crystallises from

hot water in lustrous plates; the calcium salt is readily soluble in water, but the barium salt and the lead salt are insoluble.

Orthonitrometamethoxycinnamic acid (m. p. 224·5—225·5°) is soluble in glacial acetic acid and ethyl acetate, but only sparingly soluble in benzene, ether, and chloroform, and almost insoluble in light petroleum. The *silver* salt, $C_{10}H_6NO_5Ag + \frac{1}{2}H_2O$, crystallises from dilute alcohol in colourless needles, quickly turns brown on exposure to light, and is readily soluble in alcohol and ammonia, but only sparingly in hot water. The *calcium* salt, $(C_{10}H_6NO_5)_2Ca + 2H_2O$, crystallises from dilute alcohol in colourless needles, and is insoluble in water; the *barium* salt and the dark blue *copper* salt ($+2H_2O$) are crystalline. The *ethyl* salt, $C_{12}H_{13}NO_5$, is readily soluble in alcohol and ethyl acetate, but more sparingly in benzene and chloroform, and very sparingly in ether and light petroleum; it crystallises from alcohol in long needles melting at 72·5°.

Paramethoxydihydroxydihydroquinoline (*loc. cit.*), prepared from orthonitrometamethoxyphenyllactic acid, crystallises from cold water in colourless needles, melts at 177°, and is readily soluble in alcohol, ethyl acetate, and warm water, but only sparingly in chloroform and benzene, and almost insoluble in ether and light petroleum; when warmed with ferric chloride in aqueous solution, it gives a blood-red coloration, which changes to a brownish-red at a higher temperature.

Paramethoxycarbostyryl [OH : OMe = 2' : 3] separates from ethyl acetate in yellow or brown, rhombic crystals ($a : b : c = 0.8280 : 1 : 0.3866$), melts at 218—219°, and is readily soluble in alcohol, chloroform, and ethyl acetate, but only sparingly in benzene and water, and insoluble in ether and light petroleum. F. S. K.

Synthesis of Quinaldine. By W. v. MILLER (*Ber.*, 24, 1720—1728).—The author gives in detail the various hypotheses which have been advanced to explain the mechanism of the formation of quinoline derivatives when aniline is heated with certain aldehydic compounds in the presence of hydrochloric acid. The assumption that the initial interaction takes place between the aldehydic oxygen and the hydrogen atom in the ortho-position to the amido-group of aniline, a side chain being introduced which subsequently forms a closed ring, appears at first sight plausible, and is in accordance with the view that the methyl group in quinaldine occupies the position 2'; it seems specially to apply to those cases in which the formation of a quinoline derivative is possible; for in cases in which it is not possible, the aldehyde residue takes up the para-position to the amido-group, as instanced in the formation of a triphenylmethane derivative from aniline and benzaldehyde. This hypothesis fails, however, to explain the fact that the yield of 2'-phenylquinoline, by heating cinnamic anilide with hydrochloric acid, is not improved by the presence of cinnamaldehyde. It is well known that alkyl derivatives of aniline are formed as bye-products in the synthesis of quinoline derivatives; and it seems feasible that when aniline, aldehyde, and hydrochloric acid are heated together, ethyldiene aniline is first produced, and that this interacts with another molecule of aldehyde, giving rise to the compound $NPh:CH:CH:CHMe$.

This could not be put to the test, as, according to Tollens (*Ber.*, 17, 659), ethylideneaniline cannot be prepared. When, however, valerylideneaniline (Lippmann and Strecker, *Abstr.*, 1879, 462) is mixed with valeraldehyde in molecular proportion, and hydrochloric acid added, a violent reaction ensues, and, after boiling the mixture for several hours, a good yield of 2'-isobutyl-3'-isopropylquinoline (Spady, *Abstr.*, 1886, 263) is obtained. When the order of the reagents is altered, or when valerylideneaniline is heated with hydrochloric acid alone, the yield of the quinoline derivative is greatly diminished. The author is of opinion, therefore, that the intermediate compound $\text{CHMe}_2\text{CH}_2\text{CH}:\text{C}(\text{CHMe}_2)\text{CH}:\text{NPh}$ is initially formed, which then undergoes isomeric change into isobutylisopropylquinoline. The same result is obtained when valerylideneaniline is fused with anhydrous zinc chloride. When toluidopyruvic acid,

is fused with zinc chloride, a considerable yield of toluquinaldine and paramethyl- α -cinchoninic acid is obtained. Schultz (*Ber.*, 16, 2600) found that the initial product of the action of aldehyde on aniline was the compound $\text{NPh}:\text{CH}:\text{CH}:\text{CHMe}:\text{NH}_2\text{Ph}$; assuming that aniline is split off when this is fused with zinc chloride, crotonylideneaniline, $\text{NPh}:\text{CH}:\text{CH}:\text{CHMe}$, would be the intermediate compound in this instance. When the side-chains of these intermediate bases form a closed ring, dihydroquinoline derivatives might be expected to be formed, and this finds confirmation in the investigation of aldehyde-green (compare v. Miller and Plochl, this vol., p. 1070). In the case of dihydroquinaldine, however, this is so unstable that a portion is oxidised to quinaldine, whilst another portion is converted into tetrahydroquinaldine.

A. R. L.

Colouring Matters from Hydroquinaldine. By W. v. MILLER and J. PLOCHL (*Ber.*, 24, 1715—1720).—Tetrahydroquinaldine is purified by means of the acetyl derivative. When tetrahydroquinaldine (17 grams) and paranitrobenzaldehyde (8 grams) are dissolved in absolute alcohol and heated on the water-bath for two hours with zinc chloride (20 grams), and the residue, after removing the zinc with a concentrated solution of sodium hydroxide, is collected, washed, dried, and dissolved in hot alcoholic hydrochloric acid, yellow flocks separate on cooling. The base obtained by treating the latter with ammonia is amorphous, and dissolves readily in benzene, alcohol, and ether; on adding petroleum to its solution in benzene, yellow, amorphous flocks separate; but the substance was not obtained in the pure state. On treating it with chloranil in alcoholic solution, a green dye is formed.

Amidophenyltetrahydroquinallylmethane, $\text{C}_{27}\text{H}_{31}\text{N}_3$, is formed when the last-described base is reduced with tin and hydrochloric acid. After removing the tin by a current of hydrogen sulphide, the base is precipitated by ammonia; it is dissolved in alcohol and evaporated, redissolved in hydrochloric acid, and again precipitated by ammonia; it is then repeatedly dissolved in benzene and reprecipitated by light petroleum. It is a colourless, amorphous substance, soluble in alcohol,

ether, and benzene, but insoluble in petroleum and water, and yields a reddish-violet dye on treatment with chloranil in alcoholic solution. Solutions of its salts give amorphous precipitates with platinum or mercuric chlorides. The *monobenzoyl derivative*, $C_{24}H_{23}N_3O$, is prepared by shaking a solution of the base in benzene with benzoic chloride and sodium hydroxide; it forms small, silky, nodular aggregates of crystals.

Conversion of the Amido-compound into the Quinaldine Derivative.—The amido-compound (40 grams) is dissolved in concentrated hydrochloric acid (100 grams) and heated on the water-bath; aldehyde (25 grams) is gradually added and the heating continued for three hours; it is well diluted and treated with hydrogen sulphide and sulphurous anhydride, when resinous substances are precipitated; after removing these, ammonia precipitates the leuco-base as a brownish, amorphous compound which is readily soluble in alcohol, less in benzene and ether, and still less in light petroleum. It yields a bluish-green dye on oxidation with chloranil.

Tritetrahydroquinoldylmethane, $CH[C_6NH_2Me]_3$, is formed when the last-mentioned crude leuco-base is heated on the water-bath with tin and hydrochloric acid. A certain quantity of the hydrogenation product is extracted, after the addition of sodium hydroxide to the solution, by ether, whilst the main quantity is obtained from the stannochloride which separates out; the latter is repeatedly heated with sodium hydroxide, the dried cake extracted with ether, and the ethereal solution filtered and evaporated. The residue is dissolved in dilute hydrochloric acid, and after adding water and filtering, the base is precipitated with ammonia; it is then dissolved in benzene, and the resinous substances precipitated by adding light petroleum: the base then separates after a while in almost white flocks. It is soluble in alcohol, ether, and benzene; its solution in benzene, when not too concentrated, is not precipitated by light petroleum. A beautiful, bluish-violet dye is obtained on oxidation with chloranil in ethereal solution, which is converted into a green dye by heating with methyl iodide, but not by hydrogen sulphide and sulphurous anhydride; hydrochloric acid also determines the change from blue to green, but in this case the blue is reproduced by diluting with water; its analogy to methyl-violet is therefore unmistakable. A. R. L.

Fluorescent Derivatives of Aromatic Diamines. By W. v. MILLER (*Ber.*, 24, 1729—1745; compare Schiff and Vanni, *Annalen*, 253, 319; Abstr., 1890, 139).—The results described below are altogether at variance with those of Schiff and Vanni (*loc. cit.*). When metaphenylenediamine hydrochloride (15 grams) is dissolved in about 1 litre of alcohol and heated on the water-bath for $1\frac{1}{2}$ hour with cœnanthaldehyde (35 grams), a green, fluorescent solution is obtained, and on adding an alcoholic solution of picric acid and some ether, the picrate separates after a time, together with much brown oil; it is crystallised from glacial acetic acid, and the crystals treated with ammonia, the resulting brown oil being extracted with ether. A brown, crystalline mass is obtained on evaporating the ethereal solution, which, on repeated crystallisation from alcohol, forms, on drying,

white, felt-like needles of the composition $C_{24}H_{32}N_2$. The pure base is readily soluble in most solvents, but sparingly in alcohol; its alcoholic solution does not exhibit fluorescence, and the latter property in solutions of the crude base appears to be due to the presence of a hydrogenised derivative; it melts at $50-51^\circ$. The *hydrochloride* dissociates when heated with water. The *platinochloride*,

is obtained when concentrated hydrochloric acid and platinic chloride is added to an alcoholic solution of the base, and the precipitated compound crystallised from alcohol containing hydrochloric acid and platinic chloride; it forms an orange-yellow, crystalline powder, and melts at $201-210^\circ$ with decomposition. The composition of the latter compound is, according to Schiff and Vanni, $2C_{24}H_{32}N_2 \cdot H_2PtCl_6$. The *picrate* crystallises from alcohol in small, bright-yellow, felt-like needles, and melts at 104° . The base is a *diamylthiethylphenanthroline*, and its constitution is proved by the following experiments:—

Nitroumthiethylquinoline,

is prepared by heating metanitraniline (15 grams) dissolved in alcohol (500 c.c.) on the water-bath with cenanthaldehyde (20 grams) for $1\frac{1}{2}$ hour. The solution of the crude substance exhibits a faint-green fluorescence, and the base is purified by converting it into the *picrate* and crystallising the latter from glacial acetic acid, decomposing with ammonia, and extracting with ether; on repeatedly crystallising from alcohol, it forms small, white, felt-like needles, dissolves readily in benzene, chloroform, and carbon bisulphide, but less easily in ether, petroleum, acetone, and alcohol; it is insoluble in dilute acids, and melts at 53° . The *platinochloride* crystallises from alcohol in reddish-yellow needles; the *picrate* separates from alcohol in glittering, friable plates, and melts at 153° .

The *amido-derivative*, $C_{27}H_{38}N_2$, is obtained when the nitro-compound (10 grams) is dissolved in alcohol and heated on the water-bath for an hour with stannous chloride (25 gram-) and hydrochloric acid; the solution is poured into a hot, concentrated solution of sodium hydroxide, and, after diluting with water, extracted with ether; on distilling off the latter, a red oil is obtained, which solidifies to a reddish-brown mass and dissolves in alcohol with a green fluorescence. It is crystallised from petroleum, and forms a white, felt-like mass of crystals which change to red in the air, especially in the moist condition; it is readily soluble in alcohol, ether, benzene, and chloroform, sparingly in petroleum, and melts at $68-69^\circ$. The *picrate* crystallises from alcohol in long, yellow, woolly needles, sinters at 180° , and melts at 194° with decomposition. The *platinochloride* separates from alcohol containing platinic chloride and hydrochloric acid in small, dense, orange-yellow plates containing 4 mols. H_2O which effloresce in the air. When the amido-derivative (20 grams) is dissolved in 1 litre of water and heated on the water-bath for an hour with cenanthaldehyde (20 grams), a dark-red solution having a green fluorescence is obtained; sodium nitrite (10 grams) is then added to decompose the unaltered amido-derivative, and the

base isolated by means of the picrate; it is identical with the above-described diamylidihexylphenanthroline, and has the following constitution:—

Dimethylphenanthroline, $\text{C}_{14}\text{H}_{12}\text{N}_2$, is prepared by heating meta-phenylenediamine hydrochloride (25 grams) and concentrated hydrochloric acid (75 grams) at 110° in a sulphuric acid bath, with the gradual addition of paraldehyde (60 grams); the temperature is then raised to $150\text{--}160^\circ$, and the mixture maintained at this for four hours; it is then diluted with water (2 litres), filtered, and boiled with sodium nitrite; on again filtering the solution, it exhibits a green fluorescence when diluted with water. Sodium hydroxide is added, and the precipitate collected and dried, both the latter and filtrate being then extracted with ether; on distillation, the base passes over above 360° as a yellow oil which solidifies to a transparent cake; the yield is 16 grams. It is purified by dissolving in dilute hydrochloric acid and nearly neutralising with ammonia; the dark-brown substance which precipitates is then quickly filtered off, an excess of ammonia added to the filtrate, and the crystalline, hydrated base, which separates after a time, collected; it melts at $76\text{--}78^\circ$, and forms long, colourless, anhydrous needles on crystallisation from light petroleum, and then melts at $97\text{--}98^\circ$. It is readily soluble in most organic solvents, and in dilute acids, but sparingly soluble in cold light petroleum and water, more readily in a hot aqueous solution of ammonia. Solutions of the pure base do not exhibit fluorescence; it is not very volatile with steam. When heated with tin and hydrochloric acid on the water-bath for five hours, the resulting solution exhibits no fluorescence. It is rendered alkaline by sodium hydroxide and extracted with benzene; the benzene solution is then shaken with benzoic chloride and 10 per cent. sodium hydroxide for 10 hours, and after separating from the aqueous portion, repeatedly extracted with very dilute hydrochloric acid, from which, on neutralisation with ammonia, the *monobenzoyle derivative* of the *octahydro-base* separates. It is crystallised once from dilute alcohol, and twice from a mixture of light petroleum and benzene, and melts at $167\text{--}168^\circ$; it forms a solid *nitroso-derivative*. From the above benzene solution, extracted with dilute hydrochloric acid, a second compound is obtained as a viscid mass which does not solidify when kept over sulphuric acid. When meta-phenylenediamine hydrochloride is dissolved in alcohol and heated on the water-bath for four hours with twice its weight of aldehyde, a small yield of the dimethylphenanthroline is formed, and the latter is likewise obtained by the condensation of metamidoquinaldine with aldol, or with paraldehyde; it must therefore have the constitution

Triquinylmethane. By E. NOELTING and C. SCHWARTZ (*Ber.*, **24**, 1606—1609).—The authors call the group C_6NH_5 quinylyl.

Triquinylmethane, $CH(C_6NH_5)_3$, is obtained by heating a mixture of pararosaniline (22 grams), glycerol (64 grams), sulphuric acid (52 grams), and picric acid (7 grams) for 3—4 hours at 140—150°. The cold melt is poured into water, carefully neutralised with soda, and the brown precipitate dried and extracted with benzene. The benzene solution is shaken with dilute sulphuric acid, and the base reprecipitated with ammonia in ice-cold solution. It is obtained as a greenish powder, which is dissolved in benzene, and petroleum added as long as resinous compounds are precipitated; the solution is then filtered and allowed to crystallise in a vacuum over paraffin and sulphuric acid. It crystallises in white needles and melts at 202°; from alcohol it crystallises in plates, melts at 97—98° with loss of water, or alcohol, of crystallisation, solidifies at a higher temperature, and melts finally at 202°. It is easily soluble in alcohol, benzene, and ether, sparingly in light petroleum, carbon bisulphide, and boiling water, and gives no coloration with chloranil and lead peroxide in acetic acid solution. The salts are easily soluble, with the exception of the picrate and platinochloride. The *trihydrochloride* is obtained by leading hydrogen chloride into a solution of the base in benzene; it crystallises in white plates, is soluble in water and alcohol, and insoluble in benzene and absolute ether. The *picrate* is obtained by mixing alcoholic solutions of triquinylmethane and picric acid, and crystallises from dilute alcohol in slender, yellow needles. The *platinochloride*, $4C_6H_5N_3Cl_3 \cdot 3PtCl_4 + 3H_2O$, is obtained in yellow crystals; it is sparingly soluble in cold water, more easily in hot water and alcohol, and crystallises with 3 mols. H_2O , which it loses at 120°. The *methiodide*, $CH(C_6NH_5MeI)_3$, is obtained by heating the base with excess of methyl iodide at 105° for three hours. It crystallises in yellow plates or needles, melts at 265—266° with decomposition, and is easily soluble in water, sparingly in alcohol, and insoluble in ether.

Triquinylcarbinol, $OH \cdot C(C_6NH_5)_3$, is obtained by oxidation of triquinylmethane with chromic acid in acetic solution. It crystallises in white needles, melts at 108°, dissolves easily in benzene and alcohol, sparingly in light petroleum, and forms easily soluble salts and a yellow, well-crystallised platinochloride. The authors have been unable to obtain dyes from triquinylmethane.

Diquinylketone, $CO(C_6NH_5)_2$, is obtained by heating a mixture of diamidobenzophenone (10 grams), glycerol (29 grams), sulphuric acid (24 grams), and picric acid (3 grams) at 140—150° for four hours. It crystallises from dilute alcohol in long needles, melts at 174°, is easily soluble in alcohol, sparingly in boiling water, forms easily soluble salts, and yields quinoline when heated with soda-lime. The *hydrochloride* forms long, white needles, very soluble in water and alcohol, and melts above 200°; with platinic chloride it yields a sparingly soluble double salt.

E. U. R.

Derivatives of Pyrazole. By L. CLAISEN and P. ROOSEN (*Ber.*, **24**, 1888—1894).—3:1-Methylphenylpyrazole has been prepared by Knorr (*Annalen*, **238**, 202), and the 5:1-derivative by Knorr and

Laubmann (Abstr., 1889, 409). When the methylphenylpyrazole obtained from acetoacetaldehyde (Claisen and Stylos, Abstr., 1888, 671) is cooled by a freezing mixture, it solidifies in part to a crystalline mass which has all the properties of the 3 : 1-derivative (Knorr, *loc. cit.*), and yields on oxidation a phenylpyrazolecarboxylic acid melting at 146° , whilst the phenylpyrazolecarboxylic acid obtained from the liquid portion resembles the 1 : 5-derivative. The methylphenylpyrazole obtained from acetoacetaldehyde is therefore a mixture of the 3 : 1- and 5 : 1-derivatives.

Phenylhydrazine and acetopyruvic acid react together with the formation of a methylphenylpyrazolecarboxylic acid (compare Claisen and Stylos, Abstr., 1888, 676); this crystallises in short prisms containing 1 mol. H_2O , and melts at 106° ; the *methyl salt* is a liquid boiling at $255\text{--}256^{\circ}$ under a pressure of 109 mm.; the amide melts at 146° . The sodium salt has a strongly diuretic action. When heated, the carboxylic acid yields 5 : 1-methylphenylpyrazole, whose identity with that of Knorr and Laubmann (*loc. cit.*) is established by a study of the *methiodide*, the *ethiodide*, and the *platinochloride*, an account of which will be given later.

1 : 5-Phenylpyrazolecarboxylic acid is obtained on oxidising the corresponding methylphenylpyrazole with potassium permanganate; it melts at 183° , and is not identical with that obtained by Knorr and Laubmann (*loc. cit.*, 410); the latter must, therefore, have the constitution 1 : 4.

1 : 3 : 5-Phenylpyrazoledicarboxylic acid (Balbiano, Abstr., 1890, 1164) is most conveniently prepared by heating 5 : 1-methylphenylpyrazolecarboxylic acid with a solution of potassium permanganate for 1—2 hours; the acid melts at 266° with decomposition; the *dimethyl salt* melts at $127\text{--}128^{\circ}$, and the *diumide* at 190° . When either the dicarboxylic acid or its calcium salt is heated, 1 : 3-phenylpyrazolecarboxylic acid is obtained.

As the 1 : 4-phenylpyrazolecarboxylic acid is the only one which distils with but slight decomposition, it would appear that the carboxyl group is most firmly attached when it occupies the position 4; and it also seems that this group is more firmly attached in the position 3 than in the position 5. It is, therefore, probable that, as in the case of the three pyridinecarboxylic acids, the stability of the phenylpyrazolecarboxylic acids is the greater the further the carboxyl group is removed from the nitrogen atom. Skraup has shown that the melting points of the amidobenzoic acids and of the pyridinecarboxylic acids are the higher the further the carboxyl groups are removed from the nitrogen atom; this applies also to the phenylpyrazolecarboxylic acid, the 1 : 4-acid having the highest melting point.

The *dimethylphenylpyrazolesulphonic acid*, $\text{SO}_3\text{H}\cdot\text{C}_6\text{H}_4\text{<}\begin{matrix} \text{CMe}\cdot\text{CH} \\ \text{N}=\text{CMe} \end{matrix}$, is obtained when acetylacetone is heated with phenylhydrazinepara-sulphonic acid; it is a crystalline compound, sparingly soluble in water, and yields the corresponding *phenol* on fusion with potash. A description of these and analogous compounds will form the subject of a future communication.

A. R. L

Amidisoiazole. By HANRIOT (*Compt. rend.*, 112, 796—799).—When propionylpropionitrile is dissolved in concentrated aqueous potash, and the solution is mixed with hydroxylamine hydrochloride, there is considerable development of heat, and an oily liquid separates. This is converted into a crystalline hydrochloride by the action of gaseous hydrogen chloride, and the base is again liberated by the action of potash.

The base has the composition $C_6H_{10}N_2O$; it crystallises in long needles, melts at 44° , and shows great tendency to remain in superfusion, and boils at 180° under a pressure of 200 mm.; it is slightly soluble in water, and insoluble in light petroleum, but dissolves readily in alcohol, ether, or chloroform. The *hydrochloride*, $C_6H_{10}N_2O \cdot HCl$, is crystalline, and the *platinochloride* forms orange octahedra, but both compounds are unstable in solution. When heated with hydrochloric acid at 120° , the base is completely converted into ammonium chloride, hydroxylamine hydrochloride, and diethyl ketone. With acetic chloride, it yields a derivative $C_6H_9AcN_2O$ which melts at 160 — 162° , and is only slightly soluble in water, ether, or chloroform, but dissolves readily in alcohol or acetone.

Nitrous acid interacts energetically with a solution of the base in dilute hydrochloric acid, and the product separates in yellow lamellæ which melt at 65° , and detonate violently if heated above 100° ; it dissolves in alkalis forming a red solution, and is reprecipitated by acids.

A solution of the base in anhydrous ether combines directly with 1 mol. of bromine, and a dibromide separates.

From its mode of formation, the compound should be the oxime of propionylpropionitrile, but the latter would be acid and not basic, and, being saturated, would not combine directly with bromine. Its composition and properties agree with the view that it is an isomeride of the oxime, methylethylamidisoiazole, $\begin{matrix} CMe:C(NH_2) \\ | \\ CEt:N-O \end{matrix}$, the oxime being first formed, but combining with a molecule of water and undergoing molecular transformation, the molecule of water being afterwards eliminated under the influence of heat or potassium hydroxide.

The product of the action of bromine on the base is amorphous, and is decomposed by water into equal molecular proportions of ammonium bromide and bromomethylethylloxazolone, $\begin{matrix} CMeBr-CO \\ | \\ CEt=N-O \end{matrix}$, which crystallises in bulky, highly refractive octahedra, insoluble in water, but soluble in alcohol, ether, or chloroform. It melts at 41° , and cannot be distilled even in a vacuum. It dissolves in solutions of alkali hydrogen sulphites, and yields a crystalline compound with hydroxylamine hydrochloride. Sodium amalgam removes all the bromine and yields two crystalline products. C. H. B.

Azonium Bases. By O. N. WITT (*Ber.*, 24, 1511).—The method for the synthesis of azonium bases recently published by Kehrman and Messinger (this vol., p. 945) has been described four years ago by the author (*Abstr.*, 1887, 729).

Azonium Bases. By F. KÖHRMANN and J. MESSINGER (*Ber.*, 24, 1799).—A reply to the communication of O. N. Witt (preceding abstract), in which the latter claims priority for the reaction for preparing azonium bases described a short time ago by the authors (this vol., p. 945). They express their regret at their oversight of Witt's previous paper.
H. G. C.

Azonium Bases. By F. KÖHRMANN and J. MESSINGER (*Ber.*, 24, 1874—1876; compare preceding abstracts).—The compound obtained by the interaction of benzile and phenylorthophenylenediamine is quite different from that obtained from benzoin and phenylorthophenylenediamine; the latter compound, prepared according to the method of O. Fischer, melts at 116—117° with previous softening, is insoluble in water and dilute mineral acids, but dissolves in alcohol with a bluish-green fluorescence. The salts are blood-red, and readily undergo dissociation on the addition of water. The relations between the azonium bases, the quinoxaline bases, and the indulones are shown by the following formulæ:—

Azonium base from benzile and phenylphenylenediamine.

Quinoxaline base from benzoin and phenylphenylenediamine.

Indulone from oxyquinone and phenylphenylenediamine.

J. B. T.

A New Class of Fluorescent Colouring Matters of the Quinoxaline Series. By O. FISCHER and M. BUSCH (*Ber.*, 24, 1870—1874; compare this vol., p. 747).—Reference is made to a recent paper by O. N. Witt (*Ber.*, 24, 1511), regarding the identity of these quinoxaline derivatives with the azonium bases; since the latter compounds contain oxygen, whilst the former do not, Witt's claim appears to be a mistake.

1-2 3-Triphenyl-1-2-hydronaphthaquinoxaline, prepared from benzoin and β -phenylorthonaphthylenediamine, when treated with ferric chloride, is converted into the corresponding *azonium base*

which crystallises from alcohol in yellow, lustrous prisms, and melts at 167° with previous softening at 162°. The solution in alcohol, benzene, or ether exhibits a yellowish-green fluorescence; the addition of hydrochloric acid to an alcoholic solution of the base produces a yellow colour. The normal salts are strongly fluorescent in aqueous solution, but this disappears on adding mineral acids. The *nitrate* is sparingly soluble in water, and is deposited in yellow crystals; the *hydrochloride* crystallises from dilute alcohol in dark-yellow needles.

The same base is also formed by heating benzoïn and β -phenylorthonaphthylenediamine with zinc chloride at 200° ; the zinc chloride acts, therefore, like acids and facilitates the oxidation of intermediate hydro-derivatives.

1-3-Diphenylethonaphthazonium bromide is prepared by heating bromacetophenone with β -phenylorthonaphthylenediamine in alcoholic solution for a short time; it crystallises in lustrous, yellow plates, and exhibits a yellowish-green fluorescence when dissolved in dilute alcohol. The corresponding hydrowide, $C_{10}H_8 \begin{smallmatrix} N \\ \text{---} \\ NPh(OH):CH \end{smallmatrix} Ph$,

is obtained by the action of soda on the preceding compound, and is deposited from alcohol in lustrous, transparent crystals melting at 148° with previous softening at 100° . In glacial acetic acid or alcoholic solutions, the base is highly fluorescent, but does not show this property when dissolved in ether, benzene, or light petroleum. The nitrate crystallises in yellow, silky, lustrous needles, and is sparingly soluble in cold water.

J. B. T.

Formation, Properties, and Constitution of Osotriazoles.

By H. v. PECHMANN (*Annalen*, 262, 265—277). — Osotriazole, $\begin{smallmatrix} CH:N \\ | \\ CH:N \end{smallmatrix} > NH$, is one of the four isomeric compounds which can, theoretically, be derived from pyrroline by substituting two CH-groups by two atoms of nitrogen; derivatives of two of the three remaining isomerides, namely, of triazole, $\begin{smallmatrix} CH:N \\ | \\ N:CH \end{smallmatrix} > NH$, and of pyrrodiazole, $\begin{smallmatrix} N:CH \\ | \\ N:CH \end{smallmatrix} > N$, are known, but the fourth isomeride, $\begin{smallmatrix} N=N \\ | \\ CH:CH \end{smallmatrix} > NH$, and its derivatives have not yet been prepared.

Three derivatives of osotriazole have been previously described (*Abstr.*, 1888, 1287) as "osotriazone" derivatives; the more suitable term osotriazole will be used in future.

Osotriazole derivatives containing a hydrocarbon radicle in the place of the hydrogen of the imido-group are formed, or can be obtained, by the following reactions:—(1.) By boiling osotetrazones with acids (*loc. cit.*); the yield is about 20 per cent. of the theoretical. (2.) By the decomposition of the phenylosazones, either by boiling with acids or by dry distillation; the yield is small in both cases. (3.) By treating hydrazoximes with phosphorus pentachloride (yield about 20 per cent. of the theoretical), acetic anhydride (yield 25 per cent. of the theoretical), or very dilute alkalis (yield about 50 per cent. of the theoretical). (4.) By the elimination of alcohol from hydrazoximes which are derived from a secondary hydrazine containing at least one fatty radicle; the yield in the only case yet investigated is at least 80 per cent. of the theoretical.

The reactions (3) and (4) are fully described in the following abstracts.

The osotriazole derivatives are yellowish or colourless oils, having a slight alkaloid-like smell; they boil at a temperature above 200°

without decomposition, and solidify at a low temperature. Osotriazole itself is a feeble acid, but its *n*-alkyl derivatives are weak bases. *n*-Phenylosotriazole and its alkyl substitution products have, generally speaking, the properties of aromatic compounds, and form nitro-, amido-, and sulphonic acid derivatives; on oxidation, the fatty alcohol radicle is converted into the carboxyl-group, which can be eliminated by the usual methods.

The reaction with diazobenzene salts previously described (*loc. cit.*) is not given by pure osotriazoles.

The constitution of the osotriazoles is proved by their methods of formation and by their properties.

F. S. K.

Methyl-*n*-phenylosotriazole and its Derivatives. By A. JONAS and H. v. PECHMANN (*Annalen*, 262, 277—302).—The *acetyl* derivative $\text{NHPh} \cdot \text{OMe} \cdot \text{CH} \cdot \text{N} \cdot \text{OAc}$ is best prepared by adding dry, finely-divided methylglyoxalphenylhydrazoxime (Abstr., 1889, 47) to acetic anhydride (3 parts) heated at 50° , stirring vigorously until the acetate begins to separate out with development of much heat, and then immediately cooling in a freezing mixture with constant stirring, so that the temperature does not rise above 70 — 80° . After about 10 minutes, the whole solidifies; the product is then mixed with water, kept until the acetic anhydride is decomposed, and finally washed with water. It crystallises from dilute alcohol in long, flat, colourless needles, melts at 163° , and is readily soluble in acetone, chloroform, boiling alcohol, glacial acetic acid, and benzene, but more sparingly in light petroleum, ether, and carbon bisulphide, and insoluble in water and cold dilute soda; when heated alone or with acetic anhydride, it is converted into methylphenylosotriazole.

Methyl-*n*-phenylosotriazole, previously described as an osotriazone derivative (Abstr., 1888, 1287), is best prepared by boiling the crude acetyl derivative of methylglyoxalphenylhydrazoxime (100 grams, 2 parts) with crystalline sodium carbonate (1 part) and water (30 parts) for 24 hours; after adding a little soda, the oily osotriazole is distilled with steam to free it from resinous substances, methylglyoxalphenylhydrazoxime (10 grams), and the hydrazone of pyruvic acid (10 grams), and the distillate treated with small quantities of an alkaline solution of potassium permanganate until a permanent coloration is produced. The peroxide of manganese is then dissolved by the addition of sodium sulphite and sulphuric acid, the osotriazole distilled with steam, extracted with ether, and purified by fractional distillation; the yield is about 50 per cent. of the acetyl derivative employed. It boils at 149 — 150° under a pressure of 60 mm., at 242° under the ordinary atmospheric pressure, and its sp. gr. is 1.1071 , $17^\circ/4^\circ$.

*Trinitromethyl-*n*-phenylosotriazole*, $\text{C}_6\text{H}_4\text{N}_3(\text{NO}_2)_3$, is obtained when the preceding compound is introduced into well-cooled, fuming nitric acid (5 parts), concentrated sulphuric acid (5 parts) gradually added, and the mixture then kept at 70 — 80° until a small portion immediately solidifies when treated with water. It crystallises from alcohol in long, colourless needles, melts at 138° , and is readily soluble in ether, glacial acetic acid, acetone, chloroform, carbon bisulphide, and

hot alcohol, but only very sparingly in boiling water, and insoluble in cold water and light petroleum.

Methyl-n-phenylosotriazolesulphonic acid is formed, with development of heat, when the osotriazole is dissolved in fuming sulphuric acid; the barium salt is only moderately easily soluble in cold water, and the sodium salt crystallises from cold water in colourless, hexagonal plates.

n-Phenylosotriazolecarboxylic acid (20 grams) is produced, together with the corresponding amide (50 grams), small quantities of the nitrile, and phenylosotriazaldoxime (10 grams), when the acetyl derivative, $\text{NOH}\cdot\text{CH}\cdot\text{C}(\text{N}_2\text{HPh})\cdot\text{CH}\cdot\text{N}\cdot\text{OAc}$ (100 grams), prepared from dinitrosoacetonehydrazone exactly as described in the case of the glyoxalhydrazoxime, is boiled with 10 per cent. sodium carbonate (1 litre) for 24 hours; on cooling, the oily mixture of the neutral products solidifies to a mass of crystals, and is separated from the alkaline solution of the acid by filtration. The filtrate is treated first with potassium permanganate, and then with sodium sulphite and sulphuric acid as described above, and the precipitated acid separated by filtration. The crystalline mixture of the neutral products is agitated with soda to dissolve the aldoxime, and the insoluble residue then dissolved in boiling benzene, from which, on cooling, the amide is deposited almost completely, whilst the nitrile remains in solution. When the acid is the desired product, this separation is unnecessary; the mixture of acid and neutral products is boiled with soda until the evolution of ammonia is at an end and the amide and nitrile are completely converted into the acid, and the cold solution is saturated with carbonic anhydride to precipitate the aldoxime. The filtrate is then treated with potassium permanganate, and the acid isolated as before; the yield of acid is 65 grams, and of aldoxime 8 grams. In the above reaction, the first product is phenylosotriazaldoxime; this compound is converted into the nitrile by the elimination of water, then into the amide, and finally into the acid.

n-Phenylosotriazolecarboxylic acid prepared in this way melts at $191-192^\circ$, and is identical with the acid obtained by oxidising methylphenylosotriazole (*loc. cit.*). The *potassium* salt, $\text{C}_8\text{H}_5\text{N}_3\text{O}_2\text{K} + \text{H}_2\text{O}$, crystallises from 90 per cent. alcohol in efflorescent plates. The *barium* salt, $(\text{C}_8\text{H}_5\text{N}_3\text{O}_2)_2\text{Ba} + 2\text{H}_2\text{O}$, crystallises from hot water in transparent plates; the *cadmium* salt, $(\text{C}_8\text{H}_5\text{N}_3\text{O}_2)_2\text{Cd} + 2\text{H}_2\text{O}$, in long, colourless needles. The *methyl* salt, $\text{C}_{10}\text{H}_7\text{N}_3\text{O}_2$, prepared by passing hydrogen chloride into a methyl alcoholic solution of the acid, crystallises from methyl alcohol in long, colourless needles, melts at $89-90^\circ$, boils at $285-286^\circ$, and is soluble in most ordinary solvents. The *ethyl* salt, $\text{C}_{11}\text{H}_9\text{N}_3\text{O}_2$, crystallises in lustrous needles, melts at 59° , and boils at $305-307^\circ$.

When phenylosotriazole or its homologues is treated with sodium in boiling alcoholic solution, it seems to be converted into hydroderivatives; traces of ammonia and aniline are formed, but no fatty diamine. Phenylosotriazolesulphonic acid is decomposed by sodium amalgam in boiling alcoholic solution, yielding ammonia and sulph-anilic acid, but fatty diamines are not formed. When phenylosotriazolecarboxylic acid (10 grams) is treated with 4 per cent. sodium

amalgam (280 grams) in alkaline solution, it is decomposed into hydrogen cyanide and phenylhydrazidoacetic acid (5 grams); the last-named compound melts at 159° , and is identical with the acid obtained by Elbers (*Annalen*, 227, 353) by the reduction of the hydrazone of glyoxylic acid.

n-Phenylosotriazole, $\begin{array}{c} \text{CH:N} \\ | \\ \text{CH:N} \end{array} \text{NPh}$, is obtained, together with aniline

and hydrogen cyanide, when the silver salt of phenylosotriazole-carboxylic acid is submitted to dry distillation; the yield is 3 grams from 15 grams of the silver salt. It can also be prepared by warming glyoxalosotetrazone (Abstr., 1888, 1287) with ferric chloride and hydrochloric acid until it is completely converted into a brown oil; the yield is 3.5 grams from 20 grams of the crude tetrazone. It is an almost colourless oil, boils at $223\text{--}224^{\circ}$ (716 mm.), and is volatile with steam; it is readily soluble in ordinary organic solvents and in concentrated mineral acids, but only sparingly in water, dilute acids, and alkalis. It is not acted on by potassium permanganate. When boiled with sodium in alcoholic solution, it gives a solution which gradually turns red on cooling. The *nitro*-compound, $\text{C}_6\text{H}_5\text{N}_3\text{NO}_2$, is formed when the osotriazole is treated with well-cooled, fuming nitric acid, and the mixture then warmed for a few minutes on the water-bath; it crystallises from alcohol in colourless needles, melts at $183\text{--}184^{\circ}$, and is readily soluble in ether, acetone, chloroform, and benzene.

n-Phenylosotriazolecarboxylamide, $\begin{array}{c} \text{N:CH} \\ | \\ \text{NPh:N} \end{array} \text{C}\cdot\text{CO}\cdot\text{NH}_2$, prepared as

described above, crystallises from water in lustrous needles, melts at $143\text{--}5^{\circ}$, and is readily soluble in alcohol, ether, acetone, chloroform, glacial acetic acid, and hot benzene, but only sparingly in light petroleum; on distillation with zinc-dust, it is converted into the corresponding nitrile.

n-Phenylosotriazaldoxime, $\begin{array}{c} \text{N:CH} \\ | \\ \text{NPh:N} \end{array} \text{C}\cdot\text{CH}\cdot\text{NOH}$ (see above), melts at 115° (compare Pechmann and Wehsarg, Abstr., 1889, 35).

n-Phenylosotriazaldehyde, $\begin{array}{c} \text{N:CH} \\ | \\ \text{NPh:N} \end{array} \text{C}\cdot\text{CHO}$, is formed when the aldoxime is boiled for a short time with dilute sulphuric acid; the product is distilled with steam and purified by dissolving it in a solution of sodium hydrogen sulphite. It melts at 70° , distils without decomposition, and is soluble in most ordinary solvents except water; it has a pungent odour, gives the usual reactions of aldehydes, and dissolves unchanged in dilute alkalis. The *hydrazone*, $\text{C}_{15}\text{H}_{13}\text{N}_5$, is precipitated on adding phenylhydrazine to a dilute aqueous solution of the aldehyde; it crystallises from alcohol in colourless plates, sinters together at $109\text{--}110^{\circ}$, and melts between 118° and 140° according to the manner in which it is heated. It is readily soluble in alcohol, ether, acetone, glacial acetic acid, chloroform, benzene, and carbon bisulphide, but only sparingly in light petroleum, and insoluble in water and dilute soda; it dissolves in concentrated sulphuric acid,

yielding a yellowish-red solution, which turns dark blue on the addition of ferric chloride.

n-Phenylosotriazyl alcohol, $\begin{array}{c} \text{N} : \text{CH} \\ | \\ \text{NPh} \cdot \text{N} \end{array} \text{C} \cdot \text{CH}_2 \cdot \text{OH}$, is formed, together with phenylosotriazolecarboxylic acid, when the aldehyde is treated with soda at the ordinary temperature. It crystallises from a mixture of chloroform and light petroleum in small, colourless prisms, melts at 67° , and is very readily soluble in alcohol, ether, glacial acetic acid, acetone, and hot light petroleum, but rather more sparingly in chloroform and benzene, and only very sparingly in cold water; it dissolves unchanged in warm, dilute soda, and with concentrated sulphuric acid it gives a pale-yellow solution.

Cyano-n-phenylosotriazole, $\begin{array}{c} \text{N} : \text{CH} \\ | \\ \text{NPh} \cdot \text{N} \end{array} \text{C} \cdot \text{CN}$, is formed in the preparation of phenylosotriazolecarboxylic acid as described above; it can also be obtained by distilling the corresponding amide with zinc-dust, and by treating glyoxylylcyanosotetrazone (Abstr., 1889, 47) with acids, but it is best prepared by boiling the acetyl derivative of dinitrosoacetonehydrazone with acetic anhydride for about two hours. It crystallises from dilute alcohol in colourless plates, melts at 94.5° , and boils at $190\text{--}192^\circ$ under a pressure of 60 mm.; it has an odour recalling that of benzonitrile, is readily volatile with steam, and dissolves freely in ether, acetone, glacial acetic acid, chloroform, benzene, and carbon bisulphide, but is only sparingly soluble in cold alcohol and light petroleum, and insoluble in water and dilute alkalis.

n-Phenylosotriazolethiamide, $\begin{array}{c} \text{N} : \text{CH} \\ | \\ \text{NPh} \cdot \text{N} \end{array} \text{C} \cdot \text{S} \cdot \text{NH}_2$, is precipitated in long, yellowish needles when hydrogen sulphide is passed for some time into a hot ammoniacal solution of the nitrile, and the solution then mixed with water; it melts at $131\text{--}132^\circ$, darkens on exposure to the air, and is readily soluble in ether, alcohol, acetone, chloroform, glacial acetic acid, and carbon bisulphide, but more sparingly in light petroleum, and insoluble in cold water.

n-Phenylosotriazylamine, $\begin{array}{c} \text{N} : \text{CH} \\ | \\ \text{NPh} \cdot \text{N} \end{array} \text{C} \cdot \text{CH}_2 \cdot \text{NH}_2$, can be obtained by reducing the thiamide with zinc and hydrochloric acid in alcoholic solution, and decomposing the product with soda. It is a colourless oil, boils at $222\text{--}223^\circ$ under a pressure of 100 mm., and is readily soluble in alcohol, ether, acetone, and chloroform, but only sparingly in water and light petroleum. It absorbs carbonic anhydride from the air with great avidity, being thereby converted into a crystalline carbonate of the composition $(\text{C}_9\text{H}_{10}\text{N}_4)_2 \cdot \text{H}_2\text{CO}_3$. The hydrochloride, $\text{C}_9\text{H}_{10}\text{N}_4 \cdot \text{HCl}$, crystallises from cold water in plates, melts at $228\text{--}229^\circ$, and is readily soluble in alcohol and water. The platinochloride, $(\text{C}_9\text{H}_{10}\text{N}_4)_2 \cdot \text{H}_2\text{PtCl}_6$, crystallises from water in long, yellow prisms, and is readily soluble in hot, but only sparingly in cold, water. The tartrate forms well-defined, transparent crystals. On adding carbon bisulphide to an ethereal solution

of the base, a compound melting at 122—123° is precipitated; nitrous acid converts the base into the alcohol described above.

F. S. K.

Homologues of *n*-Phenylosotriazole. By O. BALTZER and H. v. PECHMANN (*Annalen*, 262, 302—313).—*Diacetylphenylhydrazacetoxime*, $N_2HPh.CMe.CMe.N.OAc$, is prepared from diacetylphenylhydrazoxime, exactly as described in the case of methylglyoxalhydrazoxime (compare preceding abstract); it crystallises from alcohol in yellowish plates and melts at 171°.

Dimethyl-*n*-phenylosotriazole, previously described as an osotriazone derivative (Abstr., 1888, 1287), is best prepared by boiling the preceding compound with sodium carbonate; the product is separated from regenerated diacetylphenylhydrazoxime and obtained in a pure condition by the same methods as those used in the case of methyl phenylosotriazole (compare preceding abstract); the yield is 30 per cent. of the hydrazoxime employed.

Diacetylphenylhydrazoxime, $NPh_2.N.CMe.CMe.NOH$, crystallises in small, colourless prisms and melts at 126—127°; it cannot be converted into an osotriazole derivative under any conditions.

Diacetylmethylphenylhydrazoxime, $NMePh.N.CMe.CMe.NOH$, is precipitated as an oil on adding a solution of methylphenylhydrazine sulphate (34 grams) and sodium acetate (55 grams) in water (310—360 grams) and glacial acetic acid (20 grams) to a solution of methylnitrosoacetone (20 grams) in water (120 grams); the yield is quantitative. It crystallises from dilute alcohol in yellowish needles, melts at 105·5°, and dissolves in alkalis and acids with a yellow coloration; it is decomposed by boiling dilute sulphuric acid with formation of diacetyl, and it gives a cherry-red coloration with nitrous acid; its solution in concentrated sulphuric acid is coloured red on the addition of ferric chloride. The acetyl derivative is a liquid. When diacetylmethylphenylhydrazoxime is boiled with acetic anhydride, it is decomposed into dimethyl-*n*-phenylosotriazole and methyl alcohol; the yield of the former is more than 80 per cent. of the theoretical.

*Dinitrodimethyl-*n*-phenylosotriazole*, $C_{10}H_8N_3(NO_2)_2$, is formed when a solution of the osotriazole in concentrated nitric acid (6 parts) is mixed with concentrated sulphuric acid (9 parts); it crystallises from alcohol in yellow needles and melts at 139°. A mixture of warm, fuming nitric acid and concentrated sulphuric acid converts the osotriazole into a compound, probably a trinitro-derivative, which melts at 227°.

*Methyl-*n*-phenylosotriazolecarboxylic acid*, $\begin{matrix} N.CMe \\ NPh.N \end{matrix} > C.COOH$ (5 grams), is formed, together with *n*-phenylosotriazole dicarboxylic acid (2 grams), when dimethylphenylosotriazole (10 grams) is boiled with an alkaline solution of potassium permanganate (40 grams) for 12 hours; the two compounds are separated by taking advantage of the fact that the sodium salt of the monocarboxylic acid is soluble, that of the dicarboxylic acid insoluble, in alcohol. It crystallises from dilute alcohol in long needles, melts at 198°, and is readily soluble in

alcohol, but only sparingly in water. The *silver* salt, $C_{10}H_8N_3O_2Ag$, is a colourless compound, sparingly soluble in hot water. The *calcium* salt and the *barium* salt crystallise from hot water in small needles; the *zinc*, *manganese*, and *cadmium* salts are only sparingly soluble in boiling water.

Ethyl methylphenylhydrazonitrosoacetoacetate,

prepared by treating ethyl nitrosoacetoacetate with methylphenylhydrazine, separates from a mixture of chloroform and light petroleum in the form of a light-yellow, crystalline powder, and melts at $77-80^\circ$; when it is boiled with acetic anhydride, and the product hydrolysed with soda, methylphenylosotriazolecarboxylic acid is obtained; the yield is almost quantitative.

Phenylosotriazolecarboxylic acid, $NPh \begin{smallmatrix} N:C \cdot COOH \\ N:C \cdot COOH \end{smallmatrix}$ (see above),

separates from boiling water in the form of a colourless, crystalline powder, and melts at $255-256^\circ$ with liberation of water and formation of the anhydride (m. p. 104°); it gives the fluorescein reaction with resorcinol. The *silver* salt, $C_{10}H_8N_3O_4Ag_2$, crystallises from boiling water in thread-like forms. The *calcium* salt and the *cadmium* salt are only sparingly soluble, but the *zinc* salt and the *manganese* salt are readily soluble, in water.

Acetylpropionyl- α -phenylhydrazacetoxime, $N_2HPh:CMe:C\cdot Et:N \cdot OAc$, prepared from ethyl ethylacetoacetate, crystallises from alcohol in long, colourless needles and melts at $147-148^\circ$.

Methylethyl-n-phenylosotriazole, $\begin{smallmatrix} C\cdot Et:N \\ CMe:N \end{smallmatrix} > NPh$, is obtained by boiling the preceding compound with water; it melts below 0° and boils at 270° . The *dinitro*-derivative, $C_{11}H_{11}N_3(NO_2)_2$, crystallises from alcohol in lustrous needles and melts at 113° . When methylethylphenylosotriazole is treated with an alkaline solution of potassium permanganate, it is rapidly oxidised, yielding methylphenylosotriazolecarboxylic acid (m. p. 198°) and small quantities of a dicarboxylic acid. F. S. K.

Osootriazole. By O. BALTZER and H. V. PECHMANN (*Annalen*, 262, 314-323).—*Nitro-n-phenylosotriazolecarboxylic acid*,

is obtained when phenylosotriazolecarboxylic acid (compare Jonas and Pechmann, this vol., p. 1111) is dissolved in fuming nitric acid (10 parts), the solution kept for half an hour and then poured on to ice; it crystallises from glacial acetic acid in yellowish needles, melts at 236° , and is soluble in hot alcohol, but more sparingly in ether, chloroform, and boiling water. The *ammonium* salt crystallises in long needles, and is comparatively sparingly soluble, but the *sodium* salt and the *potassium* salt are readily soluble, in water; the salts of the heavy metals are insoluble.

Amido-n-phenylosotriazolecarboxylic acid, $C_6H_4N_3O_2NH_2$, is prepared by reducing the nitro-compound with stannous chloride and hydrochloric acid; it separates from glacial acetic acid in the form of a colourless, crystalline powder, and from dilute alcohol in needles, melts at 252° with decomposition, and is readily soluble in hot water, the solution darkening on boiling. In aqueous solutions of the acid, a solution of bleaching powder produces first a reddish-brown coloration and then a yellow, flocculent precipitate. The *ammonium* salt crystallises from alcohol in long, flat needles; the *calcium*, *barium*, and *manganese* salts crystallise well, but the salts of most of the heavy metals are insoluble.

Osotriazolecarboxylic acid, $\begin{array}{c} N:CH \\ | \\ NH \cdot N \end{array} > C \cdot COOH$, is formed, together with a considerable quantity of another acid, probably an azoxy-derivative, when a warm saturated solution of potassium permanganate is added to a warm, dilute alkaline solution of the amido-acid until a permanent coloration is produced; after decolorising with alcohol, the filtered solution is concentrated by evaporation, acidified with acetic acid, and the oxalic acid precipitated with calcium chloride; the filtrate is then treated with a solution of copper acetate in slight excess, the precipitated copper salt washed well with cold water, decomposed with hydrogen sulphide, and the filtered solution evaporated, when the osotriazolecarboxylic acid is deposited in grey crystals. It separates from water in the form of a colourless, crystalline powder, melts at 211° , decomposes at a higher temperature with evolution of carbonic anhydride, and is readily soluble in boiling water, but only sparingly in alcohol and cold water, and practically insoluble in ether, chloroform, glacial acetic acid, and acetone. It is only very slowly oxidised by potassium permanganate, is not acted on by nitrous acid, or by boiling fuming nitric acid, and crystallises unchanged from hot hydrochloric acid. The *calcium* salt, $(C_6H_4N_3O_2)_2Ca + 2H_2O$, crystallises from hot water in prisms; the salts of the alkalis are readily soluble and the silver salt is explosive.

Osotriazole, $\begin{array}{c} CH:N \\ | \\ CH:N \end{array} > NH$, can be prepared by distilling the dry carboxylic acid, in small quantities at a time, from a retort heated at 230 – 240° in a metal-bath; if the retort is heated over the free flame, explosions are liable to occur; the yield is almost quantitative. It is a colourless oil, having a slight, alkaloid-like smell, and a sweetish, repulsive taste; it melts at 22.5° , boils at 203 – 204° (715 mm.), and is soluble in water and most ordinary solvents, except light petroleum, in all proportions; the aqueous solution has a neutral reaction. The *hydrochloride*, $C_6H_4N_3 \cdot HCl$, is a colourless, crystalline powder, and is decomposed by water; the *platinochloride* is very unstable. The *silver* derivative, $C_6H_4N_3 \cdot Ag$, is precipitated on adding silver nitrate to an aqueous solution of osotriazole; it is insoluble in ammonia, but soluble in nitric acid, and it explodes when heated. The compound $C_6H_4N_3 \cdot HgCl$, prepared by precipitating a solution of osotriazole with mercuric chloride, crystallises in lustrous needles, is soluble in hydrochloric acid, and burns when heated on platinum foil, leaving a very

voluminous ash. In an aqueous solution of osotriazole, copper sulphate produces a blue precipitate which dissolves in excess of the reagent, yielding a blue solution; a calcium derivative, which is decomposed by carbonic anhydride, is formed when calcium hydroxide is added to an aqueous solution of osotriazole. Sodium dissolves in an ethereal solution of osotriazole, yielding a solid sodium derivative.

Benzoylosotriazole, $\begin{matrix} \text{CH}_2\text{N} \\ | \\ \text{CH}_2\text{N} \end{matrix} > \text{NBz}$, is precipitated in the form of a colourless, crystalline powder, when an aqueous solution of osotriazole is shaken with 10 per cent. soda and benzoic chloride; it separates from chloroform and ether in lustrous crystals, melts at 100° , and is decomposed by soda and by boiling alcohol. The corresponding acetyl derivative is a colourless liquid. F. S. K.

Alkylation of Secondary and Primary Bases by Potassium Alkyl Sulphates. By M. PASSON (*Ber.*, 24, 1678—1682).—*Methyl coniine* is obtained by adding a concentrated solution of potassium methyl sulphate (25 grams) to a concentrated solution of coniine (9 grams) and heating on the water-bath until the mixture reacts neutral. The unaltered coniine is separated by conversion into its nitroso-compound and extraction with ether; the solution is made alkaline and distilled, the base precipitated from the distillate with sodium hydroxide, dried over potash, and distilled. The pure base is a colourless oil, which floats on water, boils at 175.5° , and smells like coniine. The *hydrochloride* is similar to coniine hydrochloride, but melts at 188 — 189° . When heated at 240° , it sublimes in white needles, is easily soluble in water and alcohol, crystallises from the latter in beautiful, white needles, and has the same physiological action as coniine hydrochloride. The *avrochloride* is insoluble in cold, sparingly soluble in hot, water, and separates first as an oil, afterwards in long, slender needles, and melts at 79° . The *platinochloride* is easily soluble, insoluble, however, in a mixture of ether and alcohol, and melts at 158 — 160° .

Dipropylmethylamine is obtained from normal dipropylamine in a similar way to the above base. It boils at 117° . The *platinochloride* crystallises from water in beautiful, orange-red needles and melts about 200° .

Dipropylethylamine is obtained in a similar way to the methyl compound. The reaction, however, does not take place so easily, and a large excess of potassium ethyl sulphate must be used. It boils at 132 — 134° and is sparingly soluble in water. The *platinochloride* is easily soluble in water, but insoluble in a mixture of ether and alcohol. The *avrochloride* is fairly easily soluble in water, crystallises in beautiful needles, and melts at 96° .

Diethylmethylamine, obtained in a similar way, is a colourless liquid, smells like trimethylamine, and boils at 63 — 65° . The *hydrochloride* forms large, colourless plates, and is extremely soluble. The *avrochloride* crystallises in short, yellow needles and is fairly soluble in water. The methyl-diethylamine, prepared from methylamine and

potassium ethyl sulphate, boils at 63—66° and gives a similar aurochloride.
E. C. R.

New Alkaloid from *Conium maculatum*. By A. LADENBURG and G. ADAM (*Ber.*, 24, 1671—1676).—The authors have received from E. Merck a new alkaloid obtained from *Conium maculatum*. The preparation was a white powder, easily soluble in water, alcohol, ether, and benzene, and yielded salts with acids. It was purified by distillation and by crystallisation from toluene; both methods gave identical products. Analysis gave numbers agreeing with the formula $C_8H_{17}NO$. Since the new base is very like conhydrine, and probably has a similar constitution, the authors have called it pseudoconhydrine.

Pseudoconhydrine is a strong base, reacts alkaline, yields easily soluble salts, boils at 229—231° (uncorr.), melts at 100—102°, and sublimes in slender needles. It is, like conhydrine, a secondary base, since the hydrochloride, when warmed with sodium nitrite, yields a nitrosamine. The *hydrochloride* forms colourless, hygroscopic crystals, easily soluble in water and alcohol, and also soluble in ether. The *hydrobromide* crystallises in tablets.

When pseudoconhydrine is heated with fuming hydriodic acid and amorphous phosphorus for eight hours at 180°, an *iodide* of the formula $C_8H_{16}NI_2HI$ is obtained. It crystallises from water in nodular aggregates, darkens at 143°, melts at 155°, and yields on reduction a volatile base, but, owing to the small amount of material, this was not examined. When heated with fuming hydrochloric acid, it also yields a base easily volatile with steam.

From the above results, the authors conclude that pseudoconhydrine belongs to the class of alkines, and has a constitution analogous to that of conhydrine. The authors attempted to synthesise the compound by reduction of the condensation product of α -ethylpyridine with formaldehyde with the following results:—

α -Lutidylalkine, $C_8NH_9 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot OH$, is obtained by heating α -ethylpyridine with formaldehyde and water for eight hours at 160°. The product is freed from unaltered ethylpyridine by steam distillation, extracted with chloroform, the solution dried with potassium carbonate, the chloroform distilled off, and the residue distilled under reduced pressure. It boils at 128—131° under 17 mm. pressure, and is easily soluble in water and alcohol, sparingly in ether. The *platinochloride*, $(C_8H_{11}NO)_2 \cdot H_2PtCl_6$, is easily soluble and melts at 142°. The *aurochloride* is sparingly soluble, crystallises from water in ill-characterised, yellow crystals, and melts at 71°.

α -Lupetidylalkine, $C_8NH_{10} \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot OH$, is obtained by reduction of the above base in absolute alcohol with sodium. It is purified by extraction with ether and distillation, boils at 232—234° under the ordinary pressure, and closely resembles pseudoconhydrine in boiling point, odour, and solubility, but has a much lower melting point, and does not yield crystalline salts. Lupetidylalkine will not crystallise either when sown with crystals of conhydrine or pseudoconhydrine; when cooled with solid carbonic anhydride and ether, it crystallises, but melts again below 0°. Neither the hydrochloride

nor hydriodide is crystalline. The hydrobromide crystallises, after remaining some time in the desiccator, in feathery crystals which liquefy on exposure to air. When reduced with fuming hydriodic acid and amorphous phosphorus, a base is obtained which is volatile with steam, and yields a sparingly soluble aurochloride crystallising in silky needles and melting at 118—119°. Analysis gave numbers corresponding to the formula $C_9H_{15}N, HAuCl_4$.

Hence lupetidylalkine is not identical either with conhydrine or with pseudoconhydrine. E. C. R.

Paraxanthine. By G. SALOMON (*Zeit. physiol. Chem.*, 15, 319—320).—Paraxanthine crystals have been previously described by the author (*Zeit. klin. Med.*, 7, 72) as containing no water of crystallisation. In another preparation of these crystals, it is now proved that some of them on being heated to 110° become cloudy and whitish from loss of water, while others, isomorphous with them, remain bright. Owing to the admixture, it was not found possible to determine the water of crystallisation quantitatively. W. D. H.

Violet Colouring Matter Derived from Morphine. By P. CAZENEUVE (*Compt. rend.*, 112, 805—807).—Seven grams of morphine are boiled for 100 hours in a reflux apparatus with an equal molecular proportion (5 grams) of paranitrosodimethylaniline hydrochloride and 500 c.c. of methyl alcohol. A crystalline compound separates, having all the properties of the tetramethyldiazoamidobenzene formed by the action of aniline on paranitrosodimethylaniline. The alcoholic liquid is evaporated to dryness, the residue treated with hot water, the solution filtered, the filtrate again evaporated to dryness, and dissolved in dilute hydrochloric acid. A violet solution is thus obtained, from which sodium hydroxide precipitates the base; the latter, after being washed free from morphine, is treated with amyl alcohol, which dissolves the violet compound, but leaves a blue substance undissolved. Analysis of the platinochloride, precipitated by a mixture of alcohol and ether, shows that the violet compound has the composition $C_{17}H_{19}NO_4 \cdot N \cdot C_6H_4 \cdot NMe_2$. The free base is amorphous, and is slightly soluble in water, from which it is precipitated by addition of sodium chloride; it is readily soluble in methyl, ethyl, or amyl alcohol, yielding strongly dichroic solutions which are violet by transmitted, and red by reflected, light. It dyes wool, silk, and guncotton directly, giving a beautiful bright violet, which, however, fades when exposed to light.

This colouring matter is not a safranine, but seems comparable to dimethylamidodiphenylimide (Bindschedler's green). Substitution does not take place in the phenol group, for a similar product is obtained from codeïne, the methyl group in which would prevent condensation by union of the oxygen with nitrogen. It is probable that the formation of the violet compound is due to the tendency of the morphine to form oxymorphine. At the same time, its formation and character invalidate Polstorff's view that pseudomorphine is formed from 2 mols. of morphine with elimination of 2 atoms of hydrogen; if this were so, the pseudo-compound should yield a

safranine, and not an indamine. It is also possible to regard the colouring matter as a phenanthrene derivative. C. H. B.

Pseudocodeïne. By E. MERCK (*Arch. Pharm.*, 229, 161—164).—*Pseudocodeïne*, $C_{18}H_{21}NO_3 + H_2O$, a strong base discovered during the preparation of apocodeïne, forms a white, crystalline mass, easily soluble in alcohol, especially when hot. From this solution it is precipitated by water in white needles. It is sparingly soluble in ether, from which solution it separates in brilliant, transparent needles. It melts at 178—180° (uncorr.). A 1.91 per cent. alcoholic solution rotates the plane of polarisation 1.423° towards the left; hence its specific rotatory power is -91.040° . Ferric chloride gives no reaction. The base yields well-crystallisable salts, of which the hydrochloride, hydrobromide, nitrate, platinochloride, mercuriochloride, and picrate are described. The physiological action of pseudocodeïne is similar to that of codeïne, but weaker. J. T.

Conversion of Cupreïne into Quinine. By E. GRIMAUD and A. ARNAUD (*Compt. rend.*, 112, 774—775).—When cupreïne, perfectly free from quinine, is boiled for several hours in a reflux apparatus, with an equivalent quantity of sodium and an excess of methyl iodide dissolved in methyl alcohol, quinine methiodide is obtained in slender, white needles, and quinine dimethiodide in yellow prisms, identical in composition, melting point, and rotatory power with the methiodides obtained from natural quinine. The methiodides from both sources dissolve in dilute sulphuric acid with a beautiful blue fluorescence.

If the cupreïne is heated in sealed tubes at 100° for about 12 hours with sodium methoxide and methyl chloride, free quinine is obtained identical in all its properties with the natural product.

It follows that cupreïne is a substance with a phenolic function, and quinine is its methyl ether. This result throws little light upon the constitution of quinine, but establishes the presence of a methoxy-group OMe. It is remarkable that a methyl group is frequently found in the products obtained from plants, whilst an ethyl group never occurs. This is, doubtless, due to the mode of nutrition of plants, which absorb carbonic anhydride, and convert it first into formaldehyde and afterwards into methyl alcohol. C. H. B.

Isoecinchonine. By E. JUNGLEISCH and E. LÉGER (*Compt. rend.*, 112, 942—945).—Chiefly polemical and a question of priority. The isocinchonine obtained by Hesse's method (*Abstr.*, 1888, 379) is a mixture of cinchonigine, cinchoniline, and a non-crystallisable base.

C. H. B.

Tropine. By A. LADENBURG (*Ber.*, 24, 1628—1633).—The first part of this paper contains crystallographic descriptions and measurements of tropine platinochloride and *tropine aurochloride*. The former belongs to the monosymmetric system; the latter melts at 202°, and is deposited in pale-yellow, transparent crystals of the

asymmetric system. *Tropine mercuriochloride*, $C_8NH_{15}O, HCl, 6HgCl_2$, melts at 246° .

With reference to the production of the bibasic tropic acid by the oxidation of tropine, the author points out that in the case of piperidine, pipercoline, and coniine, the piperidine ring is resolved and an α -carbon atom oxidised to carboxyl; as tropine contains a carboxyl group in the side chain, this would probably undergo change and yield a bibasic acid; hence the formation of tropic acid, contrary to the opinion of Liebermann, is not opposed to the author's formula for tropine (compare this vol., p. 749).

J. B. T.

Amarylline and Bellamarine, two new Alkaloids. By K. FRAGNER (*Ber.*, 24, 1498—1500).—It has long been known that the plants of the family *Amaryllidaceae* are poisonous, but hitherto they have not been chemically examined. The author finds that the bulbs of *Amaryllis formosissima*, which is indigenous to South America, contain a new alkaloid, for which he proposes the name *amarylline*. It crystallises from alcohol in aggregates of short needles, is slightly soluble in water, readily in chloroform and ether. It gives precipitates with the usual alkaloidal reagents, and shows a characteristic reaction with sulphuric acid, giving a reddish-brown solution, which passes after a long time into brown, and becomes green on addition of a little water. The alkaloid becomes yellow at 190° , brown at 194° , and melts completely at 196° .

Another alkaloid, which the author terms *bellamarine*, may be obtained from the bulbs of *Amaryllis belladonna*, and crystallises in colourless needles, readily soluble in chloroform, alcohol, and ether. It becomes yellow at 175° , brown at 179° , and melts at 181° . With sulphuric acid, it gives a grey coloration, which becomes a beautiful red on warming, and yellowish-green on addition of a grain of potassium nitrate. With sulphuric acid and a little potassium dichromate, it gives first a yellowish-green and then a brown coloration.

H. G. C.

Morrenine. By P. ARATA and C. GELZER (*Ber.*, 24, 1849—1851).—The authors have examined the roots of *Morrenia brachystephana* (tásis), the sap of which is employed in the Argentine Republic as a specific for deficient lacteal secretion. The finely divided roots were extracted with ether, which removes wax, fatty acids, and resinous substances; one of the latter is soluble in alcohol and melts at 60° . The exhausted roots are boiled with alcohol, the solution filtered, and the alcohol removed; the residue contains a new alkaloid which has a very bitter taste, is readily soluble in water, chloroform, or amyl alcohol, and melts at 106° . Precipitates are obtained with all the ordinary alkaloidal reagents, and it is proposed to term it *morrenine*. The compound may be prepared more readily by digesting the roots for three to four days with 2 per cent. hydrochloric acid, neutralising the filtered solution with magnesia, evaporating to dryness, and extracting the residue with warm alcohol. (See also p. 1088.)

J. B. T.

Crystalline Egg Albumin. By S. GABRIEL (*Zeit. physiol. Chem.*, 15, 456—464).—In a repetition of Hofmeister's (Abstr., 1890, 182)

work, a half saturated solution of ammonium sulphate was found to be too strong, causing precipitation. The proteid was dissolved in water, and then a saturated solution of ammonium sulphate added until a cloudiness appeared, which was dissolved on adding a little more water. The formation of all stages of crystallisation can then be easily observed. The "globuliths" which are first formed soon lose their homogeneity and show a radiating appearance. The sphaeroliths are bundles of needles which soon separate. After drying, the proteid is no longer crystalline. Drawing an analogy from Pawlewski's experiments on paraffin dissolved in acetic acid (*Ber.*, 23, 327), it is believed that colloidal proteid is a polymeride of the crystalline material. The question whether these crystals were composed of pure albumin or of albumin in combination with ammonium sulphate was left open by Hofmeister. Harnack (this vol., 476) states they contain only 5 per cent. of proteid. In the present research their composition was found to be as follows:—

Egg albumin.....	80.86	} in 100 parts.
Ammonium sulphate ...	15.56	
Water.....	3.39	
Ash.....	0.19	

The percentage of nitrogen in pure egg albumin is 14.96. It thus appears to contain less nitrogen than other proteids. W. D. H.

Artificial Melanin. By G. POUCHET (*Compt. rend.*, 112, 884—885).—A substance having the general properties of the melanins is found in old anatomical preparations preserved in alcohol, and is also obtained by treating fresh blood with alcohol and mercuric chloride; the exact conditions which determine its formation have not yet been ascertained. It forms black grains insoluble in alcohol, ether, carbon bisulphide, and hydrochloric acid. Since all other constituents of blood are soluble in hydrochloric acid, the melanin can easily be separated from them. The grains dissolve in a 2 per cent. solution of potash, but a flocculent, brownish substance is precipitated on addition of hydrochloric acid; they dissolve in sulphuric acid forming a reddish solution, or if the acid is slightly diluted, a ponceau-coloured solution. Hydrogen peroxide or chlorine-water bleaches the grains, and they are then seen to have a radiating structure. In contact with hydrochloric acid and potassium ferrocyanide, they give no blue coloration. C. H. B.

Physiological Chemistry.

A New Method for Estimating the Specific Gravity of the Blood. By J. B. HAYCRAFT (*Proc. Roy. Soc. Edin.*, 18, 251—254).—The advantages of the new method are accuracy, small amount of apparatus, speed, and that only one drop of blood is required. Two

mixtures of benzyl chloride (sp. gr. 1.100) and toluene (sp. gr. 0.8706) are made, one (*a*) having a sp. gr. of 1.070, and the other (*b*) having a sp. gr. of 1.020: 1 c.c. of (*a*) is measured off in a pipette graduated to 0.01 c.c., and run into a glass tube in which is also the drop of blood, which floats on the surface in globules. (*b*) is now added until the globules of blood show no tendency to rise or sink; the sp. gr. of liquid is then calculated, and a correction made for temperatures other than 15.6 (60° F.), namely, 0.88 sp. gr. for every 2° above 60° F. E. W. P.

The Blood in Leucocythæmia. By E. FREUND and F. OBERMAYER (*Zeit. physiol. Chem.*, 15, 310—318).—A large quantity of blood was obtained from a large hæmatoma occurring in a case of leucæmia. The amount of hæmoglobin in it was 25 per cent. of the normal; the number of red corpuscles was a little over a million per cubic millimetre, instead of the normal five millions, and the white corpuscles were nearly as numerous (945000). The general analysis may be usefully contrasted with other analyses in the following table:—

In 1000 parts of Blood.

	Present case.	Normal. C. Schmidt.	Normal. Becquerel and Rodier.	Chyluria. Hoppe-Seyler.	Sarcoma. Hoppe-Seyler (this vol., p. 484).
Water	895.8	788.71	779.0	796.78	793.36
Solids	104.2	211.29	221.0	203.22	206.64
Proteids and hæmatin	72.0	—	—	—	—
Proteids	—	—	76.0	33.54	59.16
Fibrin	—	3.93	2.2	—	—
Proteids and extractives	—	192.10	—	—	—
Peptone	12.3	—	—	—	—
Hæmoglobin	—	7.38	134.5	149.6	129.70
Fat	7.1	—	1.60	1.7	2.31
Lecithin	3.8	—		3.48	2.01
Cholesterol	2.1	—		1.58	2.26
Extractives and salts	—	—	6.80	—	—
Salts	9.8	7.88	—	6.98	5.01

The most striking points about leucæmic blood are these: a low percentage of solids, the high percentage of fatty substance, and the presence of peptone, which has, however, been previously described in this disease by Bockendal and Landwehr (*Virch. Arch.*, 84, 561). Several other tables are given to illustrate minor points of composition, but the two following, which appear to be the most important, may be quoted.

100 parts of Solids contain.

	Present case.	Chyluria (Hoppe-Seyler).	Melanotic sarcoma (Hoppe-Seyler).
Fat.....	6·81	0·83	1·11

W. D. H.

Formation of Lactic Acid and Glucose in the Organism. By T. ARAKI (*Zeit. physiol. Chem.*, 15, 335—370).—Lactic acid has been shown to be one result of activity or death in various active tissues, and occurs in the urine in phosphorus poisoning, and after extirpation of the liver. In the present research, the influence of diminishing the supply of atmospheric oxygen on the urine was considered. The lactic acid was estimated in the ethereal extract as the zinc salt. Preliminary experiments with muscular tissue showed that Hoppe-Seyler's, and also Werther and Drechsel's modifications (*Pflüger's Archiv*, 46, 68) are both good methods yielding a zinc salt free from potassium chloride.

A series of experiments on dogs (which were supplied with less oxygen than there is in the atmosphere by the use of an apparatus constructed on the Regnault principle) gave the following results:—

the urine was always acid, contained lactic acid (the quantity of zinc lactate being generally less than 0.5 per cent.), generally gave the tests for sugar and albumin readily; if, however, the animals were in a condition of inanition, the urine yielded lactic acid and albumin, but no sugar. Experiments with hens gave corresponding results.

The same results followed poisoning by carbonic oxide, curare, and strychnine; and also after epileptic seizures, where the respiration is greatly retarded. Diminution of oxidation in the body is a factor common in all these conditions, and is doubtless a primary cause of the abnormal metabolism.

W. D. H.

Lactic Acid and Glucose in Organs with Impeded Circulation, and in Hydrocyanic Acid Poisoning. By H. ZILLESSEN (*Zeit. physiol. Chem.*, 15, 387—404).—From experiments on dogs and rabbits, the following conclusions are drawn:—

1. By artificially diminishing the amount of oxygen supplied to the muscles and liver during life (this was done by ligaturing the arteries supplying the parts in question), lactic acid is formed in those organs in increased amount.

2. In poisoning by hydrocyanic acid, lactic acid passes into the blood, diminishing its normal alkalinity. The amount of sugar in the blood is also increased.

3. Bernard and Preyer pointed out that when frogs are poisoned with hydrocyanic acid, the venous blood becomes of a bright, cherry-red colour, but in mammals this appearance very soon fades away. The cause of this change of colour is not known, but in the present research, the difference between cold and warm blooded animals is shown to be simply a matter of body temperature; a frog kept at a mammal's temperature in a warm bath behaving in this respect just like a mammal.

W. D. H.

Chemical Composition of the Notochord. By A. KOSSEL (*Zeit. physiol. Chem.*, 15, 331—334).—A considerable quantity of the material of which the notochord is constructed was obtained from large lampreys. Stenberg (*Du Bois Reymond's Arch., Anat. Abh.*, 1881, 105) states that neither gelatin nor chondrin is obtainable from the notochord; and Neumann (*Arch. Mikr. Anat.*, 14, 54) states that the cells stain with iodine as though they contained glycogen.

The notochord in the present research was found to contain from 95 to 96 per cent. of water; this contrasts very forcibly with cartilaginous tissue, and corresponds to what one would expect in an embryonic structure. The amount of ash present was 0.85 per cent. (0.805 soluble, and 0.047 insoluble, salts). The amount of glycogen present constituted 12 to 15 per cent. of the solids present. There was not much more than a trace of proteid matter soluble in water. Gelatin, collagen, and mucin were all absent; and the bulk of the solid matter was an insoluble proteid, easily digested by artificial gastric juice, and yielding no reducing sugar on treatment with mineral acids.

W. D. H.

Mucoid Substance in Ascitic Fluid. By O. HAMMARSTEN (*Zeit. physiol. Chem.*, 15, 202—207).—Only a few observations of mucoid material (paralbumin and metalbumin, or pseudomucin) occurring in ascitic fluid have been previously published. The present communication relates to six such cases. No. 1 occurred in a man, aged 66, suffering from cirrhosis of the liver. The fluid (sp. gr. 1.012) was alkaline, greenish, and opalescent; the opalescence remained after the separation of fibrin by spontaneous coagulation. Acetic acid gave no precipitate. By dialysing into water, the fluid became cloudy from precipitation of globulin; the fluid also gave Trommer's test (produced not by glucose, but by some unfermentable substance); the proteid in the fluid yielded, after treatment with boiling mineral acid, a reducing substance in the same way as does mucoid. The latter substance was isolated in the following way:—The fluid was acidified and boiled, the resulting coagulum was filtered off, and the filtrate concentrated on the water-bath, alcohol being added, and the precipitate which formed was collected; this was dissolved in water and again precipitated by alcohol, again dissolved in water, and dialysed to get rid of adherent sodium chloride. To the filtered liquid acetic acid was added, and the result was a white, flocculent precipitate nearly insoluble in excess of the acid. It was dissolved in a weak alkali, reprecipitated by acetic acid, and washed with water, alcohol, and ether. The filtrate, from which the precipitated mucoid had been separated, gave a further precipitate with alcohol, which was purified by repeated solution and reprecipitation. It also belonged to the mucin group of substances, and was found to be similar in its reactions to an albumose formed by the action of alkali on mucin, and is termed *mucin-albumose*.

Mucoid is insoluble in water, but soluble in feebly alkaline or acid liquids, which solutions remain clear on boiling. It gives Heller's test and the xanthoproteic reaction. It is precipitated by acetic acid; it is soluble in great excess of this acid, and again becomes cloudy on the addition of potassium ferrocyanide, or of tannic acid, but not of sodium acetate. Hydrochloric acid gives a precipitate readily soluble in excess. Mercuric chloride gives no precipitate. Potassio-mercuric iodide with hydrochloric acid gives a precipitate, but copper sulphate produces only a cloudiness.

The substance, moreover, gives Millon's, the Adamkiewicz, and the biuret colour reactions. On boiling with copper sulphate and potassium hydroxide, no reduction occurs; but if the mucoid has previously been heated with 2 per cent. hydrochloric acid on the water-bath, it then readily gives Trommer's test. Mucoid contains 51.4 carbon, 6.8 hydrogen, and 13.01 nitrogen, per cent. It also contains sulphur.

Mucin-albumose is easily soluble in water. This solution is not changed by boiling. Acetic acid, with or without potassium ferrocyanide, and hydrochloric acid give no precipitate. It is precipitated by nitric acid, but not by tannic acid, unless acetic acid be added as well. Various salts of the heavy metals give either no precipitate, or only an opalescence. The substance gives the xanthoproteic, Millon's, the Adamkiewicz, and the biuret colour tests. It does not give

Trommer's test unless it is previously boiled with dilute hydrochloric acid. It is precipitated by saturating its solution with ammonium sulphate, but not by sodium chloride. It contains 49.79 carbon, 6.96 hydrogen, and 11.42 nitrogen per cent. It also contains sulphur.

These two substances are considered to be derived from a more complex mother substance of proteid nature pre-existent in the fluid.

Analysis of the fluid led to the following result; the numbers are percentages:—Water, 96.847; solids, 3.153; proteid, 1.917; mucoid substance, 0.118; salts, 0.866.

The other five cases gave very similar results. The following further elementary analyses may be quoted:—

Case 2.—Mucoid, N, 13.1 per cent.; mucin albumose, C, 49.87; H, 6.88; N, 11.4.

Case 3.—Mucoid, N, 12.4; mucin albumose, N, 10.8.

Case 4.—Mucin albumose, N, 11.37.

Concerning the significance of the appearance of mucoid substances in ascitic fluid, it is at present premature to speak. W. D. H.

Excretion of Iron. By R. GOTTLIEB (*Zeit. physiol. Chem.*, 15, 371—386).—The question of the absorption of iron salt is of high importance, but still involved in obscurity; one of the difficulties in the way is the want of knowledge concerning the excretion of iron. Very little passes away by the urine, even after intravenous or subcutaneous injections of neutral iron-containing compounds. Observers differ as to whether it passes away with the bile or not. Buckheim and Mayer (*Inaug. Diss. Dorpat*, 1850) believe that not only the bile, but the whole intestinal mucous membrane, takes part in the excretion. Quincke (*Du Bois Reymond's Archiv*, 1868, 150) could, however, find none of the metal in a Thiry's intestinal fistula. Previous observations have been, however, merely qualitative. In the present research quantitative analyses were made for the first time. Dogs were used for the investigation, and the salt injected was the double tartrate of iron and sodium, dissolved in a feebly alkaline solution.

100 milligrams of iron were subcutaneously injected during four days. During this time, and 24 days following, the fæces contained a total of 96.9 milligrams of iron in excess of that found there before the injection was made. In other words, practically the whole of the iron passed into the intestinal canal. Several experiments were then made in which the metallic compound was injected intravenously; about 70 per cent. of the metal was ultimately found in the intestine. After protracted injections, the greatest part of the metal left in the body was found in the liver. Other metals, like copper and magnesium, behave similarly. The question arises, how does the iron ultimately reach the intestine from the liver? Apparently it is not by the bile, but by the circulating blood, the iron being in the end removed from the blood by the intestinal epithelium, and excreted into the intestine. W. D. H.

Alcaptonuria. By M. WOLKOW and E. BAUMANN (*Zeit. physiol. Chem.*, 15, 228—285).—The word alcapton was originally used by

Bödeker (*Zeit. rat. Med.*, 7, 130) for a nitrogenous reducing substance occurring in certain urines, which became brown on the addition of an alkali in the presence of oxygen. Similar cases were described by Ebstein and Müller (*Virchow's Arch.*, 62, 554), and Fleischer (*Derlin. klin. Woch.*, 1875, Nos. 39 and 40). Fürbringer (*ibid.*, No. 28) first advanced the theory that alcapton was not nitrogenous, but was identical with catechol, a view which, until recently, was generally accepted. W. Smith (*Dublin J. Med. Science*, 1882, 465) showed, however, that in one case protocatechuic acid, and not catechol, was the substance in question, and Kirk (Abstr., 1890, 188) has in another series of cases described a new acid which he terms uroleucic acid. Marshall (*Amer. J. Pharm.*, 1887, 131) describes a very similar acid as glycosuric acid. In all these cases, however, alcaptonuria does not appear to be pathological, but rather evidence of the presence of an idiosyncrasy in metabolism lasting throughout, or during long periods of otherwise healthy life.

In the present case, the questionable material was obtained from the greatly concentrated urine by rendering it strongly acid, and shaking it with ether. From the ethereal solution, it was obtained by evaporating off the ether, taking up with water, and precipitating by lead acetate; the lead was removed from the precipitate by hydrogen sulphide. The acid was once more extracted with ether, which on evaporation yielded crystals. These consisted of a substance very similar to, but not identical with, Kirk's uroleucic acid, and the name *homogentisic acid* is given to it. Analysis of the dried crystals correspond very well with the formula $C_8H_6O_4$. It reduces alkaline cupric salts and silver salts readily, but bismuth salts with great difficulty. With Millon's reagent, it gives a yellow coloration which turns red on boiling. It is monobasic, and contains two phenolic hydroxyl groups, but it is not identical with any of the hitherto described 16 acids with the same formula. It melts at $146.5-147^\circ$. *Lead homogentisate*, $(C_8H_6O_4)_2Pb + 3H_2O$, crystallises in colourless, brilliant, transparent needles and prisms. Its melting point is $214-215^\circ$. It dissolves in 675 parts of water at 20° , and is insoluble in alcohol and in ether. *Ethyl homogentisate*, $C_8H_6O_4Et$, is formed by passing hydrogen chloride through an alcoholic solution of the acid, diluting with water after 24 hours, adding excess of sodium hydroxide, and then shaking with ether. Its crystals are colourless prisms, soluble readily in hot, less readily in cold, water, readily soluble in alcohol and ether, but with difficulty in chloroform and benzene; they melt at $119-120^\circ$. The *methyl* salt crystallises in clinorhombic plates and melts at 45° .

Dimethylhomogentisic acid, $C_8H_6O_4Me_2$, melting at 124.5° , was also prepared.

By fusing homogentisic acid with alkali, short, colourless prisms melting at $196-198^\circ$, and with all the properties of gentisic acid, were obtained.

By heating the acid for a short time above its melting point, it is changed into its *lactone*, $OH \cdot C_6H_3 < \overset{O}{\text{C}} > CO$, which forms short, prismatic crystals and melts at 191° .

From these and similar considerations, homogentisic acid is believed to be quinol, in which one hydrogen is replaced by an acetic acid residue, $C_6H_4(OH)_2CH_2COOH$ [$(OH)_2 : CH_2 = 1 : 4 : 3$]. Kirk's uroleucic acid is trihydroxyphenylpropionic acid; the present acid is dihydroxyphenylacetic acid.

Further researches showed that the excretion of sulphates (pre-formed and combined) in the urine remains normal. A method is also given by which the new acid can be estimated in the urine, by means of its reducing action on silver salts.

Theoretical considerations lead to the conclusion that the proteïds of the body form the source of the acid, and further, that tyrosine is an intermediate product in this metabolism. When dogs are fed upon it, it is split up into carbonic anhydride and toluquinol.

W. D. H.

Proteïd in Normal Urine. By H. WINTERNITZ (*Zeit. physiol. Chem.*, 15, 189—201).—Senator states that normal urine always contains a trace of proteïd matter, but distinguishes between this and physiological albuminuria. Posner (*Berlin. klin. Woch.*, No. 41) also states that a trace of albuminous material can always be obtained from normal urine. The urine was carefully filtered and concentrated; the proteïd tests employed were Heller's nitric acid test and the acetic acid and potassium ferrocyanide reaction. The present research is mainly a repetition of Posner's work; larger quantities of urine were, however, employed, and in only one case was the precipitate produced by acetic acid and potassium ferrocyanide found to contain proteïd. The general conclusion drawn, which coincides with that of Leube (*Zeit. klin. Med.*, 13, Heft 1), is that normal urine seldom contains even a trace of proteïd.

W. D. H.

Hæmatoporphyrin in Urine. By E. SALKOWSKI (*Zeit. physiol. Chem.*, 15, 286—309).—A full communication on a subject concerning which a preliminary account has already appeared (this vol., p. 601).

W. D. H.

Physiological Action of Nickel-Carbon Oxide. By J. G. MCKENDRICK and W. SNODGRASS (*Brit. Med. J.*, i, 1891, 1215—1217).—This compound, $Ni(CO)_4$ (Mond, Langer, and Quincke, *Trans.*, 1890, 749), is a powerful poison when injected into animals subcutaneously; its vapour even to the extent of 0.5 per cent. in air is dangerous. The symptoms are those of respiratory poisoning, and are similar to those caused by carbonic oxide. The spectrum of the blood of an animal poisoned in this way is that of carbonic oxide hæmoglobin. When the substance is injected subcutaneously, it is probably in part dissociated in the tissues; there is evidence of the presence of nickel in the tissues and also in the blood. The substance produces a remarkably prolonged fall of body temperature, probably by interfering with respiratory processes. Its poisonous qualities are, however, at present a bar to its clinical use as an antipyretic.

Chemistry of Vegetable Physiology and Agriculture.

Osmotic Experiments on Living Bacteria. By A. WLADIMIROFF (*Zeit. physikal. Chem.*, 7, 529—543).—As De Vries investigated the phenomena of osmotic equilibrium between living plant cells and various salt solutions, so the author has undertaken an analogous research with living bacteria. The method adopted was to examine the movements of the bacteria in a drop of salt solution and meat broth hanging from the cover-glass of a suitable microscopic slide, and to observe at what concentration there remained a few bacteria which retained the ability to swim slowly, and in what slightly stronger solution the last swimming bacterium had vanished. The mean of these concentrations gives what the author terms the “limiting solution,” which he has determined for various organisms and a considerable number of salts. From the numerical results he concludes that in the majority of cases the relations between salts and bacteria obey the laws of osmosis (osmotic pressure). Some neutral salts, however, seem to have a poisonous effect on certain bacteria, whilst others appear to be able to penetrate the protoplasm of particular organisms, both of these being disturbing elements in the study of the purely osmotic phenomena.

The following table gives the limiting solutions in gram-molecules per litre :—

	<i>Bacterium</i> <i>Zopfii</i> .	<i>Bacillus</i> <i>cyanogenus</i> .	<i>Bacillus</i> <i>typhi</i> .	<i>Bacillus</i> <i>subtilis</i> .	<i>Spirillum</i> <i>rubrum</i> .	Intestinal bacterium.

Secretions of Microbes: Transformation and Elimination of Nitrogenous Organic Matter by the Pyrocyanic Bacillus in a given Cultivation Medium. By A. ARNAUD and A. CHAREIN (*Compt. rend.*, 112, 755—758).—The fluid in which *Bacillus pyrocyanicus* was allowed to develop contained per litre 5 grams of asparagine, 0.100 gram of dipotassium phosphate, 0.100 gram of crystallised disodium phosphate, 0.134 gram of potassium hydrogen carbonate, 0.050 gram of calcium chloride, and 0.050 gram of crystallised magnesium sulphate. The liquid after inoculation was kept at 25—30°, and the blue colour appeared after about 24 hours, but the quantity of pyrocyanin formed is not proportional to the general activity of the bacillus. The asparagine disappears after about 60 hours; aspartic acid is formed from the beginning but afterwards is destroyed, the decomposition being complete after about 72 hours. At this time the whole of the nitrogen has been converted into ammonia, with the exception of the small quantity that has gone to form the protoplasm of the microbes, and a small quantity that has been converted into compounds not yet defined. The weight of the microbes varies with the age of the cultivation. When the proportion of asparagine is varied the same products are obtained in the same times in absolutely the same proportions.

The bacillus splits up the asparagine by means of a diastase. The filtered liquid has no action on the asparagine *in vitro*, but if the bacilli are washed and transferred to an asparagine solution containing chloroform to prevent vital action, the asparagine is converted into aspartic acid.

C. H. B.

Assimilation by Lichens. By H. JUMELLE (*Compt. rend.*, 112, 888—891).—Under favourable conditions of light, humidity, and season, all lichens can decompose the carbonic anhydride of the air so energetically that the quantity decomposed exceeds that evolved from the lichen by the process of respiration, and consequently the organism gains in carbon. The intensity of the assimilation of lichens varies enormously, however, with the species, and is relatively strong with lichens such as *Cladonia* or *Parmelia*, but is very feeble in the case of crustaceous lichens such as the *Lecidea*. Other conditions remaining

the same, direct sunlight is more favourable to assimilation than diffused light. C. H. B.

Influence of Salt on the Quantity of Starch contained in the Vegetating Organs of *Lepidium sativum*. By P. LESAGE (*Compt. rend.*, 112, 891—893).—The plants were watered with solutions containing from 1 to 25 grams of salt per litre, or, in a second series 4 to 100 per cent. of sea water. With 12 to 15 grams of salt per litre, starch disappears completely from every part of the plant. The disappearance of the starch, however, is not directly proportional to the quantity of salt present in the water. In both series there is a minimum in the leaves and root when the water contains 1.66 grams of salt per litre or 6.7 per cent. of sea water, and with stronger solutions the quantity of starch again increases, until with the amount already stated it disappears altogether. It is not improbable that the real maximum is obtained by watering with solutions containing a quantity of salt between 0.0 and 1.66 grams per litre. C. H. B.

Dextrose from Ipecacuanha Root. By E. MERCK (*Arch. Pharm.*, 229, 169—170).—When preparing emetine from ipecacuanha root, about 5 per cent. of a compound identical with dextrose was obtained. This compound does not appear to exist in all varieties of the root, as no sugar could be detected in samples from other sources. J. T.

Macassar Oil. By K. THÜMMEL and W. KWASNIK (*Arch. Pharm.*, 229, 182—197).—Macassar oil is obtained from the seed of *Schleichera trijuga*, Willd., *Cussumbium spinosum*, an East Indian tree of the order Sapindaceæ. The oil can be obtained from the seed either by pressure or by treatment with light petroleum. The brown scale of the seeds amounts to 45 per cent., whilst the cotyledon containing the oil is 55 per cent. The cotyledons yield 68 per cent. of fatty oil by pressure, yellowish in colour, of the consistency of soft butter. The oil is composed of glycerides of acetic, oleic, palmitic, and arachidic acids. The fatty acids are present in the relative proportion of oleic acid 70 per cent., palmitic 5 per cent., and arachidic 25 per cent. It also contains free hydrocyanic acid and other volatile acids (formic, acetic acid). J. T.

Constituents of *Rhizoma podophylli*. By R. KÜRSTEN (*Arch. Pharm.*, 229, 220—248).—The results of the present investigation supplement the work done by Podwyssotzki (*Abstr.*, 1882, 976). The podophyllotoxin prepared by Podwyssotzki's method was not constant in composition, and its melting point varied from 100° to 125°: further, the podophyllinic acid of that author is composed mainly of a crystallisable, active, but very impure substance. Podophyllotoxin, $C_{22}H_{24}O_8 + 2H_2O$, is obtained by extracting the coarsely powdered rhizome with cold light petroleum, until freed from fat; after drying in the air, the extraction is continued with chloroform, until the liquid comes away almost free from yellow colour. As it is not possible to work with alcohol-free chloroform, too prolonged extraction

with chloroform would yield a more impure extract. The chloroform extract is distilled, and the residue is dried over a not too warm water-bath, partially dissolved in benzene, filtered, and the filtrate allowed to remain from 3 to 8 days, when a brownish-yellow mass of well formed, thick, strongly refractive prisms is produced, which is purified by washing with 50 per cent. alcohol, then with ether, recrystallising first from boiling benzene, and finally from solution in hot 45 per cent. alcohol. The compound is thus obtained in long, well-formed prisms. It melts at 93—95°, and at a higher temperature chars without subliming. 100 c.c. of water at 15° dissolves 0.014 gram; hot water dissolves somewhat more. It is very slightly soluble in ether and cold benzene, easily soluble in acetone and strong alcohol, and with difficulty in concentrated acetic acid. When moistened with concentrated sulphuric acid the crystals give an immediate cherry-red coloration, which slowly passes through greenish-blue to violet. Concentrated hydrochloric and nitric acids produce a red coloration; ferric chloride and bromine produce no change; the compound dissolved in glacial acetic acid gives a red coloration with Millon's reagent. The alcoholic solution is strongly laevorotatory. Zeisel's method indicates the presence of three methoxyl groups. Hydroxyl does not appear to be present.

Podophyllotoxin, when oxidised in an alkaline solution in the cold, by means of potassium permanganate, yielded, besides a little carbonic anhydride and a brown, amorphous substance, principally two compounds, the more considerable of which was *podophyllic acid*, $C_{20}H_{24}O_8$, obtained as well-formed, colourless crystals, from solution in a mixture of benzene and alcohol. The compound is without action on animals. It melts at 158—160°. Its aqueous solution, neutralised with aqueous potash, gives no precipitate with gold, calcium, or barium chlorides; silver nitrate gives a white precipitate, soluble in much water; copper acetate gives a blue precipitate. The *copper salt*, $(C_{20}H_{23}O_8)_2Cu$, was prepared as beautiful, light-green prisms, and analysed.

Picropodophyllin results from the action of alkalis on podophyllotoxin; thus, on heating the latter with aqueous ammonia, a well crystallised product is obtained, which at first was recrystallised from strong alcohol; but this was found to be unnecessary, as the melting point, 227°, was not affected by it. *Picropodophyllin* has the same composition as podophyllotoxin, but they differ in melting point: 227° and 95°; in their action on polarised light: inactive, laevorotatory; as to solubility, the former is less soluble in all liquids than the latter; the latter gives Millon's reaction, the former does not. By oxidation and reduction the two compounds yield the same products. The residue of the chloroform extract, freed from crystalline podophyllotoxin, yielded a little *picropodophyllic acid* in crystals melting at 156—158°; no other definite substance could be obtained from the extract.

Podophylloquercetin, $C_{23}H_{16}O_{10}$, is best obtained from the rhizome, after extraction by light petroleum and chloroform, by further extracting with ether, distilling off the ether, and treating with cold glacial acetic acid. The crude crystals are purified by repeated recrystallisation, best in an atmosphere of carbonic anhydride. It melts at 275—277°, is almost insoluble in water, sparingly soluble

in cold glacial acetic acid, more soluble in the hot acid and in ether, easily soluble in strong alcohol. Alkaline copper solution is easily reduced when warm, also ammoniacal silver solution. Probably this compound is not identical with quercetin. J. T.

Decomposition of the Silicates in Soil by Lime and Gypsum. By G. DE MARNEFFE (*Bied. Centr.*, 1891, 294—296).—Three classes of soils were ignited and extracted with dilute hydrochloric acid to remove all soluble silicates. They were then mixed with lime, some being exposed to air; others were kept air-tight, but water was given in all cases. The result was that insoluble silicates were rendered soluble, but the presence or absence of air made no difference. Another set of samples were treated in like manner, but mixed with gypsum; this addition produced no change in composition. E. W. P.

Value of Nitrates and Ammonium Salts as Food for Ferments and other Plants. By E. LAURENT (*Bied. Centr.*, 1891, 358—359).—Ammonium sulphate and phosphate, potassium and sodium nitrates, and also potassium nitrite, were applied to plants. The last compound is poisonous, and so is ammonium nitrate, if the solution be acid, for the ferment reduces nitrate to nitrite. Several mildews prefer ammonium salts to nitrates. With green plants in water culture, it was found that the roots of the "ammonia plants" ramify more in solutions of ammonium salts, but, on the other hand, the roots are shorter than when in solutions of nitrates. When grown in soil, plants fed with nitrates do best. E. W. P.

Characteristic of Fig Wine. By P. CARLES (*Compt. rend.*, 112, 811—812).—Figs, when moistened with tepid water acidified with tartaric acid, rapidly ferment, and yield a wine of about 8° alcoholic strength and very free from acidity. This wine is largely made in Algeria, although the figs from Asia Minor give the best results; it is used for adulterating grape wines, and also for defrauding the revenue.

If the fig wine is evaporated to a syrup, and left in a cool, dry place, it does not remain liquid, but after 24 hours solidifies to a crystalline mass, consisting chiefly of mannitol, together with glycerol, and a small quantity of sugar and organic acids. The proportion of mannitol amounts to from 6 to 8 grams per litre, whilst in the ordinary wines it does not exceed a few decigrams per litre. Estimation of the mannitol, therefore, makes it possible to detect the addition of as little as 25 per cent. of fig wine to ordinary wine.

C. H. B.

Analytical Chemistry.

Measurement of Gases. By G. LUNGE (*Ber.*, 24, 1656—1657).—A criticism of a recent paper of F. R. Japp on this subject (compare Proceedings, 1891, 68).

Estimation of Small Quantities of Alkali and Recognition of the Neutrality of Water. By F. MYLIUS and F. FOEBSTER (*Ber.*, 24, 1482—1498).—The authors' previous researches on the action of aqueous solutions on glass (*Abstr.*, 1889, 828) were in many respects incomplete, owing to the fact that no alkalimetric method was known sufficiently delicate for those investigations. They have, therefore, endeavoured to obtain an indicator which would be sufficiently delicate to allow of the employment of millinormal solutions, and find that iodeosin answers the purpose admirably. The crude colouring matter must be purified by dissolving in aqueous ether, shaking the filtered solution with soda solution, and precipitating the sodium salt by the addition of concentrated soda solution. The salt is recrystallised from alcohol, dissolved in water, acidified with hydrochloric acid, and the precipitated iodeosin well washed with water. If used in the ordinary manner, this colouring matter is useless as an indicator, but if the titration is carried on in a stoppered bottle, in presence of ether, and the whole shaken on addition of the reagent, the point of neutrality is very distinctly shown, as in presence of the slightest excess of alkali the iodeosin passes from the aqueous to the ethereal solution, leaving the former almost colourless.

The titration with millinormal solutions allows of the detection of quantities of alkali equivalent to 0.1 milligram Na_2O , and even smaller amounts may be estimated by employing a colorimetric method. In carrying out the latter process a large number of precautions must be taken with regard to the neutrality of the water, the quality of the glass vessels employed, &c. For details of this method reference must be made to the original, as they do not admit of a curtailed description.

H. G. O.

Estimation of Available 'Oxygen in Peroxides by Means of Gaseous Hydrochloric Acid. By L. L. DE KONINCK and A. LECREVIER (*Chem. News*, 63, 280).—A modification of Bunsen's method. The oxide under examination is placed in a flask along with sufficient water to dissolve the chloride formed during the ensuing reaction, and, while gently heated, is submitted to the action of hydrogen chloride, conveyed in a current of carbonic anhydride; as soon as the oxide is dissolved, the supply of hydrogen chloride is stopped, but the current of carbonic anhydride is continued, and when the hydrogen chloride has been expelled, the liberated iodine in the receiver is titrated in the usual manner.

D. A. L.

Estimation of Nitrate by the Phenolsulphonic Acid Method. By G. H. BARTRAM (*Chem. News*, 63, 228—229).—Noting discrepancies in the results obtained in duplicate estimations of nitrates in water by the phenolsulphonic acid method, investigations were instituted which show that accurate results are obtained with freshly prepared phenolsulphonic acid, but that shortly after preparation, this reagent becomes susceptible to the action of chlorine when the quantity present is as much as, or more than four times, that of the nitric nitrogen, and the results may then be vitiated to the extent of showing a deficit of 20 or even 40 per cent. of the total nitric

nitrogen actually present. This can, however, be obviated, either by removing the chlorides or by using freshly prepared phenolsulphonic acid.
D. A. L.

Estimation of Sulphur. By F. P. TREADWELL (*Ber.*, 24, 1937—1941).—The method is applicable to insoluble sulphides. It consists in heating the sulphide with excess of iron to dull redness in an atmosphere of dry carbonic anhydride for five to ten minutes, and after cooling, decomposing the iron sulphide with hydrochloric acid (1 : 5). The iron used is commercial ferrum reductum, and as this contains some sulphur, it is necessary to perform a blank experiment first. The hydrogen sulphide is absorbed in a Fresenius-Vollhard absorption apparatus; the first absorption bottle contains 50 c.c. of hydrogen peroxide solution (2 per cent.) and 10 c.c. of ammonia (2/1 N.), the second bottle contains 10 c.c. of the ammonia. After absorption of the hydrogen sulphide, the contents of the absorption apparatus are washed into a beaker, boiled for half an hour, acidified with hydrochloric acid, and evaporated to dryness on the water-bath. The dry mass is treated with a few drops of hydrochloric acid, dissolved in water, filtered, and the filtrate precipitated with barium chloride.

The results obtained compare very favourably with those obtained by other methods.
E. C. R.

Estimation of Sulphur in Coal, &c. By T. NEILSON (*Chem. News*, 63, 192).—The author has obtained satisfactory results by estimating sulphur in coal, &c., in the following manner:—A gram of coke mixed with 2 grams of sodium carbonate and half a gram of manganese carbonate is heated at a low red heat in a flat platinum dish for an hour, then fused, cooled, dissolved in hydrochloric acid, evaporated to dryness, redissolved in hydrochloric acid, filtered, and the sulphuric acid precipitated with barium chloride, &c., as usual. A blank experiment of equal duration should be made at the same time as the actual estimation.
D. A. L.

Estimation of Barium as Sulphate. By F. W. MAR (*Amer. J. Sci.* [3], 41, 288—295).—The author finds that in precipitating barium by means of sulphuric acid, it is highly advantageous to have the solution strongly acidified with hydrochloric acid, as the precipitate is then formed in a more or less crystalline condition, settles rapidly, and can be safely filtered with or without pressure in ten minutes. It is not necessary to add the reagents drop by drop, but the whole quantity required to complete the reaction may be added at once. Ordinary quantities of barium salts, in presence of a considerable excess of sulphuric and hydrochloric acids are precipitated completely and at once, but when only a few milligrams are present, the precipitate requires more time, usually from two to three hours, to separate under the same conditions. If sulphuric acid is being estimated by means of barium in the presence of alkali salts, the barium sulphate can be purified by dissolution in concentrated sulphuric acid and subsequent evaporation to dryness, when the sulphate is left

in large crystals, which can be filtered off as readily as sand. This is far better than the old method of solution and reprecipitation by dilution.
H. C.

Separation of Cadmium and Copper. By H. N. WARREN (*Chem. News*, 63, 193).—Copper is completely precipitated from its solutions by glucose in the presence of Fehling's tartrate solution, and may be readily and efficiently separated from zinc and cadmium by dissolving the alloy containing the three metals in nitric acid, diluting, mixing with excess of Rochelle salt and sufficient sodium hydroxide, then adding a dilute solution of glucose in quantities of not more than 4 c.c. at a time to the clear boiling solution.

D. A. L.

Precipitation of Manganese as Ammonium Manganous Phosphate. By A. G. MCKENNA (*Chem. News*, 63, 184—186; from *Tech. Quarterly*, 3, No. 4).—The author shows that glass vessels may be used for the precipitation of ammonium manganous phosphate from the solution of the chloride; that in several experiments boiling in the beaker has been continued, with constant stirring, until the precipitate assumed a silky appearance, some eight minutes, without getting silica from the glass. It is shown to be important that the precipitate be obtained crystalline; experimental data indicate that the ammonium manganous phosphate is only very slightly soluble either in hot water, aqueous ammonia (1 : 4), or ammonium nitrate, but least of all in the first, which, moreover, does not affect its appearance; the author, therefore, washed the precipitate with hot water. In the presence of iron, a manganese compound is formed, which is soluble in ammonia when an excess of an alkaline phosphate is not present.

D. A. L.

Alcohol Method for Estimating Iron and Aluminium Oxides in Phosphates. By H. H. B. SHEPHERD (*Chem. News*, 63, 251).—This method, modified to meet objections raised at meetings called by the Chemical Manure Manufacturers' Association, is conducted in the following manner:— $2\frac{1}{2}$ grams of phosphate is dissolved in 10 c.c. of hydrochloric acid, evaporated to dryness, redissolved in hydrochloric acid, heated to boiling, washed with as little water as possible, into a 250 c.c. flask, where it is mixed with 10 c.c. of strong sulphuric acid, and agitated frequently during five minutes. Alcohol (95 per cent.) is now added, the mixture is cooled, made up to the mark with alcohol, and well shaken; as contraction occurs on mixing, it must again be made up to 250 c.c. After an hour, 200 c.c. of the filtered solution is gently evaporated to a small bulk or to a paste if organic matter is present, mixed with 50 or 100 c.c. of water and boiled for a short time with bromine or other oxidising agent. Ammonia is now added in excess, the whole boiled for half an hour, cooled, a little more ammonia added, the precipitate of the phosphates of iron and alumina collected, washed with a hot solution of ammonium chloride, ignited, and weighed. The phosphoric acid is determined in the precipitate, and its weight deducted; the iron may also be determined if desired. Teschemacher and Smith suggest that if any magnesia is present, it should be removed from the precipitate by boiling with water and a little ammonium nitrate, repeating the treatment if needful.
D. A. L.

Separation of Iron from Cobalt and Nickel. By G. A. LE ROY (*Compt. rend.*, 112, 722—723).—A solution containing iron, manganese, nickel, and cobalt in the form of sulphates is mixed with a large excess of a concentrated and strongly ammoniacal solution of ammonium sulphate, after addition of sufficient citric acid or other acid to prevent precipitation of the metals. The solution is then electrolysed with the current from two Bunsen cells (or their equivalent); manganese separates at the anode, and iron, nickel, and cobalt at the cathode. The cathode is washed, and is then put into a concentrated solution of ammonium sulphate saturated with ammonia. It now serves as the anode, a weighed platinum plate being the cathode, and when the circuit is closed, the nickel and cobalt are transferred to the new cathode, whilst ferric hydroxide partly remains on the anode and partly floats in the liquid, but is free from any appreciable traces of nickel or cobalt. C. H. B.

Separation and Estimation of Nickel and Cobalt. By C. KRAUSS (*Zeit. anal. Chem.*, 30, 227—242).—The author has submitted to a critical study most of the hitherto published methods for separating nickel and cobalt. Many of them are entirely worthless. Fleischer's method (*Zeit. anal. Chem.*, 10, 219) yields passable results, owing to a compensation of errors. Cobalt can be estimated by a modification of Donath's method (*Abstr.*, 1880, 287; 1882, 555), in which the solution is boiled with potash and hydrogen peroxide, the cobalt peroxide then treated with potassium iodide, and the liberated iodine titrated. Rose's method, and those of Liebig, as well as Wöhler's, Rose's, and Gauhe's modifications of the latter, give satisfactory separation. Dirvel's method (*Abstr.*, 1880, 287) yields satisfactory results if skillfully performed. Fischer's potassium nitrite method is serviceable, and that of Ilinski and Knorre (*Abstr.*, 1885, 840) is excellent. M. J. S.

Precipitation of Antimony from Solutions of Potassium Antimony Tartarate. By J. H. LONG and H. E. SAUER (*Chem. News*, 63, 269—270).—By making the admixture slowly, and at a low temperature, an alkali carbonate may be added to a solution of potassium antimony tartarate, in quantities more than necessary for complete precipitation, without producing a precipitate; nevertheless, polarisation phenomena, inasmuch as the rotation is decreased, show that some chemical change has taken place; moreover, such solutions gradually became turbid, but without the evolution of carbonic anhydride, and, in time, deposit a precipitate. Series of experiments were instituted to investigate this matter. In one series, 5 grams of tartarate was dissolved in 60 to 70 c.c. of water cooled to 20°, to which was added a weighed amount of sodium carbonate dissolved in a little water; the mixture was diluted to 100 c.c. at 20° and left for 24 hours; with small amounts of carbonate, the precipitation was slow, but however small the precipitate, the supernatant liquid was always clear. Analyses of the precipitates in this series showed a mean of 78.8 per cent. of antimony; some of the results are as follows:—

Experiment.	Sodium carbonate added. grams.	Percentage of potassium antimony tartrate left in solution.
1	0.1	99.93
4	0.7	56.76
8	2.0	3.88

0.7982 gram of sodium carbonate should be sufficient to precipitate the 5 grams of tartrate present; the precipitation is evidently incomplete, but, nevertheless, in this series the amount of antimony retained in solution diminishes regularly as the quantity of sodium carbonate added increases. Other series of experiments, some mixed at 100°, others also kept at 100° for an hour, show an accelerated, but still incomplete precipitation; in fact, after a certain point when about 2 grams of sodium carbonate is added, the antimony in solution, having reached a minimum, begins to increase; this is still more evident when a greater dilution was employed. As the solution, then, has not the optical properties of the tartrate, and as it is influenced by an excess of sodium carbonate, it is presumed that the antimony may be present as antimonite, which probably is formed before a maximum in the oxide is reached. No evolution of carbonic anhydride took place in the cold or in the solutions simply mixed at 100°, but in the stronger solutions kept at 100° some carbonic anhydride was evolved. It seems that complete precipitation is only possible at very low temperatures.

D. A. L.

Electrolysis of Metallic Phosphates in Acid Solution. By E. F. SMITH (*Amer. Chem. J.*, 13, 206—209; compare Abstr., 1890, 1028).—*Cadmium from Manganese*.—10 c.c. of cadmium sulphate solution (= 0.2399 gram of cadmium), 10 c.c. of manganese sulphate solution (= 0.1000 gram of manganese), 20 c.c. of disodium phosphate (sp. gr. 1.0358), 3 c.c. of phosphoric acid (sp. gr. 1.347), and 100 c.c. of water were electrolysed with a current liberating 10 c.c. of oxyhydrogen gas per minute. In 12 hours, 0.2394 gram of cadmium was precipitated. In trial No. 2, 0.2400 gram.

Platinum.—0.2590 gram of ammonioplutinic chloride (= 0.1144 gram of platinum); 30 c.c. of disodium phosphate; 5 c.c. of phosphoric acid; water to 150 c.c.; current = 0.8 c.c. of oxyhydrogen gas per minute for 10 hours; weight of platinum deposited, 0.1140 gram.

Palladium.—Palladium = 0.1825 gram; sodium diphosphate, 20 c.c.; phosphoric acid, 5 c.c.; water, 125 c.c.; current = 0.7 c.c. of oxyhydrogen gas per minute; weight of palladium deposited, 0.1817 gram. In second trial, 0.1830 gram. Palladium could not be separated from cadmium, zinc, and other metals.

Gold.—0.1338 gram of gold; 20 c.c. of disodium phosphate; 3 c.c. of phosphoric acid; water to 160 c.c.; current, 0.8 c.c. of gas per minute. The deposit was made on copper and weighed 0.1335 gram. In second trial, 0.1339 gram. Gold could not be separated from cadmium, but easily from zinc.

Gold from Zinc.—Gold, 0.1338 gram; zinc, 0.1500 gram; disodium phosphate, 30 c.c.; phosphoric acid, 3 c.c.; water to 150 c.c.; current, 0.6 c.c. of gas per minute; weight of gold deposited, 0.1338 gram.

Gold from Cobalt.—Conditions the same as those last mentioned, except for the presence of 0.2300 gram of cobalt; weight of gold deposited, 0.1338 gram.

Several details as to the condition of the deposited metals are given in the original. A. G. B.

Electrolytic Estimation of Rhodium. By A. JOLY and E. LEIDIE (*Compt. rend.*, 112, 793—796).—Rhodium can be estimated with great accuracy by the electrolysis of solutions free from all other metals except the alkali metals. The solution of the chloride or double (sodium, potassium, or ammonium) chloride is slightly acidified and should not contain more than 4 grams of metal per litre. At the beginning, the liquid is heated to 50–60°, and a current of 0.5 ampère is used, but the operation is finished at the ordinary temperature with a current of 0.1 ampère. The method is applicable to any rhodium compound that can be converted into the chloride or a double chloride. If the separation is required and not the estimation, a stronger current may be used; the metal is then more crystalline and less coherent.

The metal can also be estimated in solutions of the sulphate, provided that the liquid contains a considerable quantity of free acid and the deposition is very slow.

Nitric acid, in quantity exceeding 20 per cent., prevents separation of the metal altogether, and with more than 10 per cent. deposition is very slow. In presence of oxalic acid, no rhodium separates at the cathode, but a dark-green peroxide separates at the anode.

C. H. B.

Volumetric Estimation of Volatile Hydrocarbons. By W. HEMPEL and L. M. DENNIS (*Ber.*, 24, 1162—1164).—The authors describe a method of estimating the volatile hydrocarbons in gas. Only 100 c.c. of gas is employed for the determination. The method is based on Bunsen's, the hydrocarbons being absorbed by a small quantity of absolute alcohol. The gas is brought into an ordinary gas-burette and mixed with a small quantity of water saturated with gas. It is then transferred, by means of a capillary tube, to a gas pipette, containing 1 c.c. of absolute alcohol over mercury, and shaken three minutes. The alcohol must first be saturated with gas, to avoid any gas except the volatile hydrocarbons being absorbed. After shaking with alcohol, the gas is transferred back into the burette. To absorb alcohol vapours mixed with the gas, it is shaken in a pipette with 1 c.c. of water over mercury for three minutes and again transferred to the burette. The difference in volume gives the hydrocarbon vapours. The results are accurate.

Since the volatile hydrocarbons are appreciably soluble in caustic soda, in ordinary gas analysis the percentage of carbonic anhydride is too high. This error is easily avoided in the above method by determining the constituents in the following order: volatile hydrocarbons, carbonic anhydride, heavy hydrocarbons, oxygen, carbonic oxide, hydrogen, and marsh gas.

E. C. B.

Gayon's Aldehyde Reaction. By H. BORNTREGER (*Zeit. anal. Chem.*, 30, 208—209).—Gayon's reagent is a solution of rosaniline decolorised by a little hydrochloric acid and much sodium hydrogen sulphite. Its indications are untrustworthy, since many oxidising agents restore its red colour in the same way as aldehyde does. On the other hand, acetal destroys the rosaniline-red, and would therefore mask the aldehyde reaction. The reducing action of aldehyde on ammoniacal silver solution, and on ammoniacal permanganate, are the only certain tests at present known, but they both require the presence of a moderately large amount of aldehyde.

M. J. S.

Estimation of Acetone in Denaturised Alcohol. By L. VIGNON (*Compt. rend.*, 112, 873—875).—When iodine and sodium hydroxide act on acetone in presence of water, there are always two distinct reactions taking place simultaneously: (a) $\text{COMe}_2 + 3\text{I}_2 + 4\text{NaOH} = \text{AcONa} + \text{CHI}_3 + 3\text{NaI} + 3\text{H}_2\text{O}$, and (b) $3\text{I}_2 + 6\text{NaOH} = 5\text{NaI} + \text{NaIO}_3 + 3\text{H}_2\text{O}$, the one or the other predominating according to the conditions.

In presence of excess of methyl alcohol, the proportion of acetone amounting to 20 or 25 per cent., 13·7 atoms of iodine are required for the complete conversion of 1 mol. of acetone into iodoform, or 1 part of acetone requires 30 parts of iodine.

Ethyl alcohol alone yields no iodoform, but it greatly retards the conversion of acetone into iodoform, and tends to make the reaction (b) predominant. A mixture of acetone and water which yielded iodoform corresponding to 55·34 per cent. of acetone gave only 28·54 after dilution with an equal volume of ethyl alcohol, other conditions remaining the same. Aldehyde, on the other hand, promotes the formation of iodoform, and the preceding mixture, when an equal volume of aldehyde had been added, gave iodoform amounting to 95·93 per cent. of acetone.

It follows that in the estimation of acetone in denaturised alcohol by conversion into iodoform, a large excess of iodine must be used. 5 c.c. of the alcohol, after removal of the aldehyde by Bardy's method, is diluted to 250 c.c. with distilled water, and 5 c.c. of the solution (= 0·1 c.c. of the original alcohol) is mixed with 10 c.c. of binormal soda and 5 c.c. of binormal iodine. A second estimation is made with the same quantity of alcohol, but double the quantities of iodine and soda, and it is only when both experiments give the same result that the determination can be regarded as satisfactory.

C. H. B.

Use of Phenylhydrazine for the Estimation of Sugars. By MAQUENNE (*Compt. rend.*, 112, 799—802).—The weight of the osazones precipitated when different reducing sugars are heated for the same time with the same weight of phenylhydrazine varies considerably with the nature of the sugar, but remains constant for the same sugar so long as the conditions are precisely the same. The following results were obtained by heating for an hour at 100° 1 gram of each sugar with 100 c.c. of water, and 5 c.c. of a solution containing 400 grams of phenylhydrazine and 400 grams of glacial acetic acid per litre; after cooling, the precipitate was collected, washed with

100 c.c. of water, and dried at 110° :—Sorbitose, 0.82; levulose, 0.70; xylose, 0.40; glucose (anhyd.), 0.32; arabinose, 0.27; galactose, 0.23; rhamnose, 0.15; lactose, 0.11; maltose, 0.11. With more dilute solutions, the relative differences remain practically the same, but levulose tends to approach sorbitose. It is noteworthy that sorbitose and levulose yield a much greater quantity of osazone in a given time than any other sugars, and these are the only two isomerides or homologues of glucose that have a ketonic function. The two are readily distinguished, since the glucosazone forms easily recognisable needles, whilst sorbinosazone never forms distinct crystals. Glucosazone and galactosazone, which both crystallise well and melt at practically the same temperature, can be distinguished by their rate of formation. It is also noteworthy that the reducing saccharoses give less osazone than the non-hydrolysable sugars, and therefore less than the products of their own inversion.

A comparison of the weight of osazone obtained from the products of inversion of polyglucoses with the weight obtained from a known mixture of glucoses affords valuable help in determining the products of inversion of the polyglucoses. The following results were obtained with 1 gram of sugar completely inverted by dilute sulphuric acid, dissolved in 100 c.c. of water and mixed with 2 grams of phenylhydrazine, 2 grams of glacial acetic acid, and 5 grams of sodium acetate; in each case the result is compared with that obtained with artificial mixtures of corresponding quantities of glucoses:—

	Weight of osazone.
{ Ordinary saccharose	0.71
{ Glucose and levulose (0.526 gram each)	0.73
{ Maltose	0.55
{ Glucose (1.052 gram)	0.58
{ Raffinose (cryst.)	0.48
{ Levulose, glucose, and galactose (0.303 gram each)	0.53
{ Lactose (cryst.)	0.38
{ Glucose and galactose (0.5 gram each)	0.39

The weight of osazone is always slightly lower in the case of the products of inversion, because of the destructive action of the acid. This error can be compensated by diluting the solutions until equal volumes have the same reducing power. In this way it was found that the product of the inversion of melezitose gives the same weight of osazone as a solution of glucose of equal reducing power, and therefore glucose is the sole product of the inversion of melezitose.

C. H. B.

Saponification by means of Sodium Ethoxide. By A. KOSSEL and M. KRÜGER (*Zeit. physiol. Chem.*, 15, 321—330).—The method of saponification introduced by Kossel and Obermüller (*Abstr.*, 1890, 1474) is shown to be applicable to the analysis of butter and suet.

Practically identical results were obtained, whether the analysis was performed by the new method or by the alcoholic potassium hydroxide method.

In the saponification of cetyl palmitate by the new method, one product is sodium palmitate, the other is cetyl alcohol. In the saponification of phenyl salicylate (salol), one product is ethyl salicylate. In the saponification of salol by sodium amyloxyde, one product is amyl salicylate. The bearing of these facts on observations of Claisen (*Ber.*, 20, 646) is pointed out. W. D. H.

Saponification of Tallow. By H. N. WARREN (*Chem. News*, 63, 143).—Complete saponification is effected by boiling the fat, in a copper pan, with a solution of equal parts of sodium and potassium hydroxides for about 10 minutes. The fatty acids are liberated with dilute sulphuric acid, washed, dried by blowing air through the molten acids, and the solidifying point taken in the usual manner. D. A. L.

Estimation of Grease. By W. L. GADD and S. LEES (*Chem. News*, 63, 86).—In order to break the fall of the reflux ether and prevent its washing solid material into the flask below, when extracting light or finely pulverised matter in a Soxhlet apparatus, it is proposed to furnish the extraction tube with an annular projection inside (above the substance), upon which is placed an inverted glass cup, provided with a short stem to facilitate removal and with channels in its periphery, through which the reflux ether passes and flows quietly down the sides of the extraction tube, without disturbing the material in the filter. D. A. L.

The Analysis of Olein. By A. KÖRNER (*Chem. Centr.*, 1891, 1, 218—219; from *Deut. Chem. Zeit.*, 5, 402).—The separation of the unsaponifiable portion of olein is effected by the author as follows:—3—4 grams of olein is saponified with a slight excess of $\frac{1}{10}$ or $\frac{1}{2}$ N. alcoholic potash, mixed with a considerable quantity of ignited sand, evaporated to dryness, and the residue extracted in a 300—400 c.c. flask with 150 c.c. of hot ether, with addition of some alcohol.

To this solution is added an ethereal solution of mercuric chloride (2.42 parts of mercuric chloride to 1 part of potassium hydroxide employed) with addition of alcohol. The mercuric salts of the fatty acids separate as a voluminous precipitate, which is allowed to subside, the clear solution filtered off, the precipitate washed with ether, and the ether distilled from the filtrate until this measures about 30 c.c. This residual solution is brought to dryness in a porcelain dish, the residue extracted four or five times with 10 c.c. of light petroleum (boiling point below 50°), and the petroleum evaporated off again and the residue weighed. J. W. I.

General and Physical Chemistry.

Rotatory Dispersion of Tartrates. By G. KÜMMEL (*Ann. Phys. Chem.*, [2], 43, 509—515).—The optical rotation of solutions of the normal tartrates of potassium, sodium, lithium, and ammonium, and of certain of their double salts, was determined for the Fraunhofer lines C, D, *b*, F, and G. The solutions taken were all of normal concentration, and the temperature of the observations was 15°. The dispersion was found to be the same for all the salts examined. Observations with solutions of different concentrations showed that the rotation is proportional to the concentration. Solutions of the acid tartrates of sodium and lithium were also examined, but in this case the concentration was only half that of the solutions used in the previous experiments owing to the sparing solubility of these salts. The acid salts differ wholly in their behaviour from the normal salts, and the results are such as to justify the assumption that in aqueous solution these salts are decomposed into free acid and normal salt. On the above assumption, a calculation of the optical rotations of the solutions of the acid salts gave numbers in close agreement with those observed.

H. C.

Sensitisers for Rays of Low Refrangibility. By G. HUGHES (*Proc. Roy. Soc.*, 49, 345—346).—Directions are given for preparing solutions of the hydrogen sulphite compounds of alizarin-blue S and of coerulein, to be used as sensitisers. The actinic curves for the two substances are almost identical. Whilst possessing, in a high degree, sensitising properties for rays throughout the region comprised between λ 6200 and 8000, they do not lower the sensitiveness to the violet and ultra-violet. Numerous lines in the spectrum have been depicted which previously were not known to exist.

J. W.

Is Chemical Action affected by Magnetism? By M. LOEB (*Amer. Chem. J.*, 13, 145—153).—The close relationship between electricity and chemical affinity on the one hand, and that between electricity and magnetism on the other, have naturally raised the question whether any relation can be traced between affinity and magnetism. All experiments hitherto made have failed to answer this question, as certain non-chemical phenomena have always been introduced, due either to the inequalities in the magnetic field or to the physical heterogeneity of the reacting system, or to both of these causes at once, whereas the conditions to be realised are that the system remains homogeneous throughout, and the field of stress also practically homogeneous. Such conditions can be realised by observing the speed of some reaction which does not involve solids, in the presence of a magnet, and again, when there is no magnetic effect, provided the magnetic properties of the system could be altered by

the reaction. We might then expect that a reaction which made a system more or less amenable to magnetic action, might show evidence of acceleration or retardation by the magnetic force. Wiedemann has shown that in the ordinary form of reaction between salts, involving merely a double decomposition, the total magnetism of the system remains unaltered, but there is a marked change when the constitution of one of the ingredients is altered; the atomic magnetism of trivalent iron is 25 per cent. greater than that of the same element in the ferrous state. The author has, therefore, studied the effect of magnetism on the speed of oxidation and reduction of iron salts in solution by reagents which showed but a feeble magnetism by themselves. Two reactions were selected, namely, the oxidation of ferrous sulphate by potassium chlorate, and the reduction of ferric chloride by hydriodic acid. The results were negative and lead to the conclusion that no relation exists between magnetism and chemical affinity.

H. C.

Method of Standardising Platinum Thermometers with reference to the Boiling Point of Sulphur. By H. L. CALLENDAR and E. H. GRIFFITHS (*Proc. Roy. Soc.*, 49, 56—60).—Callendar (*Phil. Trans.*, 1887, A, 161) has shown that the difference between the readings of an air thermometer and a platinum resistance thermometer between 0° and 700° is closely represented by the formula $\delta\{t/100\}^2 - t/100$, δ being a constant for each particular wire. The present paper shows how to find δ by a single observation at a temperature other than 0° and 100°. The authors choose the boiling point of sulphur for this standard temperature; this was carefully ascertained by means of an air thermometer protected from radiation by two coaxial tubes, the inner one of metal, the outer of glass. The boiling point was found to be 444.53°, probably correct to a tenth of a degree. To obtain the constant, the boiling point with the platinum thermometer is found, and the difference between it and the above number equated to the expression containing δ .

A list of various corrected melting and boiling points obtained with different platinum thermometers is appended, the agreement being good.

J. W.

Determination of the Boiling Point with Small Quantities of Material. By H. C. JONES (*Ber.*, 24, 2251).—The author draws attention to the fact that some time ago (*Trans.*, 1878, 175) he described a form of apparatus essentially identical with that recently described by Schleiermacher (this vol., p. 873) for determining the boiling point with small quantities of material.

F. S. K.

Hydrogenation of Closed Chains. By F. STOHMANN and C. KLEBER (*J. pr. Chem.* [2], 43, 538—544).—The authors have determined the following thermochemical data since their last communication (this vol., p. 376):—

	Heat of combustion. Cal.	Heat of formation. Cal.
Δ , dihydroterephthalic acid ..	845.4	182.6
Dihydrophthalic acid	843.1	184.9
Δ , tetrahydrophthalic acid	881.6	215.4
Fumaroid hexahydromellitic acid	923.9	618.1

The heat of combustion of mellitic acid is 788.2 Cal. (Abstr., 1889, 1096). It has been shown (this vol., p. 376) that the heat of combustion of a hexahydro-compound of a benzene-ring derivative is generally $68.7 + 2 \times 45.3$ Cal. higher than that of the benzene-ring compound, and by this rule the heat of combustion of hexahydromellitic acid should be $788.2 + 159.3 = 947.5$ Cal., and not 923.9 Cal. From this it would appear that an excess of energy is stored up in mellitic acid so that less energy is brought into play in its conversion into the hexahydro-compound than is necessary in other cases.

A list is given to demonstrate the agreement between the hydrogenated compounds of the terephthalic series and those of the phthalic series.

The thermal value for the splitting up of the benzene-ring into an open chain has already been given as 54.8 Cal. for every 2 atoms of hydrogen added (*loc. cit.*); this is nearly true in the case of hexahydromellitic acid, for which the numbers vary from 51.5 to 55.0 for two atoms of hydrogen.

A. G. B.

Determination of the Specific Gravity of Viscid Substances.

By J. W. BRÜHL (*Ber.*, 24, 2455—2457).—The author is of opinion that the apparatus described by Scheibler for the determination of the specific gravity of viscid substances (this vol., p. 520) is valueless for exact work with small quantities, since it is open to the same objections as the specific gravity bottle supplied with a capillary bored stopper.

W. P. W.

Diffusion of Ammonia through Water and through Alcohol.

By J. MÜLLER (*Ann. Phys. Chem.* [2], 43, 554—567).—The volume of ammonia absorbed by a given quantity of water in equal periods of time continually decreases until at length the amount becomes stationary. When this condition is reached, the amount of gas which diffuses through the liquid in a given time is directly proportional to the area, and inversely proportional to the length of the liquid column. The volume in cubic centimeters, which will diffuse through a column of 1 cm. length and 1 c.c. area in one minute under a pressure of 1 cm. of mercury, may be termed the diffusion constant. The change of this constant with the temperature is similar to that of the absorption coefficient of the gas by water, and the diffusion constant is therefore proportional to the absorption coefficient. Between 0° and 40° the diffusion constant seems to be proportional to the absolute temperature.

With ammonia and alcohol similar results to those given above

were obtained. The proportionality between the diffusion constants and the absorption coefficients appears to be general. This is seen from the fact that at 20° the diffusion constants for water and alcohol are 0.093 and 0.047, and the absorption coefficients for the same temperature are 690 and 340.

H. C.

Objections raised against the Hypothesis of Electrolytic Dissociation. By S. ABRHMSNIUS (*Ber.*, 24, 2255—2264).—The author criticises the observations of Traube on the freezing points of dilute solutions of cane sugar (this vol., p. 874), and shows that his results are not in agreement with those of Raoult, Tammann, or Pickering. Traube gives a value for the molecular reduction in very dilute cane-sugar solutions of 36.8, but that which the author deduces from his own and Tammann's observations is only 19.5. This would contradict Traube's conclusion that non-electrolytes, such as cane-sugar, behave abnormally in very dilute solutions, and give values for the molecular reduction, which are similar to those obtained for non-electrolytes. The above conclusion is also contradicted by Pickering's observations on the behaviour of non-electrolytes in very dilute solutions, as the seven substances which he examined gave practically normal results for the molecular reduction. The author finds nothing in Pickering's recent results on the freezing points of mixed solutions which is opposed to the dissociation hypothesis.

H. C.

Distribution of a Substance between Two Solvents, &c. By W. NERNST (*Zeit. physikal. Chem.*, 8, 110—139).—This paper contains a theoretical and experimental investigation of the distribution of a substance between two solvents, which are either immiscible or only partially miscible, on the basis of the osmotic pressure and electrolytic dissociation theories. The case of the vapour pressure and boiling point of dilute solutions of volatile substances is also considered.

The agreement between calculated and observed values is satisfactory, and the author shows that valuable information regarding the molecular weights of substances in solution may be obtained in this way when other methods are inapplicable.

J. W.

Relation between Affinity and Partition Coefficients in Immiscible Solvents. By P. AULICH (*Zeit. physikal. Chem.*, 8, 105—109).—Substances which do not act chemically on each other are distributed each in a constant ratio between two solvents which are themselves immiscible. The author puts the question:—What happens if four substances which are in chemical equilibrium (for example, two acids and their salts with the same base) are distributed between two immiscible solvents? Here there are two sorts of forces which determine the final equilibrium, namely, chemical and physical. Various cases are discussed, and the author concludes that there must exist some ascertainable relations between the physical and chemical forces at work if the second principle of thermodynamics is to be upheld.

J. W.

Affinity Coefficients of Bases. By E. LELLMANN and H. GROSS (*Annalen*, 263, 286—299).—The authors have made a further series of determinations of the affinity coefficients of bases, employing the method previously described (this vol., p. 638). The values of κ in the case of α - and β -naphthylamine were found to be 0.03384 and 0.02593 respectively; in the case of metachloraniline $\kappa = 0.05112$, and in the case of tetrahydroquinoline $\kappa = 0.01333$. These values are the average result of concordant experiments made with solutions of different concentrations.

In all the experiments carried out up to this point, Guldberg and Waage's law has been found to hold good, but in the case of ortho- and para-amidobenzoic acid, metanitriline, and thiohydantoin, the value of κ in dilute solutions of the hydrochloride of the base varies greatly with the concentration, diminishing as the solution becomes more dilute; when, however, sufficiently concentrated solutions are employed, the value of κ remains constant. The behaviour of paramidobenzoic acid may be quoted as an example:—When a dilute solution, containing only 216.4 milligrams of the hydrochloride per litre, is employed, the value of κ is found to be 0.05965, but when the solution contains only 86.55 milligrams this value falls to 0.04284; when, on the other hand, a concentrated solution, containing 2769 milligrams of the hydrochloride, is used, the value of κ is 0.08495, and even on diluting the solution until it contains only 692.4 milligrams, the observed value remains 0.08947. The explanation of this phenomenon is probably to be sought for in some change in the configuration of the molecule brought about by an alteration in the degree of concentration of the solution.

Up to the present time the symbol κ has been used to denote the affinity of "butter-yellow" for hydrochloric acid, compared with that of a given base for this acid; in future κ will be employed to denote the reciprocal of this number, so that its value will increase, instead of decrease, as the affinity of the base increases. The affinity coefficient of aniline will be taken as unity, as it is one of the commonest organic bases, the hydrochloride of which is easily obtained in a pure condition; this coefficient, in accordance with the above statement, is the ratio between the number of molecules of hydrochloric acid in combination with the aniline and the number of molecules of hydrochloric acid in combination with the "butter-yellow," in a solution formed by dissolving equivalent quantities of the three substances under the conditions already described. F. S. K.

Velocity of Reaction between Metals and Halogens. By A. SCHÜKAREFF (*Zett. physikal. Chem.*, 8, 76—82).—Thin plates of the metal, 20 mm. by 40 mm., were rolled into a little cylinder, dipped into strong hydrochloric acid, and then washed with water. Thus prepared, they were dipped into a solution of the halogen, and left there for 15 minutes, the vessel being occasionally shaken. The halogens were dissolved in 1/50-normal solutions of the corresponding compounds with potassium. Before and after the experiment the solutions were titrated with thiosulphate solution, the diminution of the titre measuring the extent to which the reaction

had taken place in the given time. A constant was calculated from Guldberg's formula, $k = \frac{l_1 C_0 - l_2 C_\infty}{T}$, where C_0 and C_∞ are the concentrations, and T the time in minutes. This formula was found to be not quite applicable, the constant usually changing somewhat with the initial concentration. The quantities of halogen reacting during a given time in equally strong solutions on equal surfaces of most (probably all) metals are equal; or, in other words, the quantities of metal reacting in a given time at equal or equivalent concentrations, are proportional to the atomic weight of the metal, and inversely proportional to its valency in the compound formed.

The metals examined were zinc, aluminium, iron, copper, and tin.

J. W.

Reaction between Ferric Salts and Soluble Thiocyanates. By G. MAGNANINI (*Zeit. physikal. Chem.*, 8, 1—5).—Gladstone observed that the colour of an aqueous solution containing ferric chloride and potassium thiocyanate became more intense when excess of either of the salts was added. This points to the existence of a balanced action between the substance, and the author has made spectrophotometric observations with a view to settle the question. According to Guldberg and Waage's law, solutions should have the same coefficient of extinction when they contain in equal volumes p equivalents of the one salt and q equivalents of the other, no matter whether p refers to KCNS or to FeCl_3 , provided that there is a balanced action. The author finds this to be the case, and also that the quantity of ferric thiocyanate formed is a regular function of the quantities of potassium thiocyanate and of ferric chloride dissolved in a given volume. He therefore assumes the action to be $\text{FeCl}_3 + 3\text{KCNS} = \text{Fe}(\text{CNS})_3 + 3\text{KCl}$.

Krüss and Moraht found that the maximum of extinction took place when the salts were present in the proportion of FeCl_3 to 12KCNS , and concluded that a stable double salt, $\text{Fe}(\text{CNS})_3 \cdot 9\text{KCNS}$, was formed in the solution. The author could not confirm this observation.

J. W.

The Dead-space in Chemical Reactions. By LIEBREICH (*Zeit. physikal. Chem.*, 8, 83—104).—In a previous paper (Abstr., 1890, 1207), the author considered the shape of the dead-space formed in the reaction between chloral and sodium carbonate, and in that between iodic and sulphurous acids; and concluded that the physical character of the liquid immediately adjoining the containing walls and the free surface, was in such a degree different from that of the other parts of the liquid as to offer a certain degree of resistance to any chemical action taking place within it. He now proceeds to show, by means of various experiments, that there is a special resisting power near the surface of liquids. Cartesian divers were sunk to a considerable distance below the surface of a vessel containing water, &c. The additional pressure necessary to effect this being then suddenly removed, the diver rose, but could not penetrate the superficial layer, rebounding from it as from a solid wall.

Experiments were also made on the convection of liquids. Solutions of glycerol were employed, a light solution (coloured with azorubin) being allowed to ascend in a heavier. Vessels of various forms were employed, but it always appeared that the coloured liquid never reached the free surface, nor the walls in any capillary space unless there was subsequent diffusion.

The author replies to several criticisms on his views, and rejects the explanation given by Budde (this vol., p. 975) that the dead-space in the chloroform reaction is due to superficial evaporation and diffusion.

J. W.

Autocatalysis. By W. O-TWALD (*Chem. Centr.*, 1891, i, 486; from *Abhdl. math.-phys. Klasse K. Sachs. Ges. Wiss.*, 1890, 189—192).—The conversion into lactones by elimination of water to which hydroxy acids are subject in aqueous solution in presence of another acid, occurs in the case of γ -hydroxyvaleric acid, when merely dissolved in water; this is explained by the author on the assumption that the acid is in part dis-ociated, and that the free hydrogen ions act catalytically. The presence of a salt of the acid, for instance the sodium salt, in the solution, retards the formation of the lactone very considerably, and the amount of free acid in the solution, as determined alkalimetrically, remains constant for days together. The author considers that this fact supports the above assumption, there being fewer free hydrogen ions present.

J. W. L.

Isomorphism. By J. W. RETGER (*Zeit physikal. Chem.*, 8, 6—75).—The method adopted by the author for the detection of isomorphism in the experiments of which an account is here given, was the investigation of the colour of the crystals obtained when a coloured and a colourless salt were allowed to crystallise simultaneously from solution. Two salts, say potassium perchlorate and potassium permanganate, were dissolved in water, and a drop of each of the warm solutions brought on to a microscopic slide. The drops were either mixed, or connected by a narrow streak of liquid so that slow diffusion might take place.

If the salts, like those mentioned, are isomorphous, then crystals of all depths of colour are obtained; sometimes one crystal even may be of different depths at the two ends, with all intermediate shades between. If the two salts are not isomorphous (for example, potassium chloride and potassium permanganate), the crystals which separate show no transition, but are either colourless or dark-red (black). The thickness of the crystals is always very nearly the same, so that no disturbance is to be feared from this cause. If good results are to be obtained, the colour of one of the substances must be very intense; the blue copper salts can only be of service when the crystals formed are very thick.

By means of the above method, taken in conjunction with the usual crystallographic and optical examination of the salts, the author has studied the series $M'R^{n+}O_4$, using permanganates as the coloured salts, and $M_2'R^{n+}O_4$, the manganates being the standard crystals. He adopts as axiom: things that are isomorphous with the same thing are isomorphous with each other.

KMnO_4 , $(\text{NH}_4)\text{ClO}_4$, KClO_4 , RbClO_4 , CsClO_4 are isomorphous. $\text{LiClO}_4 \cdot 3\text{H}_2\text{O}$ and $\text{LiMnO}_4 \cdot 3\text{H}_2\text{O}$ form mixed crystals; $\text{NaClO}_4 \cdot 3\text{H}_2\text{O}$ and $\text{NaMnO}_4 \cdot 3\text{H}_2\text{O}$ were too deliquescent for examination. AgClO_4 crystals were coloured by an unstable rhombic modification of AgMnO_4 ; the mixed crystals are strongly pleochroic, changing from blue-green to ruby-red with a rotating nicol. Periodates were not thoroughly examined. The author made several attempts to obtain perbromates, but failed.

Mixed crystals containing potassium manganate keep their blue-green colour for weeks. Ammonium salts cannot be investigated along with manganates, as they at once change the green colour to blood-red. When potassium salts are being studied, the addition of caustic potash produces very sharply-defined crystals.

K_2SO_4 , $(\text{NH}_4)_2\text{SO}_4$, Rb_2SO_4 , Cs_2SO_4 , Ti_2SO_4 , K_2SeO_4 , Rb_2SeO_4 , Cs_2SeO_4 , Ti_2SeO_4 , K_2CrO_4 , Rb_2CrO_4 , Cs_2CrO_4 , K_2MnO_4 , Rb_2MnO_4 , Cs_2MnO_4 are all isomorphous, forming rhombic (pseudo-hexagonal) prisms and pyramids. $(\text{NH}_4)_2\text{SeO}_4$ forms monoclinic plates. $(\text{NH}_4)_2\text{CrO}_4$ and Ti_2CrO_4 are very slightly soluble; the former has probably an isomorphous relationship with K_2CrO_4 . Na_2SO_4 , Ag_2SO_4 , Na_2SeO_4 , Ag_2SeO_4 are isomorphous,—rhombic pyramids, strongly birefringent. Ag_2CrO_4 , Na_2CrO_4 , and Na_2MnO_4 are probably isomorphous. So are the anhydrous sulphate, chromate, and selenate of lithium; the manganate does not exist. Manganese dioxide is not attacked by fused lithium carbonate.

The double salts in the above groups were also studied to some extent. KLiSO_4 and KLiSeO_4 are not isomorphous, but morphotropic.

The author succeeded in showing that K_2WO_4 and K_2MoO_4 are isomorphous with K_2MnO_4 . Between sulphates and selenates there is mostly direct isomorphism; between sulphates and chromates isodimorphism often occurs, and between sulphates and molybdates or tungstates it is the rule. K_2UO_4 could not be prepared.

The author failed to prepare an anhydrous salt, K_2TeO_4 isomorphous with K_2SO_4 , &c. The only examples of isomorphism between tellurium and sulphur being in the tellurides and sulphides of silver and lead, he is inclined to assert that the two elements are not isomorphous, and would suggest placing tellurium (at. wt. = 128) in the eighth periodic group along with ruthenium and osmium, to which it exhibits certain analogies.

J. W.

Vacuum Desiccator arranged for Evaporation at any desired Temperature. By J. W. BRÜHL (*Ber.*, 24, 2457—2459).—Feeling the want of an apparatus in which a dissolved substance, especially one prone to decompose in solution and at higher temperatures, can be rapidly freed from the solvent and crystallised, the author has devised a vacuum desiccator in which evaporation can be carried on at any desired temperature. The plate of an air-pump is provided with two holes in addition to the one through which the bell-jar is exhausted. Through these holes pass two brass tubes about 12 cm. long and 1 cm. in diameter, which stand about 7—8 cm. above the plate, and are fixed airtight by means of caoutchouc washers and brass nuts.

The tubes are soldered above the plate to a circular box about 15 cm. in diameter and 1 cm. high, made of copper plate 2 mm. thick, and provided with internal supports to prevent bulging when the bell-jar is exhausted. The circular box serves to support the vessel containing the solution to be evaporated, and is heated by steam, hot air, or other vapours led through the brass tubes.

W. P. W.

Inorganic Chemistry.

Slow Combustion of Gaseous Mixtures. By A. KNAISE and V. MEYER (*Annalen*, 264, 85—116).—When moist electrolytic gas is heated at 305° in glass vessels over mercury for 1—2 weeks, combination takes place between the oxygen and hydrogen, and only a very small volume of gas remains; in absence of mercury, combination takes place only very slowly at 305°, and at 448° the diminution of volume is very small, but at 518° a considerable quantity of water is produced. The thin glass bulbs provided with lateral capillary tubes, which were employed in most of these experiments, can be sealed without danger of explosion if a little air is permitted to enter the point of the capillary, but even traces of air or other impurities have such a great influence on the reaction that the results are very variable, and, consequently, the relation between the time and the amount of combination could not be determined.

The temperature of explosion of electrolytic gas, and that of a mixture of oxygen and carbonic oxide in theoretical quantities, lies between 518° and 606° when thin, sealed glass vessels are employed.

A number of experiments were made in order to try and determine the rate of combination of oxygen and hydrogen under certain conditions. For this purpose, electrolytic gas, generated by the electrolysis of hot water, and consequently free from ozone and hydrogen peroxide, was passed for many days through a series of bulbs, fused together by means of very small capillary tubes. The apparatus was very carefully cleaned, the gas was dried with concentrated sulphuric acid, and india-rubber, cork, and all organic substances were carefully excluded; in some of the experiments, the bulbs were heated at a faintly, dull-red heat, and the pure electrolytic gas passed for eight days. The bulbs were then sealed before the blowpipe, and heated in the vapour of sulphur or of phosphorus pentasulphide (b. p. 518°) under the same conditions. In spite of all precautions, the results of the experiments were very variable, and no relation between time and amount of combination could be determined; it would seem, therefore, that the glass surface, even when most carefully cleaned, has a modifying but variable action on the electrolytic gas, and that this action is sufficiently different, even in the case of two exactly similar bulbs, to cause great irregularities in the experiments.

Bulbs containing pure dry, or moist, electrolytic gas can be sealed

without danger when the capillary tube is sufficiently fine ($\frac{1}{4}$ to $\frac{1}{8}$ mm. in internal and $\frac{1}{4}$ mm. in external diameter); in the case of the moist gas, a small flame can be observed running along the capillary, when the tube is being sealed, but it goes out before reaching the bulb; no flame is seen in the case of the dry gas, the volume of which undergoes no appreciable diminution by combination taking place.

The electrolytic gas employed in the above experiments was found on careful examination to be free from any appreciable quantity of air.

F. S. K.

Atomic Weight of Oxygen. By E. H. KEISER (*Amer. Chem. J.*, 13, 253–256).—The method described involves the complete synthesis of water, that is, the determination of the weight of water resulting from the combination of known weights of hydrogen and oxygen. Pure hydrogen is passed into a weighed exhausted vessel containing spongy palladium, the increase in weight after a second exhaustion giving the amount occluded. An excess of pure oxygen is then admitted, and combination takes place at the ordinary temperature under the influence of the palladium. The whole amount of oxygen having been determined by a third weighing, the excess, together with the synthesised water, is exhausted from the vessel, the water being collected in a phosphorus pentoxide tube; the decrease in weight of the vessel and tube corresponds to the oxygen removed, whilst the increase in that of the tube gives the amount of water formed. Trial determinations have given good results.

The author replies to the criticism of Noyes (*J. Anal. Chem.*, 5, 36; *Ber.*, 24, 234).

JN. W.

Atomic Weight of Oxygen. By W. A. NOYES (*Amer. Chem. J.*, 13, 354–355; compare *Abstr.*, 1890, 1370; 1891, 523).—A rejoinder to the remarks of Keiser (preceding abstract).

JN. W.

Reaction between Hydrogen Arsenide and Silver Nitrate. By L. MARCHLEWSKI (*Ber.*, 24, 2269–2271).—The products of the action of hydrogen arsenide on a solution of silver nitrate, according to Laissaique (*Journ. Chem. Med.*, 16, 685), are free nitric acid, silver, and arsenious anhydride. In order to test the truth of this statement the author has determined the strength of nitric acid necessary to dissolve finely-divided silver. The nitric acid was freed from nitrous acid by a current of carbon dioxide. The finely-divided silver was then treated in the cold with the pure acid; the mixture filtered and the filtrate tested for silver nitrate and nitrite. The results show that 0.4 per cent. of nitric acid is sufficient to attack the silver, and that with a solution containing 0.7 per cent. a considerable quantity is dissolved. The author also shows that pure dilute nitric acid, when treated with decinormal arsenious acid, is converted into nitrous acid, and that nitric acid containing a trace of nitrous acid dissolves silver much more readily than the pure acid.

The above results show that the action of hydrogen arsenide on a solution of silver nitrate cannot take place as stated by Laissaique,

for the precipitated silver would be redissolved by the nitric and nitrous acids formed at the same time. E. C. R.

Action of Light on Silver Chloride. By R. HITTMACK (*Amer. Chem. J.*, 13, 273—277).—A continuation of previous work (Abstr., 1890, 213). Slips of microscopic cover glass coated with a thin layer of the chloride were exposed to direct sunlight for about four months, and weighed from time to time. The loss of chlorine was greater than in the former experiments, and varied from 0.0821 to 0.0929 gram per gram of silver chloride. Probably even then the decomposition was not complete. On digestion with dilute nitric acid, the product gave up a quantity of silver equivalent to the amount of chlorine liberated; hence it would seem that the action of light merely separates the chlorine from the silver. J. N. W.

Preparation of Crystalline Barium and Calcium Fluorides. By H. MOISSAN (*Bull. Soc. Chim.* [3], 5, 152).—Calcium chloride solution (10 per cent.) is added to a boiling solution of potassium fluoride (0.5 per cent.) in a platinum capsule, and the mixture is boiled for 30 minutes; the collected precipitate is washed, dried, and calcined; the microscopic crystals thus obtained are transparent and correspond with the formula CaF_2 . Microscopic crystals of barium fluoride are obtained when solutions of barium chloride (3.6 per cent.) and potassium fluoride (1 per cent.) are similarly treated.

T. G. N.

Reduction of Oxides by Magnesium. By C. WINKLER (*Ber.*, 24, 1966—1984).—In his last communication the author was inclined to regard lanthanum as a member of the fourth group in the periodic system, since it forms a hydride and thus resembles the majority of the elements in that group (this vol., p. 802), but this view is now abandoned in consequence of Brauner's determination of the atomic weight of the element (this vol., p. 881). The present paper deals with the preparation of hydrides of elements in the second and third groups of the periodic system by reduction of their oxides by magnesium in an atmosphere of hydrogen. The method is inapplicable in the case of lithium, sodium, potassium, and rubidium hydroxides or carbonates, since any hydrides formed would be decomposed at the temperature of the reaction—the known hydrides of sodium and potassium being dissociated at moderately high temperatures. Reduction of caesium hydroxide and carbonate gave no evidence of the formation of a hydride.

Beryllium.—When beryllium oxide (1 mol. prop.) was heated with magnesium (1 at. prop.) in a current of hydrogen for four hours at a red heat, a slow absorption of the gas took place, and the product on analysis had the composition:—

BeH.	BeO.	MgO.	Mg.	Total.
3.33	45.40	45.03	6.24	100.00

indicating that not more than 14.96 per cent. of the beryllium employed had been converted into hydride. The product had an

unpleasant odour, and on treatment with warm water gave off hydrogen slowly. When heated in a current of oxygen, a distinct hydrogen flame and the formation of water were observed.

Magnesium.—When magnesium oxide was reduced under the conditions just described, a slow absorption of hydrogen took place with the formation of a product of the composition:—

MgH.	MgO.	Mg.	Total.
3.54	82.06	14.40	100.00

indicating that not more than 6.42 per cent. of the magnesium had been converted into hydride. The product had an unpleasant odour, evolved hydrogen slowly on treatment with water, and when heated in a current of oxygen gave evidence of the formation of water.

Calcium.—In the case of lime, the absorption of hydrogen was much more rapid and was complete at the end of four hours. The product had the composition:—

CaH.	CaO.	MgO.	Mg.	Total.
33.14	28.31	37.66	0.89	100.00

showing that 61.52 per cent. of the calcium employed had been converted into hydride. On exposure to the air it swelled up and fell to powder, and on treatment with water evolved hydrogen very rapidly. When heated, it burned with a slightly luminous flame in air, and with slight explosion in oxygen producing water in noteworthy quantities.

Strontium.—On reduction under the above conditions, strontium oxide rapidly absorbed hydrogen during two hours with the formation of a product of the composition:—

SrH.	SrO.	MgO.	Mg.	Total.
66.23	4.17	28.93	0.77	100.00

indicating that 94.91 per cent. of the strontium employed had been converted into hydride. On exposure to the air it was readily oxidised, hydrogen being evolved and strontium hydroxide formed, and on treatment with water hydrogen was rapidly given off. It burned either in air or oxygen with a hydrogen flame, a slight explosion attending the combustion in oxygen.

Barium.—The baryta employed had the composition:—

BaO.	Ba(OH) ₂ .	BaCO ₃ .	Al ₂ O ₃ .	SiO ₂ .	Total.
71.26	18.13	7.34	1.87	1.40	100.00

and on reduction under the above conditions absorbed hydrogen very rapidly during two hours, with the formation of a product which gave the following numbers on analysis:—

BaH.	BaO.	MgO.	Al ₂ O ₃ .	SiO ₂ .	O ₂ (excess).	Total.
70.33	4.27	20.99	1.66	0.97	1.73	100.00

corresponding with the conversion of 94.66 per cent. of the barium

into hydride. In properties the compound closely resembled the strontium hydride.

The author concludes this portion of his paper with speculations as to the composition of the atmosphere of the sun and fixed stars.

In the third group, boric anhydride and alumina were submitted to reduction in hydrogen with negative results, but yttrium was found to resemble lanthanum in forming a hydride, although the conversion was not so complete. When yttrium oxide was reduced under the conditions already given, absorption of hydrogen took place rapidly and was complete at the end of an hour. The product had the composition:—

Y_2H_3	Y_2O_3	MgO	Mg	Total.
12.88	72.56	10.15	4.41	100.00

indicating that 18.44 per cent. of the yttrium employed had been converted into hydride. On treatment with boiling water, it gave off a very small quantity of hydrogen, and when heated in oxygen it burned with a feebly luminous flame.

W. P. W.

Action of Ammonia on Zinc Chloride. By W. KWA-NIK (*Arch. Pharm.*, 229, 310—316).—The action of ammonia on zinc chloride has frequently been studied, but always in the presence of water. An alcoholic solution of zinc chloride treated with an alcoholic solution of ammonia, or with gaseous ammonia, until the odour of ammonia just begins to persist, yields a precipitate which does not dissolve on further addition of ammonia. The product is a light, pure white, odourless, crystalline powder, $ZnCl_2 \cdot 2NH_3$. The powder is insoluble in water and alcohol, easily soluble in dilute acids, aqueous ammonia, soda, and potash; in the two latter with evolution of ammonia. Heat is developed on dissolving it in acid. The compound is stable in the air. By distillation in a hard-glass retort a transparent, glass-like, hygroscopic compound, $ZnCl_2 \cdot NH_3$, was obtained.

J. T.

Basic Zinc Sulphite. By K. SEUBERT (*Arch. Pharm.*, 229, 316—328).—On mixing equal volumes of boiling normal solutions of zinc sulphate and sodium sulphite (28.7 grams $ZnSO_4 + 7H_2O$ and 31.5 grams of 40 per cent. sodium sulphite each dissolved in 100 c.c.), a precipitate of basic zinc sulphite, $8ZnSO_4 \cdot 7Zn(OH)_2 + 7H_2O$, appears almost immediately. Decinormal solutions mixed at a moderate temperature, dilute zinc sulphite solution heated alone, or concentrated zinc sulphite solution largely diluted with water, yields a very voluminous precipitate of the basic zinc sulphite, $5ZnSO_4 \cdot 8Zn(OH)_2$. The same basic salt is produced by boiling the normal or the monobasic sulphite for some time in water.

J. T.

Nitrite of Potassium, Lead, and Copper. By VAN LESSEN (*Rec. Trav. Chim.*, 10, 13—14).—On adding a mixture of copper nitrite and lead acetate solution to a large quantity of solution of potassium nitrite, and then adding acetic acid, a crystalline precipitate is obtained, which under the microscope is seen to consist of black,

cubic crystals. When washed with alcohol and air-dried, the crystals are of a shining dark-green, they give a brown streak, and have a sp. gr of 3.345 at 15°. The aqueous solution is yellowish-green, and yields, by free evaporation in air, thin, yellowish-brown, hexagonal plates, which change again into the blackish cubical crystals described, on the addition of a concentrated aqueous solution of potassium nitrite and a little acetic acid.

The salt is anhydrous, may be dried without decomposition at 110—120°, and has the formula $\text{PbCuK}_3(\text{NO}_3)_8$. Hence the salt is much simpler than the corresponding cobalt compound analysed by Stromeyer. W. T.

Ternary Alloys. Part III. By C. R. A. WRIGHT and C. THOMPSON (*Proc. Roy. Soc.*, 49, 156—173; compare Abstr., 1890, 336; and this vol., p. 267).—When approximately equal weights of bismuth and zinc were melted together, and then poured, after stirring up, into red-hot, narrow, clay test-tubes, in which they were heated for over eight hours, the mixture separated into two layers, a solution of bismuth in zinc and a solution of zinc in bismuth. At 650° (approximately) the solutions contained 14.28 and 97.64 per cent. of zinc respectively; at 750°, 15.18 and 97.53 per cent.

When tin was added to the mixture in varying proportions, the extent of mixing of the bismuth and zinc was increased, the tin distributing itself between the two layers. Tables and curves are given to illustrate the composition of the mixtures obtained with varying proportions of tin and at different temperatures. Notable differences appear when the curves are compared with those previously obtained with zinc, lead, and tin. The solubility of zinc in bismuth is always greater than in lead, whether tin be absent, or present to a given extent, in each case.

Similar experiments were conducted with bismuth, zinc, and silver. The mixtures show the same behaviour as analogous mixtures of lead, zinc, and silver, leading to the conclusion that two definite compounds of zinc and silver are formed under appropriate conditions. These compounds correspond with the formulæ Ag_2Zn , and Ag_3Zn_2 . The first mixes more freely with lead (or bismuth) than either pure zinc or the second compound, but is somewhat unstable on prolonged heating. The compound Ag_3Zn_2 is characterised by the peculiar red colour which is assumed by a recently cut surface on exposure to the air, and by being less soluble in lead (or bismuth), relatively to the zinc present, than either pure zinc or a mixture of zinc and silver in any other proportion. J. W.

Ternary Alloys. Part IV. Method of Graphic Representation. By C. R. A. WRIGHT, C. THOMPSON, and J. T. LEON (*Proc. Roy. Soc.*, 49, 174—193).—At the suggestion of Sir G. G. Stokes the authors have adopted a triangular mode of graphic representation analogous to that used by Maxwell for the composition of colours.

Stokes also drew their attention to the circumstance that the equilibrium between the two conjugate mixtures (see preceding abstract) should only depend on their composition at any given temperature,

and not on their quantity. This conclusion was not in accordance with results previously obtained with alloys. To test it, the authors instituted experiments with mixtures of chloroform, water, and acetic acid, and found it verified (compare Duclaux, *Ann. Chim. Phys.* [5], 7, 264, and Nernst, this vol., p. 1148). The probable reason that it is not exactly true for alloys, is that there is in this case incomplete intermixture, and also incomplete separation. J. W.

Decomposition of Potassium Manganate by Ammonium Salts.

By J. W. RETGERS (*Rec. Trav. Chim.*, 10, 1—3).—The green colour of a solution of potassium manganate is changed by any acid to the red colour of the permanganate, the reaction proceeding according to the equation, $3K_2MnO_4 + 2H_2SO_4 = 2KMnO_4 + 2K_2SO_4 + MnO_2 + 2H_2O$. The same change takes place in presence of water only if the latter be in large excess, $3K_2MnO_4 + 2H_2O = 2KMnO_4 + 4KOH + MnO_2$. A solution of manganate, to which has been added a solution of ammonium sulphate, containing a large quantity of free ammonia, undergoes the same change, in fact, if a small crystal of ammonium sulphate be plunged into an ammoniacal solution of potassium manganate, it rapidly becomes surrounded by a clear red zone, just as if a drop of acid had been introduced into the green solution. Any other salt of ammonium produces the same effect, but other neutral salts, such as sodium sulphate, do not excite any change. The decomposition by ammonium salts may be represented by the equation, $3K_2MnO_4 + 4NH_4Cl = 2KMnO_4 + MnO_2 + 4KCl + 4NH_3 + 2H_2O$. As solutions of potassium manganate are only stable in presence of a certain excess of potash or soda, the reaction is probably due to the acid in the ammonium salt, combining with the base of the manganate, giving ammonia and manganic acid, which appears not to form any ammonium salt, and hence at once decomposes; the decomposition seems to be quite analogous to that caused by ammonium salts with silicates of potassium or sodium. It is impossible to obtain isomorphous mixed crystals of ammonium sulphate and potassium manganate, whereas with potassium sulphate in various proportions they are readily formed. W. T.

Complex Inorganic Acids: Phosphotungstic Acids. By F. KEHRMANN and M. FREINKEL (*Ber.*, 24, 2326—2335).—*Phosphododecatungstic acid*, $24WO_3 \cdot P_2O_5 \cdot 3H_2O + xH_2O$, is prepared by mixing a hot saturated solution of sodium tungstate with sodium phosphate or phosphoric acid in the proportion of 12 mols. of tungstate to at least 1 mol. of phosphoric acid. To the mixture which becomes strongly alkaline hydrochloric acid is gradually added. Hydrated tungstic acid is precipitated, but again dissolves, and hydrochloric acid is then added until the normal sodium salt of the complex acid begins to separate. On cooling, the salt crystallises out, and is purified by recrystallisation from water, in which it is easily soluble. The sodium salt crystallises from a hot, saturated aqueous solution in large, transparent, colourless octahedra, which become opaque on exposure to air, and if allowed to remain in the solution, redissolve, and then separate in rhombohedral tablets, which are stable in air. The dry salt has the composition $24WO_3 \cdot P_2O_5 \cdot 3Na_2O$. The

barium salt is obtained in regular octahedra on adding a saturated solution of barium chloride to a solution of the sodium salt. It is somewhat less soluble than the sodium salt, and becomes opaque on exposure to the air. The dry salt has the composition $24\text{WO}_3, \text{P}_2\text{O}_5, 3\text{BaO}$. Both these salts are colourless when pure. The free acid is obtained by precipitating a concentrated solution of the barium salt with dilute sulphuric acid, and on evaporating the filtrate, separates in large cubic crystals, which are easily soluble in water, and are stable to air. The acid is completely converted into the barium salt on adding a concentrated solution of barium chloride. On the addition of silver nitrate, the silver salt is obtained as a sparingly soluble, white powder. When potassium or ammonium salts are added to a solution of the acid or its salts in presence of mineral acids, a white powdery precipitate of the normal potassium or ammonium salt is formed; this is almost insoluble in water. The above acid completely corresponds to the analogous molybdenum compound, $24\text{MoO}_3, \text{P}_2\text{O}_5, 3\text{H}_2\text{O}$, but is decomposed by alkalis in a different way.

The above insoluble potassium and ammonium salts dissolve easily in aqueous alkalis, and in alkaline carbonates with evolution of carbonic anhydride, yielding salts of an acid of the composition $22\text{WO}_3, \text{P}_2\text{O}_5, 7\text{H}_2\text{O}$. The barium salt, $22\text{WO}_3, \text{P}_2\text{O}_5, 7\text{BaO} + 53\text{H}_2\text{O}$, is most easily obtained by gradually adding powdered barium carbonate to a boiling concentrated solution of the salt $24\text{WO}_3, \text{P}_2\text{O}_5, 3\text{BaO}$ as long as effervescence takes place. On cooling, it crystallises in lustrous octahedra, and is purified by recrystallisation from water containing a few drops of acetic acid. The potassium salt, obtained in a similar way to the barium salt, crystallises in large, colourless quadratic octahedra, and is easily soluble in water. The ammonium salt is very soluble. The solutions of these salts are neutral to litmus. The free acid could not be obtained. When a concentrated aqueous solution of the salt $22\text{WO}_3, \text{P}_2\text{O}_5, 7\text{K}_2\text{O}$ is decomposed by hydrochloric acid, a precipitate of the salt $24\text{WO}_3, \text{P}_2\text{O}_5, 3\text{K}_2\text{O}$ is obtained, and the mother liquors on the addition of potassium chloride deposit a salt, which crystallises in six-sided scales, and is very soluble in water. The barium salt, $22\text{WO}_3, \text{P}_2\text{O}_5, 7\text{BaO}$, is decomposed in the same way.

The authors reserve the further discussion of this interesting reaction for a future communication. E. C. R.

Hydrate of Potassium Stannichloride. By J. MOREL (*Chem. Centr.*, 1891, i, 492; from *Bull. Soc. franc. Min.*, 13, 339—341).—If a solution of potassium stannichloride be allowed to crystallise at a temperature below 25° , a new hydrate is obtained which crystallises in the prismatic system, and not in the regular octahedra as the salt is usually obtained. The faces observed are 110, 101, 010; axial ratio: $a : b : c = 0.6843 : 1 : 0.7588$. The analysis gave figures agreeing moderately well with the formula $\text{K}_2\text{SnCl}_6 + \text{H}_2\text{O}$.

J. W. L.

Sublimation of Antimony Trichloride. By C. HENSGEN (*Rec. Trav. Chim.*, 9, 303—304).—A quantity of antimony trichloride is placed in a distillation flask provided with a side tube, and of about

1½ to 2 litres capacity; the flask is placed on a water-bath with the neck inclined downwards, and fitted by means of a good cork into a smaller flask serving as a receiver; the side tube passes vertically upwards, and is then bent and fitted with a drying tube. The water-bath is of such a size that the part of the flask containing liquid antimony trichloride is completely immersed in water-vapour when the sublimation is going on. The upper part of the flask is cooled by cold water dropped on to a piece of filter paper. When a sufficient quantity of the long, lanceolate crystals of the sublimate has collected on the cooled portion of the flask, the whole is allowed to cool slowly; and as soon as the trichloride on the bottom of the flask has solidified, the sublimate is shaken carefully into the receiver. The operation is then repeated until the whole of the charge has been sublimed. In this way 200 grams of sublimed trichloride can be readily prepared in a day.

W. T.

Metallurgy of Bismuth. By E. MATTHEY (*Proc. Roy. Soc.*, 49, 78—79).—The small proportion of copper frequently contained in commercial bismuth has hitherto been eliminated by a tedious wet process. The author finds that the copper may be completely removed by fusing the bismuth with successive small quantities of sodium monosulphide, and skimming off the scoria, which contains all the copper. 105 kilos. of commercial bismuth yielded 94 kilos. of bismuth free from copper, and 11 kilos. of skimmings. The temperature required is comparatively low, so that little loss by volatilisation is sustained.

J. W.

Bismuth Bromide. By V. MEYER (*Annalen*, 264, 122—125).—Bismuth bromide boils at 453°, as the average of three experiments made with the air thermometer devised by the author and Goldschmidt: the boiling point of bismuth chloride determined with a mercury thermometer was found to be 435—441° (uncorr.).

F. S. K.

Certain Properties of Metals considered in Relation to the Periodic Law. By W. C. ROBERTS-AUSTEN (*Proc. Roy. Soc.*, 49, 347—356).—In a previous paper (*Phil. Trans.*, 1888, A, 339), the effect of about 0·2 per cent. of impurities on the mechanical properties of gold was examined, the results showing that metals which diminish its tenacity and extensibility have high atomic volumes, while those which increase these properties have either the same atomic volume as gold or a lower one. The behaviour of aluminium was exceptional. In the present paper, the mode of cooling of pure molten gold and of gold containing aluminium is studied. A thermoelectric couple of platinum and platinum containing 10 per cent. of rhodium was used, in conjunction with a mirror galvanometer and a photographic recording apparatus, to give a curve for the rate of cooling. Pure gold solidifies sharply at 1045°; the curve for gold containing lead is somewhat similar, but that for gold containing 0·47 per cent. of aluminium scarcely shows a distinct freezing point. The atomic depression of the freezing point for aluminium seems to be abnormally small. Silver present in gold, up to as much as 4 per cent., does

not lower the freezing point. Aluminium combines with molten gold with great evolution of heat. J. W.

Colloïdal Sulphides of Gold. By E. A. SCHNEIDER (*Ber.*, 24, 2241—2247).—Colloïdal aurous sulphide, Au_2S , can be prepared by saturating a solution of aurous cyanide in potassium cyanide with hydrogen sulphide, warming carefully with hydrochloric acid until a brown turbidity is produced, and then submitting the whole to dialysis; there remains in the dialyser a deep-brown, colloïdal solution of aurous sulphide which can be separated from the undissolved portions by decantation and filtration. The most concentrated solutions that can be obtained in this way contain 1.74 grams of the sulphide per litre. When the colloïdal solution is heated at 200—230°, sulphuric acid is formed, and gold is deposited; when the solution is frozen and melted again, the aurous sulphide is precipitated. On adding a colloïdal solution of ferric hydrate to the colloïdal solution of aurous sulphide, no reaction takes place even on warming.

Colloïdal auroauric sulphide, Au_2S_2 , can be easily prepared by boiling the freshly precipitated sulphide with potassium cyanide until about one half of the sulphide is dissolved, and then submitting the remainder to dialysis; the dark-brown liquid obtained in this way is separated from the undissolved sulphide by decantation and filtration. The most concentrated solutions that can be obtained contain 0.8 gram of the sulphide per litre; when the solution is frozen, it behaves like the solution of aurous sulphide, but it undergoes no change when heated at 240°.

When auroauric sulphide, either the colloïdal or the ordinary modification, is warmed with a solution of auric chloride, the whole of the gold is deposited, with formation of hydrochloric acid and sulphuric acid; it is probable that the metallic gold found in nature has been formed in a similar manner by the action of hydrogen sulphide on solutions of auric chloride. F. S. K.

Derivatives of Carbonyl Chloroplatinite. By F. MYLIUS and F. FOERSTER (*Ber.*, 24, 2424—2443).—Carbonyl chloroplatinite (Schützenberger, *Ann. Chim. Phys.* [4], 21, 350; Pullinger, *Trans.*, 1891, 598) has a distinctly basic character, and dissolves in excess of hydrochloric acid with a lemon-yellow colour, due to the formation of a very soluble and unstable substance, having probably the composition $CoPtCl_5.HCl$. The solution of this hydrochloride is readily prepared by stirring the sublimate obtained in Schützenberger's reaction (*loc. cit.*) with concentrated hydrochloric acid for some time, since the dicarbonyl chloroplatinite which is also present is decomposed by the acid into carbonyl chloroplatinite, with the evolution of carbonic oxide containing a small proportion of carbonic anhydride. When rapidly evaporated to dryness in a vacuum, the solution leaves a crystallised residue of carbonyl chloroplatinite; on a water-bath, however, complete decomposition ensues, with the separation of metallic platinum. So long as the acid is concentrated, the solution of the chloroplatinite is stable; on dilution with water, no alteration seems to be produced for a short time, but suddenly the colour changes

to brownish-black, and platinum separates in flocks, owing to an almost complete decomposition of the chloroplatinite into platinum, carbonic anhydride, and hydrochloric acid, as represented in Schützenberger's equation $\text{COPtCl}_2 + \text{H}_2\text{O} = \text{CO}_2 + \text{Pt} + 2\text{HCl}$, a very small portion only of the substance remaining unaltered in the acid solution. Concentration and temperature also have a marked influence on the stability of the solution, rise of temperature bringing about a similar decomposition. The separated platinum contains a trace of chlorine, but in contact actions and other respects resembles platinum black (cf., however, Pullinger, *loc. cit.*). The hydrochloric acid solution of the chloroplatinite is a powerful reducing agent, reducing silver, gold, and mercury salts from their solutions. On the addition of stannous chloride, the solution becomes yellowish-red, and on treatment with concentrated sulphuric acid and a trace of furfuraldehyde gives a purplish-red coloration.

Carbonyl chloroplatinite not only combines with hydrogen chloride, but also forms a series of yellow, crystalline, double salts with soluble metallic chlorides; these, however, are difficult of isolation, on account of their great solubility, and the readiness with which they are decomposed by water. Double salts of the general formula $\text{COPtCl}_2, \text{RHCl}$ are obtained by combination with the hydrochlorides of amines, and these, when not too soluble, serve as an additional means of characterising the bases.

Amylamine carbonyl chloroplatinite hydrochloride,

crystallises from dilute hydrochloric acid in golden-yellow scales, melts at 184° , and dissolves readily in alcohol and ethyl acetate, less readily in ether, benzene, and chloroform, but is decomposed by water, with the production of a black colour.

Aniline carbonyl chloroplatinite hydrochloride, $\text{COPtCl}_2, \text{C}_6\text{H}_7\text{NHCl}$, crystallises in lustrous, golden scales, melts, when rapidly heated, at 210 — 212° with decomposition and blackening, and is sparingly soluble in the ordinary solvents, with the exception of alcohol and ethyl acetate.

Pyridine carbonyl chloroplatinite hydrochloride, $\text{COPtCl}_2, \text{C}_5\text{H}_5\text{NHCl}$, forms strongly lustrous, transparent, golden-yellow prisms, and can be crystallised from dilute hydrochloric acid, but is slowly decomposed by water.

Quinoline carbonyl chloroplatinite hydrochloride, $\text{COPtCl}_2, \text{C}_8\text{H}_7\text{NHCl}$, crystallises from hydrochloric acid in bright-yellow needles, melts at 166° , and dissolves readily in alcohol and ethyl acetate. These compounds, when heated frequently, give a sublimate containing platinum, and it is possible that the loss of platinum so often noticed in analyses of platinum chlorides is to be referred to the formation of compounds of this character, since it is conceivable that reactions may ensue between platinum, carbonic oxide, and chlorine during the combustion.

The determination of the percentage of carbonic oxide in these compounds by elementary analysis presents no difficulties, but as they evolve the gas on treatment with potassium cyanide, it is also possible

to estimate the percentage volumetrically. The chief reaction is represented by the equation $\text{COPtCl}_2 + \text{KCN} = \text{K}_2\text{Pt}(\text{CN})_4 + 2\text{KCl} + \text{CO}$, but the gas contains in addition from 3—8 per cent. of hydrogen, and a small proportion of carbonic anhydride. These in all probability owe their presence to two subsidiary reactions, one between the chloroplatinite and the alkaline solution of the cyanide with the production of carbonic anhydride and platinum, and a second between the platinum so obtained and the cyanide with the formation of hydrogen, in accordance with the equation $\text{Pt} + 4\text{KCN} + 2\text{H}_2\text{O} = \text{K}_2\text{Pt}(\text{CN})_4 + 2\text{KHO} + \text{H}_2$, whence it follows that the amount of carbonic oxide in the compound is given by the sum of the volumes of carbonic oxide and hydrogen evolved. The analysis is conducted in an atmosphere of carbonic anhydride, and the liberated gas collected in an azotometer filled with caustic potash solution.

Carbonyl bromoplatinite (see Pullinger, *loc. cit.*) is formed when the hydrochloric acid solution of the chloroplatinite is evaporated on a water-bath in a current of hydrogen bromide, and can be freed from traces of platinum and platinous bromide by crystallisation from benzene. It crystallises in orange-red needles, melts at 181—182° without appreciable decomposition, and dissolves readily in benzene and hydrobromic acid, but is immediately decomposed by water into platinum, carbonic anhydride, and hydrogen bromide. It yields a series of crystalline double salts with metallic bromides and with the hydrobromides of amines, and of these *pyridine carbonyl bromoplatinite hydrobromide*, $\text{COPtBr}_2 \cdot \text{C}_5\text{H}_5\text{N} \cdot \text{HBr}$, crystallises from hydrobromic acid in yellow needles, which melt at 203—205° without decomposition.

Carbonyl iodoplatinite, COPtI_2 , is obtained by adding dilute hydriodic acid to the hydrochloric acid solution of carbonyl chloroplatinite, dissolving the resulting brick-red, amorphous precipitate in hydriodic acid, evaporating to dryness on a water-bath, and crystallising the residue from benzene. It is simpler, however, to evaporate the mixture of chloroplatinites obtained in Schützenberger's reaction with concentrated hydriodic acid, and purify the residue from platinum and platinous iodide by crystallisation from benzene. It forms red, rod-like crystals, which exhibit a violet shimmer, and resemble chromic anhydride in colour. It melts at 140—150°, decomposes with the liberation of iodine at a slightly higher temperature, and dissolves readily in benzene and ether. The alcoholic solution becomes turbid on warming, owing to the separation of platinous iodide, and later of platinum. Water decomposes it somewhat slowly, with the formation of a dark-coloured precipitate containing iodine; alkalis set platinum free, and potassium cyanide reacts with it, liberating carbonic oxide. Carbonyl iodoplatinite forms double salts with metallic iodides, and of these the compound with potassium iodide, $\text{COPtI}_2 \cdot \text{KI}$, crystallises in yellowish-brown scales, melts at 150—180° with decomposition, and is readily soluble in water, alcohol, and ether, but insoluble in benzene and chloroform.

Trimethylamine carbonyl iodoplatinite hydriodide, $\text{COPtI}_2 \cdot \text{NMe}_3 \cdot \text{HI}$, crystallises in oblique-angled, orange-yellow tables, melts at 95° without decomposition, and is readily soluble in water, by which, however, it is slowly decomposed.

When a solution of carbonyl chloroplatinite in concentrated hydrochloric acid is gradually treated with a 10—20 per cent. solution of potassium thiocyanate until the precipitate first formed is redissolved, a double salt of the composition $\text{COPt}(\text{CNS})_2 \cdot \text{KCNS}$, separates in the cold, in small, yellow needles. This is readily soluble in alcohol, and the solution, on warming with water, becomes red, gas being evolved, a like result being obtained when the salt is dissolved in aqueous potassium cyanide or thiocyanic acid. The double salt is also readily prepared in the crystalline state by adding carbonyl iodoplatinite to an aqueous solution of potassium thiocyanate; the crystals dissolve when the mixture is warmed, and on evaporation platinum thiocyanate and carbonic oxide are obtained, owing to a decomposition of the carbonyl thiocyanoplatinite present in the double salt.

Carbonyl thioplatinite, COPtS , is formed as a brown precipitate, resembling platinum sulphide in appearance, when the hydrochloric acid solution of the chloroplatinite is treated with hydrogen sulphide. The compound has little stability, decomposes when placed in a vacuum, burns with a slight explosion when heated at 300—400°, with the production of platinum, sulphur, carbonic anhydride, and sulphurous anhydride, and is insoluble in the ordinary solvents. Potassium cyanide reacts with it, liberating carbonic oxide, and nitric acid decomposes it, with the evolution of carbonic anhydride and nitrous fumes. Under no conditions could carbon oxysulphide be obtained from it, heating at 100—200° in a current of hydrogen leading only to the liberation of carbonic oxide and hydrogen sulphide. On dissolution in ammonium sulphide, it yields a very unstable, acidic compound, which can also be obtained by carefully adding carbonyl iodoplatinite to a solution of sodium sulphide, and to which the formula H_2COPtS_2 is provisionally assigned.

Schützenberger failed to prepare an oxygen derivative of carbonyl platinum by the action of alkalis on the chloroplatinite. A compound of this nature, having possibly the composition COPtO , is, however, obtained when the hydrochloric acid solution of the chloroplatinite is stirred into a solution of sodium or ammonium acetate acidified with acetic acid; the mixture at first becomes violet in colour, and then deposits a bluish-black, flocculent precipitate, which, after washing with dilute acetic acid, and subsequently with water, is free from chlorine, and gives a rapid evolution of carbonic oxide on treatment with potassium cyanide. The precipitate dissolves in concentrated hydrochloric acid forming a yellow solution of carbonyl chloroplatinite, reacts with caustic alkalis or baryta, in accordance with the equation $\text{COPtO} + 2\text{NaHO} = \text{Pt} + \text{Na}_2\text{CO}_3 + \text{H}_2\text{O}$, and, though stable in a vacuum, or even on gently warming, decomposes with slight explosion at 300—400° into platinum and carbonic anhydride.

So far, all attempts to isolate carbonyl platinum (COPt), have been unsuccessful; the authors, however, intimate their intention to undertake further experiments with a view to its isolation.

W. P. W.

Iridio-ammonium Compounds. By W. PALMÉR (*Ber.*, 24, 2090—2097).—In addition to the iridium pentamine compounds

already described by the author (this vol., p. 402), derivatives corresponding to the "roseo-" cobaltic compounds have also been prepared. As these are almost colourless, the prefix "roseo-" is unsuitable, and the author therefore proposes for them the term *aquopentamine* compounds, on account of the fact that they differ from the pentamine compounds by containing an additional molecule of water.

In order to prepare the aquopentamine salts, a method is employed similar to that given by Jørgensen for the corresponding rhodium salts. Silver oxide alone is insufficient, and even when caustic potash is employed, the solution must be boiled for several hours.

Iridium aquopentamine chloride, $\text{Ir}(\text{NH}_3)_5\text{OH}_2\text{Cl}$, is obtained by mixing 5 grams of the pentamine trichloride with $1\frac{1}{2}$ times the calculated quantity of potash, and 50 c.c. of water, and boiling for five hours. The slight precipitate is filtered off, the filtrate partially frozen, and mixed with 30 c.c. of fuming hydrochloric acid. The precipitate thus produced is washed with cold hydrochloric acid (22 per cent.), and subsequently with alcohol, redissolved in water, and again precipitated with concentrated hydrochloric acid. It separates from a concentrated solution in crystalline aggregates resembling those of ammonium chloride, has a sp. gr. of 2.494 at 15°, and on heating at 100° loses water forming iridiopentamine chloride. It dissolves in 1.2—1.5 parts of water; the solution gives a yellow, crystalline precipitate with chloroplatinic acid, and on the addition of sodium pyrophosphate in small quantity yields a white, amorphous precipitate, which dissolves on further addition of the reagent, and then separates out again in irregular, crystalline scales. With chlorine-water, it gives an intense violet coloration, which changes successively to dark-blue, pale-blue, bluish-green, and green, and becomes brown on the addition of ammonia.

Iridioaquopentamine bromide, $\text{Ir}(\text{NH}_3)_5\text{OH}_2\text{Br}$, is obtained in a similar manner to the chloride, hydrobromic acid being substituted for hydrochloric acid. It is a crystalline compound, has a sp. gr. of 3.022 at 20.1, dissolves in 4 parts of water, and loses water at 100°, with formation of the pentamine salt. With potassium ferricyanide, its solution gives a precipitate consisting of reddish-brown aggregates of crystals, and with sodium pyrophosphate, behaves exactly like the chloride.

Iridium aquopentamine nitrate, $\text{Ir}(\text{NH}_3)_5\text{OH}_2(\text{NO}_3)_3$, is prepared by the addition of nitric acid to a solution of the hydroxide obtained by boiling a pentamine compound with aqueous potash, and is a crystalline precipitate consisting of microscopic, rhombic prisms. It dissolves in 10 parts of water at 17°, has a sp. gr. of 2.46 at 18°, and in its behaviour towards potassium ferricyanide and sodium pyrophosphate resembles the bromide. When heated at 100°, it loses water, forming *iridium pentamine nitrate*, $\text{Ir}(\text{NH}_3)_5(\text{NO}_3)_3$, which requires 349 parts of water at 16° for complete solution, has a sp. gr. of 2.51 at 18.3°, yields a crystalline precipitate with platinic chloride, auric chloride, and barium dithionate, and gives a violet coloration with chlorine.

The aqueous solution of iridium aquopentamine nitrate is partially converted into the pentamine salt on boiling, and the reverse reaction

takes place on boiling a solution of the pentamine nitrate. A similar behaviour was observed by Jörgensen with the corresponding rhodium compounds. H. G. C.

Mineralogical Chemistry.

Kallilite, a New Nickel Ore. By H. LASPEYRES (*Zeit. Kryst. Min.*, 19, 12—17).—A specimen of a mineral described as antimonial nickel glance, from the Friedrich mine, at Schönstein, on the Sieg, gave on analysis the following results:—

S.	Sb.	As.	Bi.	Fe.	Co.	Ni.	Total.
14.39	44.94	2.02	11.76	0.28	0.89	26.94	101.22

For this mineral the author proposes the name of *bismuth antimonial nickel glance* or *kallilite*. The mineral is an amorphous mixture of 1 mol. arsenical nickel glance, NiAsS , 13 mols. of antimonial nickel glance, NiSbS , and 2 mols. of bismuthic nickel glance, NiBiS . This last substance has, however, not been met with in a pure state.

B. H. B.

Sychnodymite, a New Cobalt Ore. By H. LASPEYRES (*Zeit. Kryst. Min.*, 19, 17—21).—A mineral obtained from the Kohlenbach mine, at Eisfeld, near Siegen, was found by the author to be a cobalt compound corresponding with polydymite, and he has given to it the name of sychnodymite. On analysis, the mineral yielded:—

S.	Cu.	Fe.	Co.	Ni.	Total.
40.33	17.23	0.82	35.64	5.74	99.76

B. H. B.

Korynite from Siegen. By H. LASPEYRES (*Zeit. Kryst. Min.*, 19, 8—12).—In 1867, Hensler described a new nickel ore from the Storch und Schöneberg mine, near Siegen. According to the analysis he published, this mineral possessed the interesting composition of a normal sulphantimonite of nickel. On analysing similar material, the author obtained the following results:—

S.	Sb.	As.	Bi.	Fe.	Co.	Ni.	Total.
16.22	42.93	10.28	0.68	0.40	1.13	28.91	100.55

The mineral is therefore a perfectly normal antimonial nickel glance (ullmannite), NiSbS , with an appreciable, but variable, isomorphous admixture of arsenical nickel glance (gersdorffite), NiAsS .

B. H. B.

Falkenhaynite from Joachimsthal. By F. v. SANDBERGER (*Jahrb. f. Min.*, 1891, i, Mem. 274—276).—In 1890 R. Scharizer described and analysed a new mineral from Joachimsthal, which he named falkenhaynite. A specimen that has been in the author's possession since 1850 is found on analysis to be identical with falkenhaynite. The author points out that this mineral so closely resembles

in composition the annivite of Brauns that the two minerals might well be included under one name. The difference between the two minerals is that antimony predominates in falkenhaynite, whilst arsenic and bismuth predominate in annivite. Both minerals are interesting links between bournonite and bismuth-copper ore.

B. H. B.

Gahnite and Columbite from Delaware Co., Pennsylvania.

By F. A. GENTH (*Zeit. Kryst. Min.*, 19, 85—86; from *Proc. Acad. Nat. Sci. Philadelphia*, 1889, 50—52).—Dark-green crystals of *gahnite* found with muscovite, quartz, albite, and garnet in a felspar quarry gave on analysis the following results:—

Al_2O_3 .	ZnO.	CuO.	MnO.	FeO.	MgO.	Total.	Sp. gr.
57.22	38.14	0.06	0.70	3.55	0.26	99.93	4.587

The author also gives an analysis of some crystals of columbite found in Mineral Hill Township, Delaware Co., Pennsylvania.

B. H. B.

Monazite from Sweden. By C. W. BLOMSTRAND (*Zeit. Kryst. Min.*, 19, 109; from *Geol. Foren. Förh.*, 11, 379).—Under the name of *kararfite*, Rodominsky distinguished the monazite from Nya Kararfvet on account of its large percentage of fluorine (4.35 per cent.). An analysis of this mineral made by the author proves it to be nothing more than an impure common monazite.

At Holma, in the parish of Luhr, monazite occurs in compact masses of a yellowish-brown colour. The mineral has a sp. gr. of 5.125, and on analysis yielded the following results:—

P_2O_5 .	SiO_2 .	ThO_2 .	Ce_2O_3 .	La_2O_3 .	Y_2O_3 .	FeO.
26.59	2.16	10.39	29.62	26.43	2.54	0.75
		CaO.	PbO.	H_2O .	Total.	
		0.88	0.31	0.52	100.19	

B. H. B.

Ochrolite from Pajsberg. By G. FLINK (*Zeit. Kryst. Min.*, 19, 96—97; from *Öfver. Sv. Vet. Akad. Förh.*, 1889, 5—13).—This mineral gave on analysis the following results:—

PbO.	Sb_2O_3 .	Cl.
76.52	17.56	7.72

Formula: $Pb_4Sb_2O_7 + 2PbCl_2$. The mineral crystallises in the rhombic system, and is isomorphous with heliophyllite.

B. H. B.

Formula of Axinite. By A. KENNGOTT (*Jahrb. f. Min.*, 1891, i, Mem. 267).—On calculating the analyses of axinite from Cornwall and from Bourg d'Oisans given by J. E. Whitefield (*Jahrb. f. Min.*, 1891, i, 44), the author obtains the formula $2(Ca_2Al_2O_6Si_2O_4) + H_2B_2O_6SiO_2$. A recalculation of Rammelsberg's analysis leads to a similar result.

B. H. B.

Gadolinite and Homilite. By W. PETERSSON (*Jahrb. f. Min.*, 1891, i, Ref. 372—374; from *Öfver. kongl. Vetenskaps Ak. Förhandl.*,

45, 179).—The author gives analyses of gadolinite from seven Scandinavian localities. The general formula deduced from these analyses is $R''_3(R''_2)Si_2O_{10}$. Microscopic examination showed, however, that in each case the mineral had undergone more or less alteration.

Homilite also undergoes alteration, and consequently the older analyses are worthless for the determination of the composition of unaltered homilite. Quite pure material obtained from the Norwegian soda-syenite gave on analysis the following results:—

H ₂ O.	Na ₂ O.	CaO.	FeO.	Fe ₂ O ₃ .	Ce ₂ O ₃ .	Al ₂ O ₃ .	B ₂ O ₃ .	SiO ₂ .	Total.
0.79	0.75	29.54	16.74	0.88	0.24	2.72	(16.51)	31.83	100.00

The formula is thus $Ca_2FeB_2Si_2O_{10}$.

B. H. B.

Garnet from Kedabek, in Caucasia. By W. MÜLLER (*Jahrb. f. Min.*, 1891, i, Mem. 272—273).—Very fine specimens of garnet are found in the vicinity of Siemens' Copper Works at Kedabek. The garnet occurs in limestone, and is used as a flux for copper smelting. In cavities in the massive mineral, yellow garnet crystals occur, measuring 4.5 cm. in length. On analysis, they yielded:—

SiO ₂ .	CaO.	Al ₂ O ₃ .	Fe ₂ O ₃ .	Ignition.	Total.
39.23	35.95	22.73	1.76	0.14	99.81

The mineral is thus a typical lime-aluminium garnet.

B. H. B.

Mesolite from Co. Antrim. By J. S. HYLAND (*Jahrb. f. Min.*, 1891, Ref. 400—401; from *Proc. Roy. Dublin Soc.*, 1890, 411—419).—An acicular zeolite from decomposed basalt from Kenbane Head, 2 miles west of Ballycastle, Antrim, gave on analysis the following results:—

SiO ₂ .	Al ₂ O ₃ + Fe ₂ O ₃ .	CaO.	Na ₂ O.	H ₂ O.	Total.	Sp. gr.
46.50	27.55	2.59	13.28	10.10	100.02	2.26

This corresponds with a mixture of 9 of natrolite and 2 of scolecite. The mineral is therefore galactite.

B. H. B.

Zircon from Australia. By A. SCHMIDT (*Zeit. Kryst. Min.*, 19, 56—58).—In a collection of Australian minerals presented by M. v. Hantken to the University of Budapest, the author has detected some rounded crystals of zircon with an unusually perfect cleavage. On analysis, the crystals gave the following results:—

ZrO ₂ .	SiO ₂ .	Total.	Sp. gr.
67.31	33.42	100.73	4.695

B. H. B.

Spherulitic Rocks from Co. Down. By J. S. HYLAND (*Jahrb. f. Min.*, 1891, i, Ref. 399—400; from *Proc. Roy. Dublin Soc.*, 1890, 420—437).—Spherulitic rocks are met with at three places in the Mourne Mountains. The rock occurring at Newcastle is porphyritic with felspar and rounded quartz. On analysis, it gave the following results:—

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO.	CaO.	MgO.	K ₂ O.	Na ₂ O.	H ₂ O.	Total.
(70·01)	13·79	1·83	0·51	1·43	0·72	6·90	3·69	1·07	100·00

Organic Chemistry.

Electrolysis of Metallic Thiocyanates, and the Decomposition of Alkaline Thiocyanates. By L. K. FRANKEL (*Chem. Centr.*, 1891, i, 615; from *Proc. Chem. Sect. Frankland Inst.*, February, 1891).—When a concentrated aqueous solution of ammonium or potassium thiocyanate is subjected to a weak voltaic current (1·5 c.c. of hydrogen and oxygen evolved per one minute), a yellow precipitate is finally formed which Bunge (*Ber.*, 3, 297) and Lidoff (*Ber.*, 17, 252 Ref.) name pseudothiocyangen. The author has observed the odour of sulphur compounds at the same time.

Mercury and gold may be completely deposited from their solutions in potassium and ammonium thiocyanates, as also cadmium, although the latter metal is obtained as a spongy mass. In the case of palladium, nickel, cobalt, and zinc, the metals are primarily deposited from the solution, but later they are redissolved, owing possibly to the formation of an alkaline cyanide, the solvent action of which is not interfered with. Iron and manganese are but partially precipitated, and the deposited metal is so liable to oxidation that it cannot be exposed to the air without suffering change. Arsenic is not deposited at all. Lead is completely precipitated, but partly as sulphide. With antimony, bismuth, and tin, no very satisfactory results were obtained.

The author considers it probable that Miller's Canarin (*D. Pat. Chem. Centr.*, 1885, 925; also *Abstr.*, 1885, 107) is identical with pseudothiocyangen, but that the precipitate obtained by the electrolysis of a solution of ammonium thiocyanate is not pseudothiocyangen. J. W. L.

Polymeride of Trimethylacetonitrile. By M. FREUND and F. LENZE (*Ber.*, 24, 2161—2167).—The colourless liquid boiling at 159—160° which is obtained in the preparation of trimethylacetonitrile from tertiary butyl iodide (compare *Abstr.*, 1890, 1388) has the empirical formula C₆H₁₂N, but vapour density determinations by Meyer's method have shown that its molecular formula is C₁₀H₁₈N₂. When heated with concentrated hydrochloric acid at 100°, it is decomposed into trimethylacetic acid, butylamine, and ammonia; it is also decomposed by alcoholic potash with formation of butylamine, but trimethylacetic acid could not be detected in the reaction product. On reduction with sodium and alcohol, it yields two bases, which seem to have the composition C₄H₁₁N and C₆H₁₃N respectively.

F. S. K.

Compound of Alcohol and Sodium Bisulphide. By L. DEMONT (*J. Pharm.*, 23, 544—547).—If a mixture of anhydrous mono- and poly-sulphides of sodium is placed in absolute alcohol, the liquid

gradually assumes a yellow colour, and a slight, although clearly perceptible, rise in temperature may be noted. The mixture is heated gradually to boiling, allowed to cool, and filtered from the excess of sulphide. On adding perfectly dry ether, an abundant, slightly crystalline precipitate is produced. If the ether is not perfectly dry, beautiful, crystalline needles first appear, followed by the less crystalline deposit above. The precipitate first formed with moist ether appears to take water of crystallisation, and when the ether has thus been rendered dry, the granular precipitate follows. The precipitate is very hygroscopic. When rapidly drained, placed over sulphuric acid, or heated at 100° , it loses about 40 per cent. of its weight. The compound thus obtained was analysed, and corresponds with the formula $C_2H_5O + 9NaS$. The original precipitate would be sensibly C_2H_5O, NaS .
J. T

Action of Phosphorus Oxychloride on Ethyl Silicates and Silicon Ethoxychlorides. By H. N. STOKES (*Amer. Chem. J.*, 13, 244—253).—Silicon ethoxytrichloride, $SiCl_3 \cdot OEt$, reacts with excess of phosphorus oxychloride at 180° to form silicon tetrachloride, ethyl chloride, and a white, amorphous substance which does not contain free silicic acid, and which gives on analysis numbers corresponding with the formula $SiP_2O_6Cl_2$. Silicon oxychloride is not formed. The author considers that this substance is a chloride of silicopyrophosphoric acid, possibly of the constitution $O=Si<\begin{smallmatrix} O \cdot POCl \\ O \cdot POCl \end{smallmatrix}>O$, and that it is formed according to the equation $4SiCl_3 \cdot OEt + 2POCl_3 = 3SiCl_4 + SiP_2O_6Cl_2 + 4EtCl$. If the ethoxytrichloride is in excess, the reaction is similar, but the silicophosphoryl chloride formed is of different composition. Neither the acid nor its salts could be isolated.

Silicopyrophosphoryl chloride, $SiP_2O_6Cl_2$, is a white, bulky, hygroscopic substance, freely soluble in alcohol and water. In contact with moist air, it loses hydrochloric acid, and when heated it gives off first phosphorus oxychloride and then phosphorus pentoxide, leaving finally a vitreous residue consisting of silica embedded in a matrix, probably of the compound $SiO_2 \cdot P_2O_5$. At 100° it is completely decomposed by phosphorus pentachloride into silicon tetrachloride and phosphorus oxychloride. A cold aqueous solution from which the chlorine has been removed by excess of silver nitrate yields, in order, on the addition of ammonia, silver pyrophosphate, silver orthophosphate, and silica.

The reaction of phosphorus oxychloride with the other silicon ethoxychlorides is essentially similar:—

Ethyl orthosilicate reacts with phosphorus oxychloride according to the equation $Si(OEt)_4 + 2POCl_3 = SiP_2O_6Cl_2 + 4EtCl$.

Hexethyl disilicate reacts with phosphorus oxychloride at 100° with the formation of ethyl chloride and a silicophosphoryl chloride much like that described above, but different in composition.

A mixture of the ethoxychlorides formed by heating the hexethyl disilicate with silicon tetrachloride at 200° reacted with phosphoric oxychloride with the formation of silicon tetrachloride, ethyl chloride, a silicophosphoryl chloride, and silica. No silicon oxychloride was formed.

JN. W.

Attempt to Prepare Tertiary Butylcarbinol. By M. FREUND and F. LENZE (*Ber.*, 24, 2150—2161).—The compound obtained by treating tertiary amylamine hydrochloride with silver nitrite (compare Abstr., 1890, 1388) is not tertiary butylcarbinol as it was at first supposed, but is identical with the dimethylethylcarbinol, $\text{CMe}_2\text{Et}\cdot\text{OH}$, previously described by Wischnegradsky (Abstr., 1878, 393); the formation of this compound from the tertiary amine can be explained by assuming that the tertiary butylcarbinol first produced undergoes an intramolecular change analogous to that which takes place in the conversion of pinacones into pinacolines.

F. S. K.

Sulphur Compounds in Ohio Petroleum. By C. F. MABERY and A. W. SMITH (*Amer. Chem. J.*, 13, 233—243; compare Abstr., 1890, 350).—In the commercial process of refining petroleum the sulphur compounds are extracted by treatment with concentrated sulphuric acid. The "sludge acid" thus obtained, on dilution and treatment with slaked lime, yielded a semi-solid mass, from which, by distillation with steam, a colourless oil was obtained containing 14.97 per cent. of sulphur. This oil was distilled first under a pressure of 150 mm. and subsequently under a pressure of 100 mm., and the following main fractions were collected:—

Fraction ...	70–76°	80–90°	98–101°	135–145°	148–155°	185–200°
Sulphur, per cent.	2.60	7.34	18.23	15.52	16.44	14.21

The fractions containing sulphur formed compounds with mercuric chloride, those of lower boiling point giving crystalline substances, and those of higher boiling point viscous oils, which solidified after a time or when recrystallised from benzene. Platinum compounds of the type $\text{R}_2\text{S}\cdot\text{PtCl}_4$ were readily formed. All the fractions combined energetically with bromine.

The products collected below 101° at 100 mm. pressure were redistilled under ordinary pressure. The fractions distilling below 125° combined with hydrobromic acid to form oily substances; the product thus obtained from the fraction boiling at 80–90° was found to be monobromheptane. Analysis of the mercury compounds obtained from the fraction boiling at 110° and upwards revealed the presence of methyl, ethyl, propyl, and butyl sulphides.

The fraction from the sulphuric acid extract boiling at 80–90° under 150 mm. pressure consisted of higher sulphides, together with oily substances free from sulphur. The sulphides were separated from the latter by means of the mercury compounds, which were precipitated by alcoholic mercuric chloride as viscous or crystalline compounds easily decomposable by hydrogen sulphide. Propyl sulphide was probably present in this fraction. The fractions of higher boiling

point were identified as ethylpentyl, normal and isobutyl, and hexyl sulphides; butylpentyl and pentyl sulphides were probably also present. The fractions of higher boiling point than hexyl sulphide were not examined.

In order to further investigate the nature of the lighter oils, crude "naphtha distillate," boiling below 150° , was treated with aqueous mercuric chloride, and the precipitate thus obtained decomposed by hydrogen sulphide in the presence of alcohol. The sulphur oils separated from the alcoholic solution on the addition of water, and on distillation under atmospheric pressure collected in fractions which were identified as methyl, ethyl, ethylpropyl, and normal propyl sulphides.

Small quantities of sulphur compounds were obtained directly from crude petroleum. JN. W.

l.-Sorbitol. By E. FISCHER and R. STAHEL (*Ber.*, **24**, 2144).—Further experiments have shown that the hexahydric alcohol obtained by the reduction of l.-gulose (this vol., p. 677) is, in fact, the optical isomeride of ordinary sorbitol. When the syrupy alcohol, purified by means of its benzal derivative, is dissolved in warm 90 per cent. alcohol (7 parts), small needles are deposited in the course of about eight days; this crystalline product contains a large quantity of water, resembles ordinary sorbitol very closely in appearance, and, after having been kept for three days over sulphuric acid under reduced pressure, it melts at about 75° and has the composition $C_6H_{14}O_6 + \frac{1}{2}H_2O$. It can only be distinguished from ordinary sorbitol by its optical properties; it is feebly laevorotatory in presence of borax, whereas ordinary sorbitol is feebly dextrorotatory ($[\alpha]_D^{20} = 1.4^{\circ}$) under the same conditions. F. S. K.

Configuration of Grape Sugar and its Isomerides. By E. FISCHER (*Ber.*, **24**, 1836—1845).—The experimental evidence afforded by a study of the members of the sugar group is in such complete accordance with the theory of the asymmetric carbon atom that it is possible, even with our present knowledge, to employ this theory as a basis for the classification of these substances.

The theory accounts for the existence of 16 isomerides having the structure of grape sugar, but this number is reduced to 10 in the case of those derivatives of grape sugar, the molecule of which is symmetrical; in the table (next page), taken from Van't Hoff and Herrmann's "Die Lagerungen der Atome im Raume," these 16 different modifications are shown, the forms numbered 11 to 16 being identical with those numbered 5 to 10 in the case of the hexahydric alcohols and dicarboxylic acids.

Now, in attempting to determine, with the aid of observed facts, which of these 16 forms should be assigned to grape sugar, it is necessary in the first place to consider the case of saccharic acid. Of this acid the two optically active forms of opposite sign are known, and, in addition, it has been shown that d.-saccharic acid can be obtained on the one hand from d.-glucose, and on the other from the stereochemical isomeride d.-gulose (this vol., p. 677); it follows,

				11	12	13	14	15	16
				+	+	+	+	+	-
				+	+	+	-	-	+
				+	-	-	+	-	-
				-	+	-	-	-	-
+	+	-	-	-	+	-	-	-	-
+	-	+	-	+	-	-	+	-	-
+	-	+	-	+	+	+	-	-	+
+	+	-	-	+	+	+	+	+	-
1	2	3	4	5	6	7	8	9	10

therefore, that the configurations of the two saccharic acids must be represented by two among the forms numbered 5 to 10, because these are the only modifications which could be produced from two stereochemically isomeric sugars. Since two of these forms, namely, those numbered 7 and 8, are optically inactive, they may at once be dismissed from consideration; those numbered 6 and 10 may also be excluded, as is shown by the following arguments:—Glucose and mannose differ from one another only in this, that the arrangement of groups around the asymmetrical carbon atom, marked in the accompanying formula with an asterisk, is not the same in the two compounds—

This is also the only difference between gluconic acid and mannonic acid, sorbitol and mannitol, saccharic acid and mannosaccharic acid. The facts on which this statement is based, and which all lead to the same conclusion, are:—(1.) Mannose and glucose yield the same osazone. (2.) l-Mannonic acid and l-gluconic acid are both produced from arabinose by means of hydrogen cyanide. (3.) When fructose is reduced with sodium amalgam, it is converted into a mixture of mannitol and sorbitol. (4.) Mannonic acid and gluconic acid can be converted one into the other at will by heating with quinoline. (5.) All attempts to resolve gluconic acid and mannonic acid into two components have been unsuccessful. If, therefore, saccharic acid or, what comes to the same, sorbitol has the configuration numbered either 6 or 10, mannosaccharic acid or mannitol must have the configuration 7 or 8; but the latter are the optically inactive systems and must, therefore, be excluded because both mannitol and mannosaccharic acid are optically active. It follows from these arguments that d.- and l-saccharic acid can only have the configurations numbered 5 and 9, and since it is immaterial which is designated with +, and which with -, the configuration numbered 5 may be assigned to d.-saccharic acid, and that numbered 9 to l-saccharic acid.

Now, there are two aldoses corresponding with d.-saccharic acid, having the configurations:—

respectively; in order to decide which of these formulæ represents d-glucose and which d-gulose, it is necessary to study some facts regarding arabinose and xylose.

In the first place, arabinose can be converted into l-glucose, whilst xylose, under the same conditions, yields l-gulose; there remains, therefore, a choice between the two formulæ:—

for l-glucose and l-gulose. If the asymmetrical carbon atom which is marked with an asterisk, and which only becomes asymmetric by synthesis, is taken away, it will be seen that there remain for xylose and arabinose the following two formulæ:—

Again, according to the theory, there may be eight isomeric pentoses having the constitution of arabinose and xylose, but this number is reduced to four when the molecule becomes symmetrical; there are, therefore, only four pentahydric alcohols of the constitution $\text{OH} \cdot \text{CH}_2 \cdot [\text{CH(OH)}]_3 \cdot \text{CH}_2 \cdot \text{OH}$ and four trihydroxyglutaric acids. Of the latter there are two optically active modifications, namely:—

and two inactive modifications, which probably could not be distinguished from one another. It is possible, therefore, to decide which of the above two formulæ represents arabinose and which xylose by observing the optical properties of the corresponding pentahydric alcohols or dicarboxylic acids; experiments have shown, in a very decided manner, that arabinose has the configuration represented by the first, and xylose that represented by the second formula.

Arabitol, prepared from arabinose, is laevorotatory in presence of borax (compare Fischer and Stahel, this vol., p. 667); this is also so in the case of the trihydroxyglutaric acid prepared from arabinose, as

will be shown below. Xylitol, obtained from xylose, is, on the other hand, optically inactive (*loc. cit.*) even in the presence of borax, and so is the trihydroxyglutaric acid prepared from xylose (see below). Now, since the hydroxy-acids, if optically active at all, invariably possess a high specific rotatory power, it may be assumed with confidence that these derivatives of xylose really are optically inactive and that the configuration just assigned to xylose is the correct one.

The configurations of the members of the hexose group are easily deduced from the above considerations and may be expressed as follows:—

ALDOSES: $\text{CHO}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{OH}$.

d.-Glucose	—	+	+	+
l.-Glucose	+	—	—	—
d.-Gulose	+	+	+	—
l.-Gulose	—	—	—	+
d.-Mannose	+	+	+	+
l.-Mannose	—	—	—	—

As regards galactose, there remains a choice between four configurations, as will be seen by a comparison with the formulæ of mucic acid and with those of allomucic acid.

KETOSES: $\text{CH}_2(\text{OH})\cdot\text{CO}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{OH}$.

d.-Fructose	+	+	+
l.-Fructose	—	—	—

The monocarboxylic acids, $\text{COOH}\cdot[\text{CH}(\text{OH})]_4\cdot\text{CH}_2\cdot\text{OH}$ have the same configurations as the corresponding aldoses.

ALDEHYDE-ACIDS: $\text{COOH}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CHO}$.

Glucuronic acid	+	+	+	—
-----------------	---	---	---	---

ALCOHOLS: $\text{OH}\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{OH}$.

d.-Mannitol	+	+	+	+
l.-Mannitol	—	—	—	—
d.-Sorbitol	—	+	+	+
l.-Sorbitol	+	—	—	—

DICARBOXYLIC ACIDS:

$\text{COOH}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{COOH}$.

d.-Saccharic acid	—	+	+	+
l.-Saccharic acid	+	—	—	—
d.-Mannosaccharic acid	+	+	+
l.-Mannosaccharic acid	—	—	—

In addition to the above, two other members of this group, namely, mucic acid and isosaccharic acid, are known. The former is optically inactive, and when treated with pyridine is converted into an inactive allomucic acid; these two isomerides have in all probability the configurations (— + — +) and (— — + +).

A second isomeride of mucic acid, which is, however, optically active, has been obtained by treating galactonic acid with quinoline and oxidising the product with nitric acid; this modification has probably the configuration $(+ - + +)$ or $(- + - -)$. There remain then for isosaccharic acid only the two configurations $(+ - - +)$ and $(- + + -)$.

The views expressed above are of course tenable only when it is assumed that the theory of the asymmetric carbon atom is true and, further, that no stereochemical intramolecular change occurs in those reactions by which trihydroxyglutaric acid and saccharic acid are produced from xylose and arabinose. Of the facts mentioned above in support of these views, the conversion of xylose into optically inactive trihydroxyglutaric acid and the proof that this acid is not identical with the compound obtained from arabinose have yet to be described.

Inactive trihydroxyglutaric acid, $C_5H_8O_7$, is formed when xylose is oxidised with nitric acid of sp. gr. 1.2 ($2\frac{1}{2}$ parts) at 40° as described by Kiliani in the oxidation of arabinose; it is isolated by means of its calcium salt, the yield of which is 18 grams from 30 grams of the sugar. It crystallises from hot acetone in well-defined, colourless plates, melts at 145.5° (corr.), decomposes at a higher temperature, and is very readily soluble in water and hot alcohol, but much more sparingly in warm acetone, and almost insoluble in chloroform and ether. It is optically inactive, and does not act on Fehling's solution, but it reduces ammoniacal silver nitrate on warming; in a solution of the acid, lead acetate and barium acetate produce precipitates, that obtained with barium acetate being soluble in excess of the reagent. The calcium salt is very sparingly soluble in water. The *potassium* salt, $C_5H_7O_7K_2$, is very readily soluble, and remains as a syrup on evaporating its aqueous solution; this syrup solidifies after some time, and can then be recrystallised from water, from which it separates in well-defined, hexagonal plates or prisms containing 2 mols. H_2O , which are expelled at 130° . This acid is easily distinguished from the isomeride obtained from arabinose by its melting point, optical inactivity, and the composition of its potassium salt. When a 10 per cent. solution of the acid is heated with phenylhydrazine, the hydrazone commences to be deposited in about half an hour; it crystallises in colourless plates, sinters together at about 175° when quickly heated, melts at about 210° with decomposition, and is very sparingly soluble in hot water and alcohol. That inactive trihydroxyglutaric acid contains a normal carbon chain is proved by the fact that, on reduction with hydriodic acid and amorphous phosphorus, it is converted into glutaric acid (m. p. $95-96^\circ$).

The specific rotatory power of the trihydroxyglutaric acid prepared from arabinose is $[\alpha]_D = -22.7^\circ$ at 20° ; the rotatory power undergoes no change in the course of 24 hours. The above views on the configuration of the members of the sugar group render it possible to foresee a whole series of reactions which can be carried out by known methods; as an example, the reduction of d.-mannosaccharic acid may be quoted. If this compound has the configuration assigned to it above, it is immaterial which of the two carboxy-groups is reduced;

in other words, only one acid, namely, d.-mannonic acid, can be produced. Experiments have proved the correctness of this supposition; when the double lactone of d.-mannosaccharic acid is treated with sodium amalgam in slightly acid solution, the only product is d.-mannonic lactone.

F. S. K.

Influence of Inactive Substances on the Rotatory Power of Very Dilute Solutions of Grape Sugar. By N. WENDER (*Ber.*, 24, 2200—2203).—A series of experiments has shown that Landolt's formula $c = 0.9434\alpha$ (*Optische Drehungsvermögen*, 1879, 182) holds good in the case of grape sugar even in very dilute solutions (0.1—0.4 gram in 100 c.c.), and also that the presence of carbamide and other inactive constituents of urine has no effect on the rotatory power of such dilute solutions.

F. S. K.

Rotatory Power of Levulose and Invert Sugar. By B. TOLLENS (*Ber.*, 24, 2000).—Ost (this vol., p. 1000) has overlooked the fact that Parcus and Tollens (*Annalen*, 257, 165) have found that the rotatory power of levulose is greater than hitherto accepted. The values given by both authors are in close agreement.

W. P. W.

Chemical Composition of the Membrane of Plant Cells. By E. SCHULZE (*Ber.*, 24, 2277—2287; see also Abstr., 1889, 916; 1890, 1456).—The constituents of the plant cell membrane are divided into those which are easily extracted with dilute mineral acids and those which are difficult to extract. The author has already described six celluloses of different origin, converted them into glucoses by the method described by Flehsig, and finally in all cases obtained grape sugar from them. He has now obtained three other cellulose preparations from pine wood (*Picea excelsa*), from rye-straw (*Secale cereale*), and from red clover (*Trifolium pratense*), and has treated them in the same way, and obtained the sugar in a crystalline condition.

The wood cellulose was prepared by the sulphite method, and before use was extracted with 4 per cent. hydrochloric acid. The other cellulose preparations were prepared by extracting the finely broken material with ether, dilute aqueous soda, 4—5 per cent. hydrochloric acid, then with F. Schulze's reagent (cold, dilute nitric acid and potassium chlorate), and finally washed with dilute ammonia, water, alcohol, and ether. These three celluloses, on hydrolysis, also yielded grape sugar, which was crystallised first from water, then from alcohol, and finally from methyl alcohol, and was identified by its specific rotation, behaviour towards yeast, and by yielding saccharic acid when heated with nitric acid.

Lastly, they have examined the cellulose preparation from sesame seeds, and have also obtained grape sugar from it. Ten celluloses have now been obtained which give grape sugar on hydrolysis, and an eleventh (cotton cellulose) has been examined by Flehsig (*Zeit. physiol. Chem.*, 7, 523).

To determine if these celluloses yielded other glucoses besides grape sugar, the mother liquors were examined. In no case was

galactose detected. Only in the crude crystallisable product from rye-straw cellulose was a small quantity of a pentaglucose detected by means of hydrochloric acid and phloroglucinol. Mannose was obtained from many of the preparations in considerable quantity; it was first detected in those prepared from coffee beans (*Ber.*, 23, 2582). A second experiment was made with a carefully prepared coffee cellulose. The preparation was obtained by extracting with $\frac{1}{4}$ per cent. hydrochloric acid, then treated with F. Schulze's reagent, and washed with dilute ammonia, water, alcohol, and ether. It yielded a syrup which contained considerable quantities of d.-mannose. Mannose is also obtained from the cellulose from cocoa and sesame seeds.

Besides these constituents, a substance is also present in the most carefully purified cellulose preparations which is convertible into xylose. The presence of the latter is shown by the violet colour produced on boiling the preparation with hydrochloric acid and phloroglucinol. Those celluloses which colour most strongly when treated in this way yield a large proportion of furfuraldehyde.

The author proposes to restrict the name cellulose to that constituent of the cell wall which is not dissolved by dilute mineral acids and alkalis, and scarcely attacked by F. Schulze's reagent, but is soluble in ammoniacal copper oxide, and yields grape sugar on hydrolysis. If, however, "cellulose" be employed as a group-name, he proposes to call the above compound dextroso-cellulose, and the cellulose-like compound which yields mannose on hydrolysis is called mannoso-cellulose. Those constituents of the cell wall which dissolve easily in dilute mineral acids, with formation of glucose, he calls hemicelluloses, and distinguishes them by the names of galactane, arabane, xylane, according as they yield galactose, arabinose, or xylose. A product which yields both galactose and arabinose he proposes to call galacto-arabane, &c.

E. C. R.

Hexamethylenamine. By L. HARTUNG (*J. pr. Chem.* [2], 43, 597—598).—Hexamethylenamine is not split up easily by hydrochloric acid into ammonia and formaldehyde as heretofore supposed; a considerable quantity of methylamine is formed, and can be separated by alcohol from the ammonium chloride and paraformaldehyde. Strong nitric acid acts on hexamethylenamine in glacial acetic acid very violently with evolution of nitrous oxide, ammonia and methylamine being also formed. Nitrous acid acts on it in glacial acetic acid evolving nitrogen and nitric oxide, and forming a white, amorphous substance which is decomposed by potash with formation of ammonia and methylamine. Sulphurous acid, acting on it in hot absolute alcohol, produces a white compound, $C_6H_{11}N_6SO_3$; when benzene is substituted for alcohol, the resulting compound is $C_6H_{12}N_6SO_3$, which loses half its SO_3 at 60—70°. Ethyl chloracetate acts on hexamethylenamine at 100°, with separation of alcohol, to form the compound $C_{14}H_{28}ClN_6O$, of which the platinochloride was analysed; if the reaction takes place in hot alcohol, hexamethylenamine hydrochloride separates, whilst the above compound is precipitated from the filtrate on addition of ether.

A. G. B.

Biguanide. By F. EMICH (*Monatsh.*, 12, 5—22) —The products of decomposition of biguanide, obtained by the action of sulphuric acid of sp. gr. 1.47 at 200°, alcoholic potash at 100°, and red-hot lime, were comparatively simple, such as carbonic anhydride, ammonia, cyanic acid, and cyanamide (Emich, *Abstr.*, 1883, 973, and 1889, 1060). The author now finds that the decomposition of the base, by boiling it with baryta water, does not proceed so far as in the above mentioned cases, carbamide and guanidine being produced. Similarly from methylbiguanide are formed methylcarbamide, carbamide, guanidine, and, perhaps, methylguanidine; whilst phenylbiguanide gives phenylcarbamide, carbamide, phenylguanidine, and guanidine.

Diethylbiguanide, $\text{NEt}_2\cdot\text{C}(\text{NH})\cdot\text{NH}\cdot\text{C}(\text{NH})\cdot\text{NH}_2$, is obtained by heating at 130°, for some hours, a mixture of equal parts of diethylamine hydrochloride and dicyanodiamide. The product is treated with chloroform, which dissolves the diethylbiguanide and any remaining diethylamine, the solution evaporated, the residue dissolved in water, and the solution thus obtained treated with copper sulphate and potash, whereby the red copper compound is precipitated. From this, by solution in dilute sulphuric acid and precipitation of the copper with hydrogen sulphide, diethylbiguanide sulphate, $\text{NEt}_2\cdot\text{C}(\text{NH})\cdot\text{NH}\cdot\text{C}(\text{NH})\cdot\text{NH}_2\cdot\text{H}_2\text{SO}_4 + 3\text{H}_2\text{O}$, was obtained as a white precipitate on the addition of alcohol to the clear filtrate. It crystallises from water in clusters of small, flat prisms, is insoluble in ether, has an acid reaction, sinters at 185°, and melts with decomposition at 197°. On heating at 100° in a closed tube for 3—4 hours with baryta water, it is decomposed with formation of diethylamine.

β -Diphenylbiguanide, $\text{NPh}_2\cdot\text{C}(\text{NH})\cdot\text{NH}\cdot\text{C}(\text{NH})\cdot\text{NH}_2$, is obtained by heating together diphenylamine hydrochloride and dicyanodiamide either alone or in alcoholic solution. It has a strongly alkaline reaction, crystallises in white needles, melts with decomposition at 160—162°, and on treatment with dilute nitric acid gives a *nitrate*, $\text{C}_{14}\text{H}_{15}\text{N}_5\cdot\text{HNO}_3$, which has a neutral reaction, and melts with blackening and evolution of gas at 201—203°. The corresponding acid sulphate, $(\text{C}_{14}\text{H}_{15}\text{N}_5)_2\cdot 3\text{H}_2\text{SO}_4$, crystallises from water in spherical aggregates of needles, and furnishes diphenylamine when heated with lime. G. T. M.

Guanidine. By F. EMICH (*Monatsh.*, 12, 23—28).—*Guanidine picrate*, $\text{CH}_5\text{N}_3\cdot\text{C}_6\text{H}_2(\text{NO}_2)_3\cdot\text{OH}$, is precipitated in a pure form when an aqueous solution of picric acid is added to a moderately concentrated solution of a salt of guanidine. The picrate is only sparingly soluble in water (1 part in 2630 at 9°), alcohol, and ether, and this property makes it available for the quantitative estimation of the base. It crystallises in very characteristic forms, does not melt at 280°, burns at a higher temperature, and when struck does not explode.

On treating guanidine carbonate with a solution of sodium hypobromite, two-thirds of its nitrogen was evolved in the gaseous form, in accordance with the equation $\text{NH}\cdot\text{C}(\text{NH}_2)_2 + 3\text{O} = \text{HCNO} + 2\text{H}_2\text{O} + \text{N}_2$, the cyanic acid being itself undecomposed by hypobromite.

Solutions of guanidine carbonate containing phosphates and other inorganic salts necessary to bacterial life were not changed by *Penicillium glaucum* or by putrefying urine; but the compound itself is not powerfully antiseptic.

G. T. M.

Oximes. By V. MEYER (*Annalen*, 264, 116—122).—It is a curious fact that the oximes of low melting point have a much more strongly marked acid character than their isomerides of high melting point; if, for example, bromacetophenone (1 mol.) or methoxyacetophenone (1 mol.) is treated with hydroxylamine hydrochloride (3 mols.) and sodium hydroxide (9 mols.), an alkaline solution is obtained from which, on the addition of a large quantity of water, the oxime of high melting point is deposited in an almost pure condition, whilst the isomeride remains in solution, and is only precipitated on the addition of acids; this difference of behaviour can be made use of for the separation of the two isomerides when only small quantities are present.

Chloralaldoxime, $\text{CCl}_3\text{CH:N}\cdot\text{OH}$, can be easily prepared by treating a mixture of chloral hydrate (1 mol.) and hydroxylamine hydrochloride (4 mols.) with a quantity of water just sufficient to moisten the crystals throughout, and then warming gently, when a colourless oil separates from the solution; after warming for a short time, the oil is washed with water, then cooled in ice, and the crystalline product repeatedly washed with water and dried between blotting paper. It forms large, compact prisms, melts at $39\text{--}40^\circ$, boils without decomposition when heated in small quantities, and is readily soluble in alcohol and ether, but insoluble in water; it is not easily obtained in crystals from its solutions, and its vapours have a very irritating action on the eyes. It is decomposed by concentrated alkalis with almost explosive violence; when treated with dilute soda, it yields hydrogen cyanide, hydrogen chloride, carbonic anhydride, and a colourless, resinous compound, but the formation of chloroform, formic acid, and hydroxylamine could not be observed; on evaporation with concentrated hydrochloric acid, the oxime suffers decomposition, and there remains a crystalline residue of hydroxylamine hydrochloride.

Acetoxime combines readily with the chlorides of benzene, paratoluene, and naphthalene- β -sulphonic acid in presence of soda, yielding crystalline compounds which will be described in another paper; analogous derivatives of benzophenone oxime cannot be easily obtained.

F. S. K.

Constitution of Aliphatic Ketones and the Action of Sodium on Acetone. By P. C. FREER (*Amer. Chem. J.*, 13, 308—322).—The author discusses at length the constitution of ethyl acetoacetate and acetone.

Powdered sodium dissolves in a solution of dry ethyl acetate in dry ethyl ether, and the resulting product yields nothing but ethyl acetoacetate when treated with hydrochloric acid. This would seem to point to the intermediate formation of Frankland's hypothetical sodium derivative of ethyl acetate (*Jahrb.*, 1865, 204).

A comparison of the properties of tetric acid, $C_8H_6O_2$ (Abstr., 1888, 1272), with those of ethyl acetoacetate seems to show that hydroxyl is present in the former, but not in the latter. Tetric acid forms a crystalline compound with phenylhydrazine, and is not reduced by sodium amalgam. The sodium salt, $NaC_8H_5O_2 + 3H_2O$, crystallises in plates, which lose their water of crystallisation in a vacuum over sulphuric acid. The anhydrous salt is stable at 130° . Sodium tetratate does not react with ethyl iodide, but the silver salt yields ethyl tetratate, an oil boiling at 176° under a pressure of 50 mm. Ethyl tetratate is insoluble in water and cold aqueous soda, but soluble in alcohol and ether. It is hydrolysed by potash, showing that the ethyl group is attached to oxygen. Tetric acid reacts with warm acetic anhydride to form a neutral, colourless oil, boiling at 178° under 50 mm. pressure. The oil, which has the composition of acetotetric acid, $C_7H_6O_4$, is reconverted into tetric acid by aqueous potash or alcoholic hydroxylamine.

The author endorses the view that in carbon compounds containing both metal and oxygen, the metal is united to the carbon only indirectly through the oxygen. This would seem to involve a difference in constitution between ethyl acetoacetate and its sodium derivative. That this is the case is shown by the fact that the latter unites with ethyl cinnamate to form a crystalline additive product, whilst the former does not. Further details of this reaction are to be published.

The formation of sodium acetate (Abstr., 1890, 956) has been further studied. The theoretical amount of hydrogen is displaced by the sodium, and a small amount of a condensation product, probably mesityl oxide, is formed (compare following abstract). JN. W.

Action of Ethyl Chlorocarbonate on Acetone-sodium. By P. C. FREER and G. O. HUBLEY (*Amer. Chem. J.*, 13, 322—326; compare preceding abstract).—Excess of acetone is added in an atmosphere of hydrogen to powdered sodium (1 gram) covered with ether, and the calculated amount of ethyl chlorocarbonate (4.7 grams) is gradually introduced. As soon as the violent reaction is complete, the process is repeated until a sufficient quantity of the product has accumulated. The sodium chloride which separates out is then extracted with water, and the ethereal residue is evaporated, leaving a yellow oil, the greater part of which boils at 128° , and appears, from analysis and vapour-density determinations, to be an isomeride of ethyl acetoacetate. The purified oil is colourless and insoluble in water, but miscible with alcohol and ether in all proportions. It does not react with phenylhydrazine or ferric chloride. Bromine combines with it slowly in the cold to form additive products, but in sunlight acts as a substituting agent. On boiling with dilute hydrochloric acid, it is decomposed quantitatively into carbonic anhydride, alcohol, and acetone. The authors suggest the formula

for the new substance, and conclude that in acetone-sodium the metal is combined with oxygen. JN. W.

"Acetone-potash" and "Acetone-soda." By W. VAUBEL (*J. pr. Chem.* [2], 43, 599—600).—When acetone is heated with solid potassium hydroxide, a crystalline substance separates on the surface of the liquid after about five minutes, and gradually increases in quantity. When it is dried by filter paper, washed free from excess of acetone by light petroleum, and left in a desiccator, it forms a white powder which is very hygroscopic, and readily loses acetone. The analyses of this substance agree with the formula $\text{KHO} + \text{COMe}_2$.

"Acetone-soda" can be prepared in like manner; it has not yet been investigated. A. G. B.

Action of Chlorine on Methyl Ethyl Ketone. By D. VLADESCU (*Bull. Soc. Chim.* [3], 5, 142—149).—Methyl ethyl ketone is chlorinated in a reflux apparatus by a slow stream of dry chlorine free from hydrogen chloride. The progress of the reaction is determined by the amount of hydrogen chloride collected in a flask containing distilled water, connected to the condenser, twenty-four hours being required in cloudy weather to form the monochloro-derivative. Hydrogen chloride and excess of chlorine are expelled from the product of the reaction by a current of carbonic anhydride, and after washing with dilute solution of potassium carbonate, it is dried over calcium chloride and fractionated.

From the fraction boiling at 114—116°, methyl chlorethyl ketone is separated by distillation, under reduced pressure, as a colourless liquid of an irritating, ethereal odour. It boils at 115° under a pressure of 758 mm., has a vapour density of 3.8, and a sp. gr. at 0° of 1.032.

By distillation, under reduced pressure, of the fraction boiling at 164—166°, a methyl dichlorethyl ketone is obtained as a colourless liquid boiling at 165° under a pressure of 753 mm.; its vapour density is 4.8, and its sp. gr. at 0° = 1.096.

Both the above chlorinated derivatives are insoluble in water, but dissolve in alcohol and ether; they form crystalline compounds with sodium hydrogen sulphite, and are reduced by nascent hydrogen to methyl ethyl ketone. Sodium hydroxide acts on monochloromethyl ethyl ketone to form dimethylketone (compare *Abstr.*, 1890, 1234), so that its constitution is probably $\text{COMe} \cdot \text{CHCl} \cdot \text{Me}$, whilst dichloromethyl ethyl ketone, on treatment with potassium hydroxide, yields diacetyl, and is probably $\text{COMe} \cdot \text{CCl}_2 \cdot \text{Me}$. T. G. N.

Preparation of Triacetin. By C. BÜTTINGER (*Annalen*, 263, 359—360).—Triacetin can be very conveniently prepared by heating glycerol (20 c.c.) with acetic anhydride (10 c.c.) and finely divided potassium hydrogen sulphate (50 grams) until the reaction is at an end and the two liquids have formed a homogeneous mixture, and then gradually adding a further quantity (20 c.c.) of acetic anhydride to the boiling solution, when a very energetic reaction takes place. After boiling for a short time, the solution is decanted from the salt, mixed with ether, filtered, the ether evaporated, and the product purified by fractional distillation. Triacetin passes over at 264—268°, and a smaller quantity of diacetin at about 285°. F. S. K.

Cyanisonitrosoacetic Acid. By H. G. SÜDERBAUM (*Ber.*, **24**, 1983—1992).—The acid previously described as frazancarboxylic acid (this vol., p. 827) closely resembles Wolff and Gans' so-called cyanonitrosoacetic acid in properties (this vol., p. 897), and the only points of difference between the author's acid and that of Wolff and Gans (stability in a desiccator and stability on boiling with caustic alkali) have been removed by a further examination of a fresh quantity of the acid under the conditions employed by Wolff and Ganz. The copper salt, $C_2N_2O_3Cu + 4H_2O$, crystallises in six-sided, or seemingly four-sided, tablets of rhombic character, is rather sparingly soluble in cold water, and, like the silver and calcium salts, agrees in all respects with the corresponding salt of Wolff and Gans' acid. W. P. W.

Alloisomerism: De-halogenisation of Ethyl Salts of α - β -Halogenised Acids. By A. MICHAEL and O. SCHULTHEISS (*J. pr. Chem.* [2], **43**, 587—596).—Hitherto support for the Van't Hoff-Wislicenus hypothesis has been sought for by de-halogenising halogen-alkyl compounds (*Abstr.*, 1889, 236, 576). These compounds are difficult to prepare in a state of purity, and the authors hope that a study of the ethyl salts of α - β -halogenised acids will prove more productive of results.

When zinc acts on a cooled solution of ethyl α - β -dibromopropionate in ether, zinc bromide is formed, and by shaking the solution with water to remove this salt, evaporating off the ether, and distilling, a good yield of ethyl acrylate is obtained. It was noted that ethyl acrylate can dissolve zinc bromide, and that the above reaction will not take place in absolute ether, a very small quantity of water being necessary.

Ethyl α - β -dibromobutyrate is obtained by saturating an alcoholic solution of dibromobutyric acid (m. p. 87°) with hydrogen chloride; it is an oil which boils at 110.5 — 111° (21 mm.) and does not dissolve in water. By acting on it with zinc in an ethereal solution at the ordinary temperature, ethyl crotonate was obtained, which, on hydrolysis, yielded crotonic acid of m. p. 72° .

Claus (*Abstr.*, 1883, 43) found that when ethyl dibromosuccinate is treated with zinc and ethyl bromide, the latter is not acted on, while 1 or 2 atoms of zinc enter into combination with the acid, without removing bromine, and syrupy liquids containing zinc are formed. The authors have repeated this experiment, and find that when the ethyl bromide is dry no reaction takes place, but on the addition of a drop of water the action is violent, and zinc bromide and ethyl fumarate (equal molecular proportions) are formed, and can be separated by shaking with water. Claus' syrupy liquids were solutions of zinc bromide in ethyl fumarate (compare above). The same results were obtained when ether was substituted for ethyl bromide; no reaction occurred if the ether was absolute. No ethyl maleate could be detected. Ethyl allobromosuccinate was similarly treated, but only ethyl fumarate was obtained; this is contrary to the Van't Hoff-Wislicenus hypothesis, according to which ethyl maleate should have

been formed. The temperature of the above reactions did not rise above 25° , and the solutions remained neutral.

Ethyl citradibromopyrotartrate, obtained by acting on ethyl citraconate in ether with bromine in daylight, boils at 164° (22 mm.).

Ethyl itadibromopyrotartrate is similarly prepared in a chloroform solution; it is a colourless oil, and boils at 158° (19 mm.). The former of these salts yields mesaconic acid when the product of the action of zinc on its moist ethereal solution is saponified, while the latter yields itaconic acid under the same conditions; the temperature did not rise above 25° during the reaction. According to the Van't Hoff-Wislicenus hypothesis, citraconic acid should be formed when ethyl citradibromopyrotartrate is dehalogenised; but the authors found no trace of it.

When ethyl α,β -trichlorobutyrate (b. p. 101.5 ; 17 mm.) is dehalogenised in the way described above, ethyl α -chlorocrotonate (m. p. $172-173^{\circ}$) is formed, and no ethyl allo- α -chlorocrotonate, which should have been formed, according to the Van't Hoff-Wislicenus hypothesis (compare Liebermann, this vol., p. 832). A. G. B.

Preparation of Ethereal Salts of β -Ketonic Acids. By J. HAMONET (*Bull. Soc. Chim.* [3], 5, 23; compare Abstr., 1890, 235, 1891, 41).—Bouveault states that the author's method for preparing alkyl β -ketonates yields only salts of the general formula

the latter replies that if these salts are first acted on by sodium, and subsequently by an alkyl iodide or an acid chloride, compounds corresponding with the formula $R \cdot CH_2 \cdot CO \cdot CR'R'' \cdot COOR'''$ are obtained.

T. G. N.

Hydroxylevulinic Acid and Acetylacrylic Acid. By L. WOLFF (*Annalen*, 264, 229—260).—It has been previously shown (Abstr., 1887, 464) that when the β -bromolevulinic acid obtained from the dibromide of angelicalactone is treated with sodium carbonate, it yields β -hydroxylevulinic acid and acetylacrylic acid; some additional facts regarding these two compounds and their derivatives are given in this paper.

The lactide, $O \left\langle \begin{smallmatrix} CH_3CO \cdot CH_2 \cdot CO \\ CO \cdot CH_2 \cdot CH_3 \end{smallmatrix} \right\rangle$, is gradually deposited in slender needles when β -hydroxylevulinic acid is kept over sulphuric acid; it is also formed, with elimination of water, carbonic anhydride, and diacetyl, when the acid is heated at 150° . It separates from boiling alcohol and chloroform in colourless needles, sinters together at 238° , melts at 240° with decomposition, and is insoluble in sodium carbonate, and only sparingly soluble in cold water, alcohol, chloroform, ether, and carbon bisulphide; it is slowly reconverted into the acid by boiling water.

When β -hydroxylevulinic acid is heated with phenylhydrazine at 100° , diacetylosazone (m. p. 244°) is formed with evolution of carbonic anhydride and ammonia.

Isanitrosohydroxyvaleric acid, $OH \cdot N \cdot CMe \cdot CH(OH) \cdot CH_2 \cdot COOH$, pre-

pared by treating 3-hydroxylevulinic acid with hydroxylamine in alkaline solution at the ordinary temperature, crystallises from water in colourless, lustrous plates or prisms, melts at 145° with evolution of carbonic anhydride, and is very readily soluble in hot water, but only moderately easily in cold water, and sparingly in ether, benzene, chloroform, carbon bisulphide, and light petroleum; in its aqueous solutions ferric chloride produces a red coloration which disappears on the addition of hydrochloric acid. The *calcium* salt, $(C_5H_7NO)_2Ca$, crystallises in needles, is moderately easily soluble in water, and seems to contain 1 mol. H_2O . The *silver* salt, C_5H_7NO, Ag , crystallises from water in lustrous needles, and is gradually decomposed by boiling water. When the acid is distilled, it is completely decomposed, yielding as principal products tetramethylpyrazine (*loc. cit.*) and diacetyldioxime; these two compounds combine together to form a colourless, crystalline substance having the composition

which separates from boiling benzene in slender needles, melts and sublimes at 178° , and is readily soluble in warm ether and alcohol, but only sparingly in cold water, chloroform, benzene, and carbon bisulphide; it is decomposed into its constituents by acids, alkalis, and boiling water.

Acetylacrylic acid is best prepared by heating β -bromolevulinic acid (1 part) with anhydrous sodium acetate (1 part) and glacial acetic acid ($1\frac{1}{2}$ parts) for half an hour at 100° ; the yield of the pure acid is 90 per cent. of the theoretical. The *ethyl* salt, $C_5H_7O_3Et$, prepared from the silver salt, or from ethyl β -bromolevulinate, is a colourless oil of sp. gr. 1.057 at 0° , and boiling at $206-207^{\circ}$; it is readily soluble in ether and alcohol, but only sparingly in water, and its vapours are very irritating. The *oxime*, $OH \cdot N : CMe \cdot CH : CH \cdot COOH$, separates from hot water in colourless, cauliflower-like aggregates, melts at 206° with decomposition, and is readily soluble in alcohol and moderately easily in hot water and ether, but only sparingly in cold water, carbon bisulphide, benzene, and chloroform; in its aqueous solution, ferric chloride produces a red coloration. The *barium* salt, $(C_5H_7NO_3)_2Ba$, crystallises from water in small plates, and is very readily soluble in warm water; in its aqueous solution, silver nitrate produces a flocculent, sparingly soluble precipitate, and ferric chloride a red precipitate which dissolves in hot water with an intense red coloration. The *hydrazine*, $N_2HPh \cdot CMe \cdot CH : CH \cdot COOH$, crystallises from boiling water in yellow needles, melts at 160° with decomposition when heated quickly, and is readily soluble in alcohol, ether, and boiling water; when heated at its melting point, it yields a basic substance which is probably identical with the phenylmethylpyridazone described by Ach (Abstr., 1889, 70).

When acetylacrylic acid is boiled with barium hydroxide, it is decomposed into acetone, oxalic acid, and two other acids, one of which is crystalline and readily soluble in ether; the other is a thick, dark syrup, sparingly soluble in ether. The crystalline *acid* has the composition $C_5H_4O_3$, melts at 207° , and is readily soluble in alcohol and hot water, but only sparingly in chloroform and benzene; its

calcium salt is readily soluble, but its silver salt, $C_5H_5O_3Ag_2$, is very sparingly soluble in boiling water.

$\alpha\beta$ -Dibromolevulinic acid, $C_5H_5O_3Br_2$, is formed when acetylacrylic acid is treated with bromine in ice-cold chloroform solution; it crystallises from hot benzene in lustrous needles, melts at 108° , and is very readily soluble in ether, alcohol, and hot benzene, but only moderately easily in cold water and chloroform, and sparingly in light petroleum and carbon bisulphide.

When acetylacrylic acid is reduced with sodium amalgam, it is converted into levulinic acid and hydroxyvaleric acid.

α -Bromolevulinic acid, $C_5H_7O_3Br$, is produced, together with dibromolevulinic acid (m. p. $114-115^\circ$) and small quantities of β -bromolevulinic acid (m. p. 59°), when acetylacrylic acid is heated with hydrobromic acid at 100° for some hours. The two compounds are separated by means of chloroform, in which the monobromoderivative is readily soluble. It crystallises from carbon bisulphide in lustrous plates, melts at $79-80^\circ$, and is readily soluble in ether and alcohol, but only moderately easily in water, benzene, and boiling carbon bisulphide, and sparingly in light petroleum.

α -Hydroxylevulinic acid, $C_5H_7O_4$, prepared by boiling the preceding compound with water, crystallises from warm water in colourless needles, sinters together at 100° , and melts at $103-104^\circ$; it is readily soluble in water and alcohol, but only moderately easily in ether and chloroform, and very sparingly in carbon bisulphide, benzene, and light petroleum; it reduces Fehling's and ammoniacal silver nitrate solutions. The calcium salt is amorphous, and the silver salt is unstable. The lactide, $C_{10}H_{12}O_5$, is formed when the acid is heated at about 100° ; it crystallises from boiling alcohol in slender needles, melts at 263° with decomposition, and is only sparingly soluble in water, ether, carbon bisulphide, chloroform, and cold alcohol; it is gradually reconverted into the acid by boiling water. F. S. K.

Action of Ammonia and Aniline on Ethyl α -Acetoglutarate.

By W. O. EMERY (*Amer. Chem. J.*, 13, 351-354; compare this vol., p. 544).—A mixture of ethyl α -acetoglutarate (1 vol.) and concentrated alcoholic ammonia (2 vols.), after standing 24 hours in the cold, and distilling off the unchanged portion, deposits white crystals of a substance which may be regarded as the lactam of ethyl α -amido- α -ethylideneglutarate, $CO < \begin{smallmatrix} NH \cdot CMe \\ CH_2 \cdot CH_2 \end{smallmatrix} > C \cdot COOEt$. It melts at 156° , and is soluble in chloroform and ether.

When aniline is substituted for the ammonia, the residue left after the distillation crystallises on the addition of ether. The white substance thus obtained may be regarded as the lactam of ethyl α -anilido- α -ethylideneglutarate, $CO < \begin{smallmatrix} NPh \cdot CMe \\ CH_2 \cdot CH_2 \end{smallmatrix} > C \cdot COOEt$. It melts at 196° , and is easily soluble in chloroform, but with difficulty in ether. Jn. W.

Tetric Acid, Oxytetric Acid, and their Homologues. By P. WALDEN (*Ber.*, 24, 2025-2039).—The compounds obtained by

Demarçay (Abstr., 1890, 625) from the monobromo- and dibromo-substitution products of ethyl alkylacetoacetates, and described under the above title, have been since then repeatedly investigated, without any certain conclusion being reached (Abstr., 1883, 730, 1085; 1884, 834). The two most recent suggestions with regard to tetric acid are those of Moscheles (Abstr., 1888, 1272), who regards it as a lactone of the formula

$$\begin{array}{c} \text{CHMe}\cdot\text{CO} \\ \text{CO} \text{---} \text{O} > \text{CH}_2 \end{array}$$

and of Wolff (this vol., p. 416), who proposes the formula

$$\begin{array}{c} \text{CH}_3 \\ \text{CO} > \text{CMe}\cdot\text{COOH} \end{array}$$

In order to ascertain whether the acid behaves as a true carboxylic acid, the author has determined the conductivity of the normal sodium salt, which, according to Ostwald's experiments, is a certain criterion of the basicity of the acid. The results obtained with tetric acid and its homologues agree well with the supposition that they are monobasic acids; for the sake of comparison, the author determined the conductivity of certain substances which behave in some respects as acids, namely, Kiliani's saccharin, which has a constitution similar to that given by Moscheles for tetric acid, and of ethyl acetoacetate, ethyl ethylacetoacetate, trihydroxyquinoline, and α -naphthol, all of which proved, as expected, to be very bad conductors, whilst the tetric acids have a conductivity five times as great as that of the fatty acids. On the other hand, it was found that ethyl orthonitrobenzoylmalonate, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{CH}(\text{COOEt})_2$ (Abstr., 1885, 263), gave numbers as high as a true carboxylic acid, and is indeed so strong an acid that it decomposes solutions of potassium acetate, succinate, &c. Hence the question of the presence of the carboxyl group in tetric acid, &c., must still be regarded as open.

Oxytetric acid and its homologues show conductivity constants which agree with the supposition that they are dicarboxylic acids, and further investigation has shown that they are in reality alkyl-substituted fumaric acids. Thus oxytetric acid is identical with mesaconic acid, oxypentic acid with ethylfumaric acid, and so on. In the same manner, the acids described by Demarçay as hydroxytetric acid, &c., and which differ from the oxy-acids in containing two additional hydrogen atoms, are identical with the alkylsuccinic acids, hydroxytetric acid being methylsuccinic acid, hydroxypentic acid ethylsuccinic acid, and so on.

The preparation of alkylfumaric acids by Demarçay's method gives a comparatively good yield, and the operations are fairly simple. The bromination of the substituted ethyl acetoacetate is best carried out in ethereal solution, cooling well with ice-cold water, the dibromo-compound remaining on evaporation of the ether, gradually adding to a mixture of 5 mols. of potash with half its weight of alcohol, with continuous shaking and cooling. After warming for half-an-hour at 100° , volatile products are removed by a current of steam, and the residue acidified and extracted repeatedly with ether. The crude product which remains on evaporating the ether is purified by several crystallisations from water, with addition of animal charcoal. To convert the substituted fumaric acids thus

obtained into the corresponding succinic acids, the best reducing agent is granulated zinc and dilute sulphuric acid.

Tetric acid and its next higher homologues are obtained by heating the monobromo-derivatives of the substituted ethyl acetoacetates under pressure at 100° for six hours, washing the product with a mixture of benzene and light petroleum, and recrystallising from water. The higher homologues are formed simply by allowing the brominated ethereal salts to remain, or more quickly by warming them in an open flask. H. G. C.

Electrolysis of Cobalt Salts of Oxalic Acid. By F. KEHRMANN and N. PICKERSGILL (*Ber.*, 24, 2324—2326).—The authors have isolated the green salt obtained by the electrolysis of cobaltous oxalate dissolved in potassium oxalate, and find it to have the composition $3K_2C_2O_4 + Co_2(C_2O_4)_3 + 6H_2O$, and to be identical with the salt obtained by dissolving cobaltic hydroxide in a concentrated solution of acid potassium oxalate (*Abstr.*, 1887, 220). Cobalt oxalate is dissolved in a boiling saturated solution of potassium oxalate, and electrolysed in a platinum dish with constant addition of acetic acid, so as to maintain the mixture faintly acid. When the green colour has reached a maximum intensity, the solution is fractionally precipitated with alcohol; cobaltous potassium oxalate and potassium oxalate are at first precipitated. The mother liquor is then precipitated with a large volume of alcohol, and the green precipitate purified by solution in water and reprecipitation with alcohol. It is thus obtained in beautiful, dark-green crystals. The aqueous solution of the salt acts as a strong oxidising agent, and on boiling is decolorised with precipitation of cobaltous oxide salt.

No corresponding compound was obtained on treating nickel potassium oxalate in the same way. Mangano-potassium oxalate gave an intense purple-red solution, but the compound is so unstable that the authors have not yet been able to isolate it. E. C. R.

Determination of the Structure of Fatty Acids by Bromination. By K. AUWERS and R. BERNHARDI (*Ber.*, 24, 2209—2233).—The bromination of fatty acids by means of bromine and amorphous phosphorus, in the manner described by Hell, Volhard, and Zelinsky, has frequently been a subject of investigation, and from the facts afforded by the experiments hitherto carried out, the following rules may be laid down:—(1.) Fatty acids yield a bromo-substitution product only when the molecule contains at least one atom of hydrogen in the α -position relatively to the carboxy-group. (2.) When bromination takes place at all, the product is invariably a monobromo-derivative. As these rules are based on very insufficient evidence, the authors have studied the behaviour of a large number of mono- and di-carboxylic acids under the conditions referred to above, and more fully described below; the following statements give a summary of their results:—(1.) All fatty mono- and di-carboxylic acids which contain one or more atoms of hydrogen in the α -position relatively to the carboxy-group are easily brominated, and the size of the molecule does not influence the course of the reaction. (2.) The greatest

number of atoms of hydrogen which are substituted by bromine under the normal conditions is equal to the number of carboxy-groups in the molecule of the acid; when, however, a very large excess of the theoretical quantity of bromine is employed, and the duration of the experiment is greatly extended, a comparatively very small quantity of a dibromo-derivative is obtained in the case of acetic, propionic (P), and normal butyric acids. (3.) Dicarboxylic acids, such as malonic acid and glutaric acid, which contain hydrogen atoms in the α -position to both the carboxy-groups, yield dibromo-substitution products; succinic acid and its alkyl derivatives form an exception to this rule (compare following abstract). It must be stated, however, that no experiments were made by the authors to prove that the bromine atom in the substitution product really occupies the α -position to the carboxy-group; that it does so in the case of α -bromisobutyric acid and α -bromopalmitic acid has been already shown by Bischoff, and by Hell and Jordanoff; judging by analogy, it may be assumed, therefore, that this is also true in the case of other fatty acids, especially as substitution takes place only when the acid contains a hydrogen atom in the α -position.

The experiments were carried out as follows:—A quantity of bromine, calculated from the equations:—

is gradually added to a mixture of the acid (10–20 grams) and the theoretical quantity of amorphous phosphorus, any considerable rise of temperature being avoided; the mixture is then gradually heated to 90–100°, and small quantities of bromine added, until the evolution of hydrogen bromide ceases; this extra quantity of the halogen is added to compensate for loss during the process. In the case of the monocarboxylic acids, the reaction usually occupies a few hours, but for the conversion of the dicarboxylic acids into dibromo-derivatives 10–15 hours are required. Finally the product is treated with absolute alcohol, and the ethereal salt produced in this way submitted to fractional distillation, or the product is decomposed with water, and the brominated acid purified by the usual methods.

The new compounds obtained in the course of this investigation will be now described.

Ethyl bromocaprylate, $C_{10}H_{18}BrO_2$, is a colourless liquid boiling at 245–247° under the ordinary pressure, and at 170–176° under a pressure of 100°.

Bromolauric acid, $C_{12}H_{22}BrO_2$, is a colourless, crystalline compound melting at 30–31·5°; it is almost insoluble in cold water, and only sparingly soluble in cold light petroleum, but readily in alcohol, benzene, ether, and chloroform. The *ethyl* salt, $C_{14}H_{27}BrO_2$, boils at 172–174° under a pressure of 10·5 mm.

Ethyl bromostearate, $C_{20}H_{38}BrO_2$, melts at 33–34·5°, and is readily soluble in ether, chloroform, light petroleum, and benzene, but only sparingly in cold alcohol, and insoluble in water.

Dibromoglutaric acid (normal), $C_6H_6Br_2O_4$, crystallises from ether in compact prisms, melts at $169-170^\circ$, and is readily soluble in ether, glacial acetic acid, and hot water, but almost insoluble in benzene, chloroform, and light petroleum; the *ethyl* salt, $C_8H_{14}Br_2O_4$, boils at about 160° under a pressure of 21 mm.

Dibromo- β -methylglutaric acid, $C_7H_8Br_2O_4$, separates from benzene in crystals melting at $151-152^\circ$.

Dibromosebacic acid, $C_{10}H_{14}Br_2O_4$, crystallises in needles, melts at $117.5-119^\circ$, and is readily soluble in hot water, alcohol, ether, chloroform, and hot benzene, but only sparingly in cold benzene, and insoluble in water.

F. S. K.

Bromination of Succinic Acid and its Alkyl Derivatives.

By K. AUWERS and A. IWHÄUSER (*Ber.*, 24, 2233-2240).—When succinic acid is treated with bromine and amorphous phosphorus in the manner described in the preceding abstract, the principal product is monobromosuccinic acid; only small quantities of the dibromo-acid are produced, even when the succinic acid is treated first at the ordinary temperature, and then for a long time at about 90° , with a quantity of bromine sufficient to convert the whole of the acid into the dibromo-derivative. Glutaric acid, like succinic acid, is only brominated with difficulty in comparison with other dicarboxylic acids; when the acid is heated with bromine at about 90° , the monobromo-derivative is the principal product, but larger or smaller quantities of the dibromo acid are formed according to the conditions of the experiment; when the mixture is heated at 107° , the principal product is the dibromo-acid, a small quantity of the anhydride of bromocitraconic acid being also produced. The bromoglutaric acid obtained in this way melts at 147° and is probably identical with citrabromoglutaric acid (m. p. 148°); the dibromo-derivative melts at $150-151^\circ$, and seems to be identical with citradibromoglutaric acid (m. p. 150°).

When either of the symmetrical dimethylsuccinic acids is treated with bromine and amorphous phosphorus under various conditions, the principal product is invariably pyrocinchonic anhydride (m. p. 96°); a small quantity of a colourless, crystalline compound melting at $135-160^\circ$ was also obtained in some of the experiments, but the formation of the monobromo-substitution product, described by Hell and Rothberg (*Abstr.*, 1889, 371), was not observed.

F. S. K.

Monoximes of Succinic Acid. By A. PIETRI (*Ber.*, 24, 2287-2290).—Hantzsch has stated that the reason for his work on these compounds (Hantzsch and Cramer, this vol., p. 823) was that the author had retained a formula which represented the nitrogen combined with two carbon atoms in spite of his (Hantzsch's) paper "On the Position in Space of Atoms in Molecules containing Nitrogen" (*Abstr.*, 1890, 348). The author states that his paper here referred to "On a New Synthesis of Asparagin" was laid before the Reale Accademia di Napoli before he had seen Hantzsch's paper.

Since then he has obtained a large number of results which agree

with those obtained by Hantzsch, and gives a list of the compounds he has prepared. E. C. R.

Electrolytic Synthesis of Bibasic Acids. By A. CRUM BROWN and J. WALKER (*Annalen*, 261, 107—128; also *Trans. Roy. Soc. Edin.*, 36, 211—224).—When an aqueous solution of potassium acetate is electrolysed, the following reactions take place at the anode:—

- (1.) $2\text{CH}_3\text{COO} + \text{H}_2\text{O} = 2\text{CH}_3\text{COOH} + \text{O}.$
- (2.) $2\text{CH}_3\text{COO} = \text{CH}_3\text{CH}_3 + 2\text{CO}_2.$
- (3.) $2\text{CH}_3\text{COO} = \text{CH}_3\text{COOCH}_3 + \text{CO}_2.$

In a weak solution, the first action predominates; in a concentrated solution, the second. The authors find that strong solutions of potassium ethyl salts of acids of the oxalic series are also decomposed according to equation 2. Thus in the case of potassium ethyl malonate we have $2\text{COOEt}\cdot\text{CH}_2\cdot\text{COO} = \text{COOEt}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOEt} + 2\text{CO}_2$, obtaining in this way succinic acid from its lower homologue malonic acid. In the same way, adipic acid may be obtained from succinic acid, and so the oxalic acid series may be ascended (compare *Abstr.*, 1890, 583).

The electrolysis is conducted in a large platinum crucible (4·8 cm. high, 4·3 cm. across), which serves as cathode. The anode is a stout platinum wire, wound into a spiral, and presenting a surface equal to $\frac{1}{30}$ th of the internal surface of the crucible. This ensures a great current density at the anode, which the authors show to be essential to the success of the synthesis. The current employed has a strength of 3—5 ampères and an E.M.F. of 12 volts. The crucible is cooled by a current of water flowing round it. All the potassium ethyl salts examined were found to be excessively soluble in water; the best concentration for electrolysis is 1·5 to 2 parts salt in 1 part water. 25 grams of potassium ethyl malonate could be electrolysed under the above conditions in an hour, giving 9·2 grams of diethyl succinate, equal to 60 per cent. of the theoretical quantity. The synthesis goes equally well with potassium methyl salts.

Besides the ethereal salts formed according to the equation, other ethereal products appear with the higher acids of the series, but these were not investigated.

The succinic and adipic acids obtained in the above manner are identical with those prepared in other ways. The yield of diethyl adipate from ethyl potassium succinate was 35 per cent. of the theoretical. From ethyl potassium adipate, the diethyl salt of ordinary sebacic acid was obtained (yield 20 per cent.), thus proving that sebacic acid is a normal bibasic acid. Similarly, from ethyl potassium glutarate ordinary diethyl suberate was prepared (yield 28 per cent.). Suberic acid is thus also normal.

Ethyl potassium suberate, on electrolysis, yielded the diethyl salt of a new acid, *normal dicarbododecanic acid*,

The diethyl salt is a crystalline mass melting at 27°. The acid melts

at 123°, and is decomposed at high temperatures. It is very slightly soluble in water, soluble in hot alcohol and ether. The alkaline salts are soluble in water; the others are insoluble. Yield 25 per cent.

Another new acid, *normal dicarbodecahexonic acid*,

was prepared similarly from sebacic acid. In this case the electrolytic solution must be warmed to 50° in order that the current may continue to flow, as the diethyl salt which is formed melts only at 43°. The acid melts at 118°, is scarcely soluble in water, slightly soluble in ether, but easily soluble in hot alcohol. Only the alkaline salts are soluble in water. Yield 20 per cent.

The potassium ethyl salts for electrolysis are prepared from the corresponding diethyl salts, which are half saponified by the calculated quantity of alcoholic potash. The alcoholic solution is evaporated to dryness, and the residue taken up with water, the resulting aqueous solution being then shaken out with ether, and evaporated to the proper concentration. The ethereal products of the electrolysis float to the surface as oils, which may be easily separated and purified.

J. W.

Synthesis of Alkyl Derivatives of Succinic Acid. By A. CRUM BROWN and J. WALKER (*Proc. Roy. Soc. Edin.*, 18, 95—97).—Ethyl potassium methylmalonate (150 grams), on electrolysis (compare preceding abstract), yielded an ethereal product (60 grams) of which half boiled between 194° and 206°.

This fraction was saponified, and the resulting potassium salt converted into acid. The crude acid was freed from a small quantity of oil, and subjected to systematic fractional crystallisation from water. Two acids were thus obtained, both having the composition $\text{C}_8\text{H}_{10}\text{O}_4$. The less soluble acid melted at 193°, the other at 120—121°. From an investigation of their properties, including the electrical conductivity, these acids were found to be identical with anti- and para-*s*-dimethylsuccinic acids (m. p. 194° and 120° respectively).

In like manner, ethyl potassium ethylmalonate yielded, on electrolysis and treatment as above, two isomeric acids of the composition $\text{C}_8\text{H}_{14}\text{O}_4$. On further examination, these proved to be para-symmetrical-diethylsuccinic acid (m. p. 192° with decomposition) and anti-symmetrical-diethylsuccinic acid (m. p. 130°).

J. W.

New Isomeride of Mucic Acid and the so-called Paramucic Acid. By E. FISCHER (*Ber.*, 24, 2136—2143).—The dicarboxylic, just like the monocarboxylic, acids of the sugar group can be partially converted into their stereochemical isomerides by heating them with quinoline, or with an aqueous solution of pyridine; when mucic acid (100 grams), which is almost insoluble in boiling quinoline, is heated at 140° for three hours with water (1 litre) and commercial pyridine (200 grams), it is partially transformed into a new isomeride, which the author names allomucic acid.

Allomucic acid, $\text{C}_8\text{H}_{10}\text{O}_8$, crystallises from water in microscopic needles, melts at 166—171° with decomposition, and is soluble in 10—12 parts of boiling water, but only very sparingly in alcohol; it

is optically inactive. It has a lower melting point than mucic acid, from which it differs also in being much more soluble in water. When its aqueous solution is boiled or evaporated, the acid is partially converted into a compound which is identical with the so-called paramucic acid, but which is in reality a lactone acid, as will be shown below. The potassium, sodium, ammonium, and magnesium salts are much more readily soluble in water than the corresponding salts of mucic acid. The calcium salt, $C_6H_8O_5Ca$, is obtained when a solution of the acid in water (50 parts) is neutralised with calcium carbonate; on evaporating the filtered solution, the salt is deposited in the form of a crystalline powder, which, when dried at 100° , seems to contain $1\frac{1}{2}$ mols. H_2O , part of which ($\frac{1}{2}$ mol.) is expelled at 130° ; the barium and cadmium salts, like the calcium salt, are crystalline and very sparingly soluble in water. The diphenylhydrazide, $C_6H_8O_5(N_2H_2Ph)_2$, is deposited in crystals when an aqueous solution of the acid is boiled for an hour with phenylhydrazine; it melts at 213° with decomposition when quickly heated, and is very sparingly soluble in hot water and alcohol. When allomucic acid (1 gram) is heated with concentrated hydrochloric acid (1 gram) and fuming hydrobromic acid (1 gram) at 150° for eight hours, it is converted into dehydromucic acid; d-mannosaccharic acid can also be transformed into dehydromucic acid by heating its lactone with a mixture of these two acids. When allomucic acid is heated with water and pyridine at 140° , it is partially converted into mucic acid.

The lactone acid of mucic acid, hitherto known as paramucic acid, is formed when a solution of mucic acid (30 grams) in water (2 litres) is boiled for 20–30 minutes, and the solution then evaporated to 300 c.c. over the free flame; the crystals of mucic acid (8 grams) are separated from the cold solution by filtration, the filtrate evaporated in a vacuum at about 50° to a thin syrup, and the residue mixed with pure acetone. The solution is again filtered from crystals of the acid, and evaporated over sulphuric acid under reduced pressure; the residue still contains a little acid, produced by the water present in the syrup, but when it is dissolved again in dry acetone, and the filtered solution evaporated over sulphuric acid, the pure lactone is obtained as a thick acid syrup. The compound has not yet been obtained in a crystalline condition, but that it is the lactone acid, and not the dicarboxylic acid, is amply proved by the whole behaviour of the compound, especially by the fact that, on titration with soda at 0° , the quantity of alkali required to neutralise the solution is only half that required when titration is carried out at 100° . When the lactone acid is heated with water at 100° , and the solution then allowed to cool, pure mucic acid is deposited in crystals; the same change takes place, but much more quickly, on warming the lactone acid with concentrated hydrochloric acid or with dilute nitric acid. It is very readily soluble in soda, being thereby converted into sodium mucate; it dissolves freely in alcohol, and is obtained unchanged as a syrup on evaporating the solution over sulphuric acid, but if the alcohol contains inorganic salts or traces of mineral acids, combination takes place between the alcohol and the lactone acid, and a crystalline compound melting at about 175° , which is probably impure ethyl

hydrogen mucate, is produced. It is readily reduced by sodium amalgam, yielding an aldehyde acid, from which it is probable that a new monocarboxylic acid of the dulcitol series can be obtained. The *hydrazide*, $C_6H_5O_7 \cdot N_2H_4Ph$, is deposited, after some time, when phenylhydrazine is added to a moderately concentrated solution of the lactone acid; it crystallises from hot water in colourless plates, melts at $190-195^\circ$ with decomposition, and is readily soluble in water.

It is clear, from the above facts, that all the present data regarding the solubility of mucic acid in hot water are incorrect; the method of estimating mucic acid, based on its slight solubility in water, is also an inaccurate process, but the errors of estimation would be considerably reduced in this case by evaporating with hydrochloric acid or dilute nitric acid to prevent the formation of the lactone acid.

F. S. K.

Ethyl Ethylenedicarbamate. By O. RHOTSSOPOULOS (*Ber.*, 24, 2268—2269).—Ethyl ethylenedicarbamate, $C_2H_4(NH \cdot COOEt)_2$, is obtained by the action of ethylenediamine on ethyl chlorocarbonate. The reaction takes place at the ordinary temperature and with development of heat. It forms long, white needles, insoluble in cold water, somewhat soluble in hot water, and easily in alcohol and ether. It melts at 113° , and when allowed to crystallise very slowly, it forms thick, monoclinic crystals. Unlike ethyl ethylenedicarbamate, it is very stable, is not decomposed by soda, and when heated sublimes for the most part without decomposition. Acetic anhydride has no action on it. An attempt to obtain ethylenedicarbimide by distilling it with phosphorus pentoxide failed.

E. C. R.

Constitution of the Tetrole Rings. By G. CIAMICIAN (*Ber.*, 24, 2122—2127).—The author criticises the views which have recently been put forward by Bamberger (this vol., p. 1032) on the constitution of closed chains of five atoms. In conjunction with Angeli, the author has lately shown that thiophen and its derivatives are more stable, as regards the breaking of the closed chain, than pyrroline and furfurole, whereas according to Bamberger all these compounds have the same character and belong to hexacentric systems, in which the nitrogen atom functions as a pentad, the sulphur and oxygen atoms as tetrads. Even if it be assumed that there are no double linkings in these compounds, there seems to be no reason for supposing that nitrogen functions as a pentad and oxygen and sulphur as tetrads; the three rings may just as well be regarded as tetracentric systems in order to account for their properties in accordance with Bamberger's ideas, and, moreover, the known facts do not warrant the assumption that pyrroline contains pentad nitrogen.

F. S. K.

Pyrone. By J. W. BRÜHL (*Ber.*, 24, 2450—2455).—Pyrone boils at $105-106^\circ$ under 13 mm. pressure, melts at $32-33^\circ$, solidifies at $31-32^\circ$, and has a sp. gr. of 1.1898 at $40.3^\circ/4^\circ$. On exposure to air and light, it rapidly becomes coloured, especially when warm. The refractive index was determined by the method recently described by the author (this vol., p. 513), and the numbers obtained at 40.3° for lithium, sodium, and thallium light were $n_{Li} = 1.51725$, $n_{Na} = 1.52383$,
4 l 2

and $n_{Ti} = 1.52994$. From these the values for the α , β , and γ hydrogen lines were calculated, that for H_α from n_{Li} and n_{Na} by Cauchy's equation, and those for H_β and H_γ from the numbers observed for French turpentine,

Li.	H _α .	Na.	Tl.	H _β .	H _γ .
1.46202	1.46252	1.46526	1.46836	1.47202	1.47779

by assuming that the differences $n_\beta - n_{Ti}$ and $n_\gamma - n_{Ti}$ stand in the same proportion as $n_{Ti} - n_{Li}$ for the two substances, the refractive indices of pyrone for the three rays being estimated, therefore, as $H_\alpha = 1.51821$, $H_\beta = 1.53726$, and $H_\gamma = 1.54880$. The specific refraction, N , that is, $\frac{n^2 - 1}{(n^2 + 2)d}$, molecular refraction, M , and molecular dispersion, $M_\gamma - M_\alpha$, for pyrone, calculated from these data, are given in the table.

N_α .	N_{Na} .	N_γ .	M_α .	M_{Na} .	M_γ .	$M_\gamma - M_\alpha$.
0.2548	0.2571	0.2673	24.46	24.68	25.66	1.20

Claisen's synthesis of chelidonic acid (this vol., p. 425) affords evidence in favour of the pyrone formula, $CO < \begin{smallmatrix} CH:CH \\ CH:CH \end{smallmatrix} > O$, first proposed by Lieben and Haitinger, but, as pyrone does not form additive compounds or a hydrazone or oxime, further confirmation seemed desirable. This is supplied by the data given, since for a compound of Lieben and Haitinger's formula the molecular refraction for H_α calculated by the author's method (this vol., p. 775) is $M_\alpha = 23.89$, and for sodium light calculated from Conrady's constants is $M_{Na} = 24.09$, numbers which agree well with the experimental values. The molecular dispersion for a compound of this formula calculated from the data given in the same paper is about 0.90, and the fact that the experimental value is 1.20 affords evidence in favour of the view there expressed, that when a carboxyl radicle is linked to unsaturated carbon atoms the dispersive power is unusually high.

W. P. W.

Action of Chlorine on Benzene in presence of Sulphuric Acid. By ISTRATI and PÉTRICOU (*Bull. Soc. Chim.* [3], 5, 165—168).—Dry chlorine is passed for six days through a mixture of benzene (200 c.c.) and sulphuric acid (300 c.c.) contained in a reflux apparatus, the temperature being increased from 80° upwards as chlorination proceeds. In addition to *franceïnes*, which are dissolved by the sulphuric acid, a solid mass of chlorobenzene is obtained, consisting of tetrachlorobenzene (1:2:4:5), pentachlorobenzene, and small quantities of monochlorobenzene and paradichlorobenzene. The author also separated some chlorobenzenesulphonic acid, $C_6H_4Cl \cdot SO_3H$, which bears out his theory that the final chloro-derivatives are formed from the action of hydrochloric acid on intermediary chlorosulphonic acids.

T. G. N.

Benzene Hexachlorides. By C. FRIEDEL (*Bull. Soc. Chim.* [3], 5, 130—138).—The author endeavours to account for the existence of the two isomeric benzene hexachlorides by arguments based on the

possible stereochemical constitution of the two substances. The original paper should be consulted. T. G. N.

New Method of Iodation in the Aromatic Series. By ISTRATI (*Bull. Soc. Chim.* [3], 5, 158—162).—In preparing franceïnes by the action of concentrated sulphuric acid on halogen derivatives of benzene, a migration of the halogen occurs, resulting in the formation of higher derivatives (compare Abstr., 1890, 51), this having also been noticed by Herzig (Abstr., 1882, 46) and by Neumann (Abstr., 1887, 573). The author's process is as follows:—Benzene (1 litre), sulphuric acid, sp. gr. 1.84 (2 litres), are introduced into a reflux apparatus of about 5 litres capacity, and so soon as sulphonation is induced by gentle warmth a corresponding quantity of iodine is added. Iodation begins at 80°, and as it progresses the temperature may be increased to 200°. The author explains the reaction according to the following equations:—(1) $C_6H_5\cdot SO_3H + I_2 = C_6H_4I\cdot SO_3H + HI$, (2) $C_6H_4I\cdot SO_3H + HI = SO_2 + H_2O + C_6H_4I_2$, and this is borne out by the fact that much SO_2 is evolved during the reaction, while the sulphonic acids which exist in quantity at that stage of the process when the diiodo-derivative is formed have almost completely disappeared when the tetraiodo-derivative is produced. In the case of the higher homologues of benzene, great care must be exercised in heating the mixture, or carbonisation ensues. T. G. N.

Iodopentachlorobenzene. By ISTRATI (*Bull. Soc. Chim.* [3], 5, 169).—Pentachlorobenzene melting at 74° and boiling at 272° (10⁶ grams), sulphuric acid, sp. gr. 1.84 (400 c.c.), and iodine (55 grams) are boiled together during 24 hours; on cooling, a substance is deposited which melts at 130—135°. The supernatant sulphuric acid contains a franceïn. After treatment of the mass with soda and washing with distilled water, the excess of pentachlorobenzene is removed by extracting with hot alcohol, and the residue of iodopentachlorobenzene is purified by recrystallisation from chloroform. The substance forms colourless, silky needles which melt at 207.5—208°, and its solution in chloroform is decomposed by sunlight. T. G. N.

Orthonitrotoluene. By F. STRENG (*Ber.*, 24, 1987).—Orthonitrotoluene is usually stated to boil at 223°, and to remain liquid at -2j°. Pure orthonitrotoluene, free from the para-compound, boils at 218°, solidifies completely at -10.5°, and has a sp. gr. = 1.168 at 15°. W. P. W.

Occurrence of Ethylbenzene in Commercial Xylene. By E. NOELTING and G. A. PALMAR (*Ber.*, 24, 1955—1958).—The occurrence of ethylbenzene in coal-tar has not hitherto been observed, although the presence of ethyl alcohol in the "first runnings" of the benzene stills has been recorded. In separating paraxylene from coal-tar xylene by Jacobsen's method (this Journal, 1877, i, 600) the authors obtained a hydrocarbon which boiled at 134—138°, and did not crystallise even in a good freezing mixture. On bromination by Friedel and Crafts' method (Abstr., 1886, 229), this gave a mixture of tetra-

bromoxylene and pentabromomethylbenzene, and as a result it was found that two-thirds of the supposed paraxylene consisted of ethylbenzene corresponding with an approximate proportion of 10 per cent. in the crude xylene. All specimens of coal-tar xylene subsequently examined have been found to contain ethylbenzene, although in smaller proportion, and the presence of ethylaniline in commercial xylydine has also been detected.

W. P. W.

Colouring Matter of Red Carbohc Acid. By E. FABINI (*Chem. Centr.*, 1891, i, 401, and 448; from *Pharm. Post*, 24, 41).—If reduced copper be dissolved in pure phenol out of contact with the air, a yellowish-brown solution is formed, which does not become red. If this solution be shaken with 1 part of water, light-brown flakes are precipitated, which are insoluble in alcohol, ether, &c. The phenol containing this compound, *copper diphenyl*, CuPh_2 , becomes intensively carmine-coloured when treated with a little ammonia and hydrogen peroxide. If the colouring matter be precipitated with water and extracted with ether, the copper diphenyl remaining has not lost weight, but is now darker coloured, owing to some change in composition. If pure phenol be treated with ammonia and hydrogen peroxide, no formation of the red dye occurs; if a knife blade be dipped into this, blood-red streaks will commence to flow from its surface. The author considers that the most probable cause of the partly liquid condition of phenol is the presence of ammonium phenoxide, which is liquid, and the brown colour is attributable to the presence of copper or iron, 0.0001 per cent. of either of these metals being sufficient to cause a dark-brown coloration. Oxygen or bleaching powder acts on ammonium phenoxide with formation of a blue colouring matter, phenocyanin, which is soluble in ether in presence of free acid. The ethereal solution is red, and the residue left on evaporation of the ether dissolves in concentrated sulphuric acid, forming a green solution, the colour becoming, later, less distinctive. This colouring matter is quite distinct from the copper diphenyl, which does not become blue on addition of ammonia.

J. W. L.

Action of Epichlorhydrin on Phenols. By T. V. LINDEMANN (*Ber.*, 24, 2145—2149).—*Phenyl α -chlorohydrin ether*,

is formed, together with phenyl glycidol ether (see below), when phenol is heated with epichlorohydrin at 150° for six hours; the two products are separated by distillation with steam, the last-named compound alone being volatile. Phenyl α -chlorohydrin ether is a yellow oil and cannot be distilled even under reduced pressure; when boiled with an aqueous solution of potassium phenate, it is converted into diphenylglycerol (m. p. $80-81^\circ$).

Phenyl glycidol ether, $\text{OPh}\cdot\text{CH}_2\cdot\text{CH}\begin{smallmatrix} \text{CH}_2 \\ \diagup \\ \text{O} \end{smallmatrix}$, boils at 234° with slight decomposition, but distills unchanged at 220° under a pressure of 520 mm.

Phenylglycerol, $\text{OPh}\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{OH}$, is formed when the

preceding compound is heated with water at 110—120°; it is a colourless, crystalline compound.

Paracresyl glycidol ether, $C_6H_4Me \cdot O \cdot CH_2 \cdot CH < \begin{smallmatrix} CH_2 \\ O \end{smallmatrix}$, separates as an oil when epichlorohydrin is added to an alkaline solution of paracresol; it boils at 210° under a pressure of 200 mm. with slight decomposition.

Diparacresylglycerol, $OH \cdot CH(CH_2 \cdot O \cdot C_6H_4Me)_2$, prepared by boiling paracresol with sodium ethoxide and epichlorohydrin in alcoholic solution, separates from alcohol and ether in colourless crystals and melts at 88°.

α-Naphthyl glycidol ether, $C_{10}H_7 \cdot O \cdot CH_2 \cdot CH < \begin{smallmatrix} CH_2 \\ O \end{smallmatrix}$, boils at about 263° with slight decomposition under a pressure of 200 mm.

Diglycidylcatechol, $C_6H_4(O \cdot CH_2 \cdot CH < \begin{smallmatrix} CH_2 \\ O \end{smallmatrix})_2$, obtained by heating an alkaline solution of catechol with epichlorohydrin at 120°, separates from ether in lustrous, waxy crystals, melts at 83—84°, and is readily soluble in alcohol and ether, but only sparingly in hot water.

F. S. K.

Action of Formaldehyde on Phenols. By W. KLEEBERG (*Annalen*, 263, 283—286).—Formaldehyde combines readily with phenol, resorcinol, and catechol, in presence of hydrochloric acid, but the products are insoluble in alkalis, and so difficult to purify that their composition could not be determined.

An acid of the composition $C_{16}H_{13}O_{10}$ is formed when concentrated hydrochloric acid is added to a warm aqueous solution of gallic acid and formaldehyde, and, on cooling, the product is deposited in an amorphous condition. It is purified by converting it into the *phenylhydrazine* salt, which crystallises in needles and has the composition $C_{16}H_{13}O_8 \cdot N_2H_3Ph$; on treating this salt with dilute hydrochloric acid, the acid is deposited in the form of a colourless, amorphous precipitate, which becomes crystalline when boiled for a long time with alcohol; the acid decomposes on heating, but without melting, and is only very sparingly soluble in alcohol, acetone, ether, benzene, and glacial acetic acid. The acid *ammonium* salt, $C_{16}H_{11}O_{10} \cdot NH_4$, is a reddish, crystalline compound.

F. S. K.

Orientation by Conversion of Paradinitro-derivatives into Quinones. By A. CLAUS, G. RAPS, E. HERFELDT, and W. BERKEFELD (*J. pr. Chem.* [2], 43, 563—586).—The following compounds were investigated with a view to ascertaining whether the method employed by Claus and Runschke (*Abstr.*, 1890, 1246) for the orientation of 4 : 6-dichlorometaxylene can be applied as a general method; the results obtained show that it can be so applied.

3 : 6-Diamido-2 : 5-dibromoparisocymene is obtained, contrary to Hömberg's statement (*J. pr. Chem.* [2], 42, 114), when the corresponding dinitro-derivative is reduced by the usual means, but the reaction takes place with difficulty; if stannous chloride be used,

sufficient alcohol must be present to keep the dinitro-derivative in solution; if zinc or iron dust be used, the temperature must not be too high. In either case, the dried product is made alkaline, if necessary, and extracted with ether; the ethereal solution is treated with hydrogen chloride, whereby the *hydrochloride* is precipitated. The diamido-derivative crystallises in small, colourless needles, dissolves easily in ether and in alcohol, and melts at 105° (uncorr.). The *platinochloride* is described.

2 : 5-Dibromoparisocymo-3 : 6-quinone is formed when the aqueous solution of the hydrochloride of the diamido-derivative is oxidised by chromic acid, and separates from the liquid product in bright-yellow leaflets; it crystallises from alcohol in thick, yellow prisms, sublimes in feathery crystals, and melts at 74° (uncorr.). By reduction with aqueous sulphurous acid in a sealed tube at 100° , it yields the corresponding *quinol* [Me : Pr^s : Br₂ : (OH)₂ = 1 : 4 : 2 : 5 : 3 : 6]; this forms white crystals and melts at 64° (uncorr.).

Detailed directions are here given for obtaining a good yield (67 per cent. of theory) of metacymene by the method of Claus and Stüsser (Abstr., 1880, 632).

4 : 6-Dibromometacymene, obtained by the action of bromine (2 mols.) on metacymene in the presence of iron filings at the ordinary temperature, is a heavy, colourless, refractive, oily liquid; it boils at $281\text{--}283^{\circ}$ (uncorr.), and is still liquid at -20° .

2 : 5-Dinitro-4 : 6-dibromometacymene is obtained by nitrating the dibromometacymene (1 part) with a well-cooled mixture (15 parts) of sulphuric acid (2 parts) and fuming nitric acid (1 part); the product is poured into ice-cold water and the precipitate crystallised, first from alcohol and finally from light petroleum. It forms long, slender, colourless needles, melts at $140\text{--}141^{\circ}$ (uncorr.), sublimes, and dissolves fairly easily in the usual organic solvents. By reduction, it yields 2 : 5-diamido-4 : 6-dibromometacymene, which crystallises in small, colourless needles, melts at 95° (uncorr.), sublimes, and dissolves in most organic solvents, but not in water; its *hydrochloride* and *platinochloride* are described.

4 : 6-Dibromometacymo-2 : 5-quinone, produced by the oxidation of the diamido-derivative in acid solution, is best obtained pure by reducing the impure quinone, which is extracted from the product by ether, to the corresponding *quinol* (see below), purifying this by distillation with steam, and reoxidising it with chromic acid. The quinone is at first a waxy, buttery, yellow mass, but on prolonged exposure in a desiccator, at a low temperature, it crystallises in yellow needles; it melts at 32° (uncorr.), and is insoluble in cold water, little soluble in hot water, but freely in organic solvents; it will not sublime. 4 : 6-Dibromometacymo-2 : 5-quinol crystallises in slender, colourless needles, and melts at $153\text{--}154^{\circ}$ (uncorr.); it distils with steam and sublimes in microscopic needles.

4 : 5-Dibromorthocymene, obtained by the action of bromine on orthocymene in presence of iron, is a colourless, oily liquid of agreeable, aromatic odour. 3 : 6-Dinitro-4 : 5-dibromorthocymene forms small, colourless needles which melt at 148° (uncorr.), and are insoluble in water, very little soluble in cold but soluble in hot alcohol; it is

stable towards alkalis and can be heated with aniline without change. The corresponding *diamido*-derivative forms small needles, melts at 126° (uncorr.), and sublimes; in air and light it is unstable when moist, especially if impure; its *hydrochloride*, *platinochloride*, and *stannochloride* are described.

4 : 5-*Dibromorthocymo*-3 : 6-*quinone*, obtained from the *diamido*-derivative in the same way as the 2 : 5-*quinone*, is left on the evaporation of its ethereal solution as a yellow oil, which crystallises on cooling, and melts at 40° (uncorr.); it will not sublime. The corresponding *quinol* forms small, white needles, melts at 131° (uncorr.), and dissolves in hot water and the usual organic solvents; it is volatile with steam and sublimes; it is not oxidised to the quinone by chromic acid in the cold, a property which it shares with most other quinols which are halogenated in the benzene nucleus.

2 : 5-*Dibromoparacymene* is a heavy, colourless, refractive oil and boils at 283—284° (uncorr.), which is 10° higher than the boiling point of the corresponding derivative of *parisocymene*; when nitrated, it yields no oxidation products (compare Abstr., 1888, 583), the chief product being 3 : 6-*dinitro*-2 : 5-*dibromoparacymene*, which crystallises in colourless, vitreous needles melting at 156—157° (uncorr.). The corresponding *diamido*-derivative forms small, white needles which melt at 120—121° (uncorr.).

2 : 5-*Dibromoparacymo*-3 : 6-*quinone*, obtained by the oxidation of the last-mentioned *diamido*-derivative, crystallises in intensely yellow needles, melts at 30° (uncorr.), and is more stable and less deliquescent than the isomeric *meta*- and *ortho*-derivatives. The *quinol* forms small, colourless needles and melts at 138—139° (uncorr.).

The above results, obtained with the three synthetic (normal propyl) *cymenes* are in accord with the difference shown by Widmann (this vol., p. 687) to exist between synthetic *paracymene* and that obtained from *camphor*.

3 : 6-*Dinitro*-4 : 5-*dichlorortho-xylene* is obtained by nitrating *dichlorortho-xylene* (b. p. 227°, 1 part) in the cold with sulphuric acid (4 parts) and fuming nitric acid of sp. gr. 1.52 (5 parts) and then heating to boiling. It crystallises in colourless, transparent needles, melts at 155° (uncorr.), sublimes, and dissolves in alcohol. The corresponding *diamido*-derivative is best obtained when a dilute alcoholic solution of the *dinitro*-derivative is reduced with stannous chloride in presence of concentrated hydrochloric acid, and is purified by sublimation; it forms slender, white needles in feathery aggregates, melts at 176° (uncorr.), and is unstable in light and air when moist, especially, if impure. When ammonium sulphide acts on the *dinitro*-derivative, 3-*nitro*-6-*amido*-4 : 5-*dichlorortho-xylene* is formed; it crystallises in yellow needles, volatilises with steam, and melts at 54° (uncorr.).

4 : 5-*Dichlorortho-xylo*-3 : 6-*quinone* is formed when the *diamido*-derivative is oxidised with chromic acid; it crystallises in thin, yellow, lustrous leaflets, melts at 159° (uncorr.), sublimes, and dissolves very easily in alcohol, from which it will not crystallise. The corresponding *quinol* can only be obtained by heating the quinone with concentrated aqueous sulphurous acid in a sealed tube at 100°; it

crystallises in long, brilliant, lustrous, transparent, colourless needles, melts at $163\text{--}164^\circ$ (uncorr.), sublimes, and dissolves in most organic solvents; its oxidation to the quinone by aqueous chromic acid is difficult.

A. G. B.

Action of Sulphur Chloride on Aniline. By L. ENELEANO (*Bull. Soc. Chim.* [3], 5, 173—175).—Sulphur chloride (20 grams) is added in drops to a solution of aniline (53 grams) in chloroform (500 c.c.), the temperature of the mixture being kept below 50° throughout the reaction. The aniline chloride formed in the reaction is filtered off, and spontaneous evaporation of the chloroform filtrate leaves a residue consisting of sulphur and of a portion which is soluble in hydrochloric acid. From the acid solution, alkalis precipitate a base, $S(C_6H_4NH_2)_2$, which crystallises from water in small, colourless, rectangular crystals melting at 107° . When sulphur chloride reacts on aniline dissolved in carbon bisulphide, a precipitate is formed of aniline hydrochloride and of diphenylthiocarbamide. No thioaniline is formed.

T. G. N.

Methylparatoluidine. By E. BAMBERGER and P. WULZ (*Ber.*, 24, 2077—2086).—In the course of their researches on the properties of tetrahydroquinolines (this vol., p. 1255), the authors have observed that when paradiazobenzenesulphonic acid acts on tetrahydro-3-methylquinoline, a mixture of an azo-colouring matter and the isomeric diazoamido-compound is formed even in presence of an excess of mineral acid. This reaction is so remarkable that the authors have also examined the action of paradiazobenzenesulphonic acid on methylparatoluidine, the "monocyclic" analogue of tetrahydro-3-methylquinoline, and find that the reaction proceeds in exactly the same manner in both cases.

To prepare methylparatoluidine, glacial formic acid and paratoluidine were heated together, the excess of the former distilled off in a vacuum, and the residue, which consists of *formoparatoluidide*, $C_6H_4Me \cdot NH \cdot CHO$, recrystallised from ether. It forms large, colourless prisms, melts at 53° , and on treatment with methyl iodide, potash, and a little alcohol, yields *methylformoparatoluidide*,

which distils at $273\text{--}277^\circ$, the distillate solidifying to large, brittle prisms. These melt at 30° , and are converted by fuming hydrochloric acid at 100° into *methylparatoluidine*, $C_6H_4Me \cdot NMe$, which distils at $207\text{--}209^\circ$ under a pressure of 715 mm. The *hydrochloride*, obtained by passing hydrogen chloride into the ethereal solution of the base, forms large, vitreous prisms, is readily soluble in water and alcohol, and melts at $119\text{--}5^\circ$. Its aqueous solution gives a reddish-brown coloration with ferric chloride, and becomes chestnut-brown on the addition of potassium dichromate and dilute sulphuric acid. The *nitroso*-compound, $C_6H_4Me \cdot NMe \cdot NO$, is readily obtained by the action of nitrous acid, and crystallises from ether in brownish-yellow, lustrous tablets, melts at $52\text{--}53^\circ$, and is reconverted into methylparatoluidine by the action of tin and hydrochloric acid. In this

manner the methylated compound may readily be separated from any unaltered toluidine still present.

By the action of diazobenzenesulphonic acid, methylparatoluidine is, as already stated, converted into a mixture of an azo colour and the isomeric diazoamido-compound. The first compound, *methylparatoluidineorthoazobenzenesulphonic acid*, $\text{NHMe} \cdot \text{C}_6\text{H}_3\text{Me} \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{H}$, crystallises in violet needles having a metallic lustre, and dissolves readily in boiling water with a dark raspberry-red colour, and also in alcohol, acetic acid, and concentrated sulphuric acid. It melts at $198-199^\circ$, and, in an acid bath, colours wool or silk dark orange. The sodium salt separates from an alkaline solution on the addition of sodium chloride in deep-red, crystalline flakes, which, on remaining under water, change to small, iridescent plates.

By the action of tin and hydrochloric acid, it is reduced to *orthamidomethylparatoluidine*, $\text{NH}_2 \cdot \text{C}_6\text{H}_3\text{Me} \cdot \text{NHMe}$, which is extracted from the solution by ether after addition of soda. Hydrogen chloride is passed into the ethereal solution, and the precipitated reddish flakes at once dissolved in alcohol, as otherwise oxidation rapidly takes place. The *hydrochloride*, after recrystallisation, forms colourless, vitreous prisms, begins to melt at 175° , and decomposes at $180-185^\circ$. The free base crystallises from ether in colourless, prismatic tablets, melts at 43° , and is identical with the reduction product of nitromethylparatoluidine described by Gattermann (Abstr., 1875, 975). Like all orthodiamido-compounds, it gives a deep-red coloration with oxidising agents in acid solution, and, on boiling with acetic acid and sodium acetate, yields the *anhydro-base* or *imidazole*, $\text{C}_6\text{H}_3\text{Me} \cdot \text{N}(\text{Me})_2$, which forms lustrous needles melting at $141.5-142^\circ$, and is identical with the compound obtained by Niementowski by the reduction of methylnitroparacetotoluidide.

Sulphobenzenediazoamidomethylparatoluidine,

is contained in the filtrate from the azo-compound. It is isolated as the sodium salt, which is a pure white substance sparingly soluble in water. With resorcinol and α -naphthylamine, it gives the colour reactions characteristic of diazoamido-compounds, and, on boiling with acids, yields nitrogen, phenolsulphonic acid, and methyltoluidine. The neutral aqueous solution gradually assumes a reddish colour, but the reaction is retarded by mineral acids. The *silver salt*, $\text{C}_{14}\text{H}_{14}\text{N}_2 \cdot \text{SO}_3\text{Ag}$, forms white, lustrous needles, and decomposes on warming, with separation of silver; the majority of the other salts are sparingly soluble in water and crystallise well. H. G. C.

Adjacent Orthoxylidine. By K. MENTON (*Annalen*, 263, 316-339).—*Acetylmethylorthoxylidine*,

can be prepared by heating a xylene solution of acetylxylidine at 140° for 2-3 hours with a slight excess of the theoretical quantity of sodium, and carefully warming the sodium compound obtained in

this way with methyl iodide; the product is extracted from the xylene solution with concentrated hydrochloric acid, the acid solution mixed with soda, and the precipitated base extracted with ether. It separates from hot light petroleum in well-defined crystals, melts at 75° , is only sparingly soluble in hot water, and is volatile with steam. It is not acted on by concentrated hydrochloric acid at 130° , or by boiling alcoholic potash, but when boiled with sulphuric acid (1 : 1.5) for 15 hours it is partially decomposed into methylorthoxylidine and acetic acid. The *platinochloride*, $(C_{11}H_{15}NO)_2, H_2PtCl_6$, crystallises from hot water in yellow needles. The *aurochloride* is precipitated in yellow crystals on adding auric chloride to a solution of the hydrochloride of the base; it has the composition

Methylorthoxylidine, $C_6H_5Me_2NHMe$, prepared by hydrolysing the acetyl derivative in the manner stated above, and purified by means of its nitroso-compound, is a pale-yellow oil boiling at $222-223^{\circ}$. The *hydrochloride*, C_6H_5N, HCl , crystallises in colourless needles; the acid *sulphate*, C_6H_5N, H_2SO_4 , and the *platinochloride*,

were also prepared. When the hydrochloride of the base is treated with sodium nitrite in ice-cold aqueous solution, the nitrosamine is precipitated as an oil, which, on treatment with alcoholic hydrochloric acid, undergoes intramolecular change, being converted into *paranitrosoethylorthoxylidine hydrochloride*, $NO \cdot C_6H_5Me_2NHMe, HCl$. The free base, obtained by decomposing this salt with sodium carbonate, crystallises from hot dilute alcohol in green needles, melts at $160-161^{\circ}$, and is only sparingly soluble in water, but readily in alcohol and benzene; when heated with aniline and aniline hydrochloride, it yields a red induline, as has been already stated by Fischer and Hepp (Abstr., 1890, 913), but owing to the difficulties experienced in hydrolysing acetylmethylorthoxylidine, a quantity of the nitroso-base sufficient for a thorough investigation of the induline could not be obtained.

Ethylorthoxylidine, $C_6H_5Me_2NHEt$ [$Me_2 : NHEt = 1 : 2 : 3$], is obtained when ethylacetylorthoxylidine, prepared from acetylorthoxylidine as described in the case of the corresponding methyl derivative, is heated with sulphuric acid (1 : 4) at $150-160^{\circ}$ for several hours, but a considerable quantity of the acetyl derivative remains unchanged; when purified by means of its nitroso-derivative, it is obtained as an oil boiling at $227-228^{\circ}$. The *hydrochloride*,

separates from alcoholic ether in crystals; the *platinochloride*,

was also prepared. The *acetyl* derivative, $C_6H_5Me_2NEtAc$, is a yellow oil.

Paranitrosoethylorthoxylidine hydrochloride, $NO \cdot C_6H_5Me_2NHEt, HCl$, prepared by treating the nitrosamine with alcoholic hydrochloric

acid, crystallises in slender, yellow needles; the free base crystallises from dilute alcohol in green needles and melts at 123—124°.

Trimethylxylidine ammonium iodide, $C_6H_3Me_3 \cdot NMe_3 \cdot I$, is formed, together with dimethylorthoxylidine, when orthoxylidine hydrochloride is heated at 180—190° for 10 hours with the theoretical quantity of methyl alcohol, and the mixture of methyl- and dimethyl-orthoxylidine obtained in this way boiled for 2—3 hours with methyl iodide; the product is treated with soda, and the dimethylorthoxylidine distilled with steam. The ammonium iodide separates from hot water in colourless crystals, decomposes on heating with liberation of methyl iodide, but without melting, and is readily soluble in water and alcohol.

Dimethylorthoxylidine, $C_6H_3Me_3 \cdot NMe_2$, is an oil boiling at 199—200°. The *hydrochloride*, $C_{10}H_{15}N \cdot HCl$, crystallises from alcoholic ether in slender needles, and is very readily soluble in water and alcohol. The *platinochloride*, $(C_{10}H_{15}N)_2 \cdot H_2PtCl_6$, separates from hot water in well-defined needles. A paranitroso-derivative of this base could not be obtained.

Benzeneazo-orthoxylidine hydrochloride, $NH_2 \cdot C_6H_3Me_3 \cdot N_2 \cdot Ph \cdot HCl$, is deposited in violet crystals when an aqueous solution of diazobenzene chloride is added, drop by drop, to an alcoholic solution of orthoxylidine heated at 40—45°; it is only sparingly soluble in alcohol and water. The free base, $C_{14}H_{17}N_3$, separates from a mixture of benzene and light petroleum in well-defined, reddish-yellow crystals melting at 98°.

Two bases are formed when paranitrosoethylorthoxylidine hydrochloride (see above) is heated with aniline and aniline hydrochloride at 130° for several hours, but they could not be obtained in a state of purity; they are both moderately easily soluble in alcohol yielding red solutions, but they have only feeble tinctorial properties.

Dimethylafranine hydrochloride, $C_{20}H_{18}N_4 \cdot HCl$, is obtained, together with resinous products, when benzeneazo-orthoxylidine hydrochloride is heated with aniline at about 150°; it is precipitated from its aqueous solution, on the addition of sodium chloride, in the form of a red powder. It separates from alcohol in crystals, and dissolves in water with a beautiful red coloration; its alcoholic solution shows a brownish-yellow fluorescence.

F. S. K.

Paranitrosobenzylaniline and Paranitrosobenzyltoluidine. By W. BOEDDINGHAUS (*Annalen*, 263, 300—313).—*Paranitrosobenzylaniline*, $C_{12}H_{12}N_2O$, can be obtained by heating an alcoholic solution of benzylaniline at 60° with amyl nitrite and a concentrated alcoholic solution of hydrogen chloride; when the reaction takes place in the cold, the principal product is benzylphenyluitrosamine. Paranitrosobenzylaniline crystallises from alcohol in beautiful green plates with a blue reflex, melts at 129°, and is readily soluble in benzene and hot alcohol, but only sparingly in cold alcohol and ether. The *hydrochloride*, $C_{11}H_{12}N_2O \cdot HCl$, crystallises in slender, yellowish-brown needles, and is soluble in hot alcohol.

Benzylparaphenylenediamine, $NH_2 \cdot C_6H_4 \cdot NH \cdot OH_2Ph$, is formed when hydrogen sulphide is passed into an alcoholic ammoniacal solution of

paranitrosobenzylaniline; it is purified by means of its *hydrochloride*, which crystallises from dilute alcohol in colourless, lustrous plates. The free base melts at 30°, and quickly turns red on exposure to the air.

Paranitrosophenylbenzyl nitrosamine, $N\langle\frac{C_6H_5}{O}\rangle N(NO) \cdot CH_2Ph$, is precipitated in yellowish needles when an aqueous solution of sodium nitrite is gradually added to a solution of paranitrosobenzylaniline sulphate with constant shaking; it melts at 77°, and is very unstable.

Paranitrosobenzylaniline combines with hydroxylamine hydrochloride in aqueous solution at the ordinary temperature, forming quinonedioxime and benzylamine hydrochloride; when boiled with dilute (1 : 20) soda, it yields paranitrosophenol, paramidophenol, benzaldehyde, and ammonia.

Paranitrosobenzyl orthotoluidine, $C_{14}H_{11}N_2O$, can be obtained by treating benzyl orthotoluidine with amyl nitrite and an alcoholic solution of hydrogen chloride as described above; it separates from hot alcohol in crystals, and melts at 115°. The *hydrochloride* is precipitated in crystals on passing hydrogen chloride into an ethereal solution of the base. When the base is boiled with dilute soda, it is completely decomposed, yielding benzaldehyde, ammonia, paranitroso- and paramido-orthocresol.

Benzyl orthomethylparaphenylenediamine hydrochloride,

is prepared by passing hydrogen sulphide into a warm, alcoholic ammoniacal solution of paranitrosobenzyl orthotoluidine, evaporating the alcohol, dissolving the residual oil in ether, and adding an alcoholic solution of hydrogen chloride to the dried ethereal solution; it crystallises in slender, colourless needles. The free base melts at a low temperature, and is very unstable.

Paranitrosobenzyl metatoluidine, $C_{14}H_{11}N_2O$, prepared from benzyl metatoluidine as described in the case of the corresponding ortho-compound, separates from alcohol in crystals, and melts at 121°.

Paranitrosobenzylmethylaniline, $C_{14}H_{11}N_2O$, is obtained when an alcoholic solution of benzylmethylaniline is heated with amyl nitrite and an alcoholic solution of hydrogen chloride at 60°, and the salt thus produced decomposed with ammonia; it separates from alcohol in crystals, melts at 56°, and is decomposed by boiling soda yielding, as principal product, benzylmethylaniline, and small quantities of benzaldehyde and methylamine.

F. S. K.

Derivatives of Ethylenephenyldiamine and its Homologues.
By H. E. NEWMAN (*Ber.*, 24, 2191—2200).—*Ethylenephenylthiocarbamide*, $OS\langle\frac{NPh}{NH}\rangle C_2H_4$, is obtained when ethylenephenyldiamine (compare Gabriel, *Abstr.*, 1889, 1166) is treated with carbon bisulphide, and the yellow, crystalline product heated with water; it is also formed in small quantities when potassium thiocarbimide is heated at

140° with ethylenephenyldiamine hydrochloride. It separates from hot water in colourless, lustrous crystals, melts at 155°, and is readily soluble in alcohol and benzene, but only sparingly in carbon bisulphide and ether, and insoluble in light petroleum and cold hydrochloric acid.

Ethylenephencylcarbamide, $C_8H_{10}N_2O$, can be prepared by heating ethylenephenyldiamine hydrochloride with potassium cyanate at 130°; it crystallises from hot water in almost colourless plates, melts at 160–161°, and is readily soluble in benzene and alcohol, but only sparingly in ether and carbon bisulphide, and insoluble in cold water and light petroleum.

Dibenzoyl ethylenephenyldiamine, $C_{22}H_{20}N_2O_2$, prepared by shaking the diamine with benzoic chloride and potash, crystallises from alcohol in colourless prisms, melts at 143.5°, and is soluble in benzene and ether, but insoluble in water and light petroleum; it distils without decomposition, and has feeble basic properties. The corresponding *acetyl* derivative, $C_{12}H_{16}N_2O_2$, separates from hot benzene in colourless, rhombic crystals, melts at 116°, and is very readily soluble in water and alcohol, but more sparingly in ether and toluene, and insoluble in light petroleum; it forms a crystalline acetate, which is readily soluble in water and alcohol, and, when heated in a stream of hydrogen chloride, it is converted into an anhydro-base, the *platinochloride* of which has the composition $C_{20}H_{24}N_4H_2PtCl_6$, and is readily soluble in water.

Orthotoluidoethylphthalimide, $C_6H_4<\begin{smallmatrix} CO \\ CO \end{smallmatrix}>N \cdot C_2H_4 \cdot NH \cdot C_6H_4Me$, is easily obtained by heating bromethylphthalimide with orthotoluidine at 130°; it crystallises from boiling alcohol in short, yellowish needles, melts at 153°, and is readily soluble in ether and carbon bisulphide, but only sparingly in cold water and light petroleum, and insoluble in water.

Ethyleneorthotolyldiamine, $NH_2 \cdot C_6H_4 \cdot NH \cdot C_6H_4Me$, is obtained when the preceding compound is boiled with concentrated hydrochloric acid for three hours, and the hydrochloride produced in this way decomposed with soda; it is an oil, boils at about 267°, is soluble in water and alcohol, and absorbs carbonic anhydride from the air. The *hydrochloride* crystallises in plates, and melts at 168–173°. The *picrate*, $C_8H_{14}N_2 \cdot 2C_6H_3N_3O_7$, crystallises in green needles, and melts at 148°. The *dibenzoyl* derivative, $C_6H_5N_2Bz_2$, forms prismatic needles, melts at 164.5°, and has feeble basic properties.

Paratoluidoethylphthalimide, $C_{17}H_{16}N_2O_2$, is formed, together with a compound melting at 200°, when bromethylphthalimide is heated with paratoluidine at 140°; the two compounds are separated by means of boiling alcohol. The imide separates from hot alcohol in yellow crystals, melts at 96°, and is very readily soluble in benzene, carbon bisulphide, and glacial acetic acid, but only sparingly in ether and cold alcohol, and insoluble in water and light petroleum. The compound melting at 200° separates from warm benzene in lemon-yellow crystals, and is readily soluble in glacial acetic acid, but only sparingly in ether and carbon bisulphide, and insoluble in water, light petroleum, and boiling alcohol; it is probably a diphtalyl

derivative of diethyleneparatolyltetramine of the constitution $C_6H_4Me \cdot N(C_2H_4 \cdot N : C_6H_4O)_2$.

Ethyleneparatolylidiamine hydrochloride, $C_6H_4N_2 \cdot 2HCl$, prepared by heating paratoluidioethylphthalimide with concentrated hydrochloric acid, crystallises from hot alcohol in long, colourless needles, sinters together at 210° , and melts at 218° ; the free base, $C_6H_4N_2$, is a colourless oil. The *platinochloride* crystallises in yellowish plates, and is only sparingly soluble in alcohol, but readily in water. The *dibenzoyl* derivative, $C_6H_4N_2 \cdot 2C_6H_5$, crystallises from alcohol in small, colourless needles, melts at 161° , and is readily soluble in alcohol and glacial acetic acid, but only sparingly in benzene, and almost insoluble in light petroleum, carbon bisulphide, and water. The *diacetyl* derivative, $C_6H_4N_2 \cdot 2Ac$, separates from hot benzene in cubic crystals, melts at 107° , and is very readily soluble in water, alcohol, and glacial acetic acid, but insoluble in carbon bisulphide and light petroleum.

Metaxyldioethylphthalimide, $C_6H_4Me_2 \cdot NH \cdot C_2H_4 \cdot N : C_6H_4O_2$, crystallises from boiling alcohol in small needles, melts at 123° , and is very readily soluble in benzene, glacial acetic acid, and carbon bisulphide, but only sparingly in cold alcohol and ether.

Ethylenemetaxylyldiamine, $NH_2 \cdot C_6H_4 \cdot NH \cdot C_6H_4Me_2$, is a colourless oil which boils at $273-275^\circ$, and absorbs carbonic anhydride from the air. The *hydrochloride* is deliquescent, sinters together at 168° , and melts at 173° . The *picrate* crystallises in reddish-yellow needles, melts at 141° , and is very readily soluble in alcohol. The *platinochloride* is readily soluble in water, but almost insoluble in alcohol, and has the composition $C_{16}H_{16}N_2 \cdot HCl \cdot PtCl_4$.

ψ-Cumidoethylphthalimide, $C_6H_4Me_2 \cdot NH \cdot C_2H_4 \cdot N : C_6H_4O_2$, crystallises from hot alcohol in orange needles, sinters together at 143° , and melts at 146° .

α-Naphthylamidoethylphthalimide, $C_{10}H_7 \cdot NH \cdot C_2H_4 \cdot N : C_6H_4O_2$, separates from boiling alcohol in yellow crystals, melts at 158° , and is readily soluble in benzene and glacial acetic acid, but only sparingly in ether; when heated with concentrated hydrochloric acid at $150-160^\circ$, it is decomposed into phthalic acid and *ethylene-α-naphthyl-diamine*, the *picrate* of which crystallises in small, red needles, melts at 211° , and has the composition $C_{12}H_{14}N_2 \cdot C_6H_5N_3O_7$.

β-Naphthylamidoethylphthalimide, $C_{10}H_7 \cdot NH_2 \cdot O_2$, crystallises from hot alcohol in almost colourless needles, melts at 141° , and is readily soluble in benzene, glacial acetic acid, and carbon bisulphide; it is not decomposed by hydrochloric acid.

Methylamidioethylphthalimide, $NMePh \cdot C_2H_4 \cdot N : C_6H_4O_2$, prepared by heating bromethylphthalimide with methylaniline at $160-170^\circ$, crystallises from alcohol in greenish-yellow, quadratic plates, melts at $104-105^\circ$, and is very readily soluble in benzene, carbon bisulphide, and hot alcohol, but only sparingly in ether and cold alcohol. It is readily decomposed by hydrochloric acid, yielding *ethylenemethylphenyldiamine hydrochloride*, $C_6H_4N_2 \cdot 2HCl$; the free base is a colourless oil boiling at $254-255^\circ$, readily soluble in alcohol and water; the *picrate* crystallises in needles, sinters together at 165° , melts at 173° , and is readily soluble in alcohol, but only sparingly in water.

F. S. K.

Hydroxyazo-compounds. By H. GOLDSCHMIDT and R. BRUBACHER (*Ber.*, 24, 2300—2317; see also *Abstr.*, 1890, 614).—The paper is a continuation of the author's work on the constitution of hydroxyazo-compounds to determine if they are hydroxylated azo-compounds or hydrazones of quinones. The authors have examined the behaviour of the acetates and benzoates of these compounds on reduction; they find that the ethereal salts of the parahydroxy-compounds behave like the compounds obtained by the action of phenyl cyanate, but the ortho-compounds in some cases are split up into their constituents, so that the position of the acid residue can be determined.

Orthohydroxyazo-compounds.—*Acetylbenzeneazoparacresol* is prepared by heating benzeneazoparacresol with acetic anhydride, and melts at 87—88°. The reduction is carried out as follows:—The acetate is dissolved in cold alcohol, zinc-dust added, and then dilute acetic acid; the solution becomes colourless. It is filtered, acidified with hydrochloric acid, and extracted with ether. The ethereal solution contains acetanilide, and the aqueous solution amidoparacresol [$\text{Me}:\text{NH}_2:\text{OH} = 1:3:4$]. The authors maintain that this reaction is not to be explained by the usual formula of the azo-compound, $\text{Ph}\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{OAc}$, which would be expected to yield aniline and othenylamidocresol, $\text{C}_6\text{H}_3\cdot\text{Me}\cdot\text{N}(\text{O})\text{CMe}$, or amidocresol and acetic acid. He explains the reaction by giving the azo-compound the formula $\text{O}:\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{N}=\text{NPhAc}$, and then benzeneazoparacresol is represented as the phenylhydrazone of orthotoluquinone. The same products of reduction were obtained by employing zinc-dust and formic acid in place of acetic acid.

Acetylbenzenehydrazoparacresol, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{Me}\cdot\text{NH}\cdot\text{NPhAc}$, is obtained by reducing the above azo-compound dissolved in alcohol and acetic acid with sodium amalgam (2.5 per cent.) in an atmosphere of carbonic anhydride. On adding water, the compound is precipitated in white, microscopic leaflets; it melts at 124—125°, is very unstable, and decomposes on recrystallisation. It dissolves at once in sodium hydroxide to a reddish-yellow solution, with decomposition, and on reduction with zinc-dust and acetic acid yields amidocresol and acetanilide.

Benzoylbenzenesazoparacresol is obtained from benzenesazocresol by the action of benzoic chloride or benzoic anhydride. When reduced with zinc-dust and acetic acid, it yields *benzoylbenzenehydrazoparacresol*. The latter crystallises from benzene on the addition of light petroleum in white needles, and melts at 152°. When treated with alkali, it remains undissolved at first, but soon goes into solution with decomposition.

Acetylbenzeneazo- β -naphthol and *benzoylbenzeneazo- β -naphthol*, when reduced with zinc-dust and acetic acid, yield amido- β -naphthol, and acetanilide and benzanilide respectively.

Acetylbenzenesazopseudocuminol crystallises from alcohol in reddish-yellow needles, and melts at 73—74°. When reduced in cold alcoholic solution with zinc-dust and acetic acid, *acetylbenzenehydrazopseudocuminol* is obtained. The latter crystallises from benzene and light petr.

oleum in white leaflets, and melts at 123°. When a large quantity of acetic acid is employed, and the reduction allowed to take place without cooling, the azo-compound is split into amidopsendocuminol and acetanilide.

The authors were unable to prepare the benzoyl derivative of benzeneazopsendocuminol.

Orthonitrobenzeneazoparacresol is obtained by the action of ortho-nitrodiazobenzene chloride on an alkaline solution of paracresol. It crystallises from alcohol in red needles, and melts at 118°. The *acetyl* derivative, obtained by boiling it with acetic anhydride, crystallises from alcohol in yellow, prismatic needles, and melts at 99–100°. The product obtained from it on reduction with zinc-dust and acetic acid could not be obtained crystalline, and lack of material prevented further experiments.

Parahydroxyazo-compounds.—The acetyl and benzoyl derivatives of parahydroxyazo-compounds, on reduction with zinc-dust and acetic acid, give only the corresponding hydrazo-compounds. These are insoluble in alkalis, which seems not to be conformable with the hydrazone formula. However, acetylparatolueneazophenol yields a phenolic compound belonging to the diphenyl series, and hence does not behave in accordance with the hydroxyazo-formula.

Acetylhydroxyazobenzene, when reduced as described above with zinc-dust and acetic acid, yields *acetylhydroxyhydrazobenzene*. The latter is obtained in white needles by precipitation from benzene with light petroleum, melts at 114–115°, and is easily soluble in alcohol and benzene, sparingly in light petroleum.

Benzoylhydroxyhydrazobenzene is obtained in a similar way by reduction of benzoylhydroxyazobenzene; it crystallises in white prisms, melts at 173°, and is easily soluble in alcohol, benzene, and ether.

Acetylparatolueneazophenol, obtained by boiling tolueneazophenol with acetic anhydride, crystallises from alcohol in orange-yellow needles, and melts at 95°. On reduction with zinc-dust and acetic acid, it yields the corresponding *hydrazo-compound*, which crystallises from benzene and petroleum in white prisms, and melts at 106°. The azo-compound is more difficult to reduce with zinc-dust and sulphuric acid, and the mixture requires heating on the water-bath for some time. When the reduction is complete, the mixture is made alkaline, and extracted with ether. The ethereal extract contains paratoluidine. The alkaline solution rapidly becomes blue; it was acidified and again extracted with ether, when a compound was obtained isomeric with the above hydrazo-compound; this melts at 141°, is soluble in acids and strong sodium hydroxide, and becomes intensely blue in alkaline solution on exposure. Ferric chloride colours the acid solution dark-red. The author believes it to be a diphenyl derivative of the constitution $[\text{OH} : \text{NH}_2 : \text{Me} : \text{NHAc} = 3 : 6 : 3' : 6']$.

Pseudocumeneazophenol is prepared by the action of diazopseudocumene chloride on phenol dissolved in soda. It is precipitated from the solution by carbonic anhydride, and may be purified by dissolving it in strong ammonia and reprecipitation, it forms small, yellow leaflets, melts at 94°, and is easily soluble in alcohol and benzene, sparingly in light petroleum. The *acetyl* compound, prepared by boiling it with

acetic anhydride, crystallises from alcohol in long, orange-red needles, and melts at 105°.

Acetylpsedocumenehydrazophenol is obtained by reducing the foregoing compound with zinc-dust and acetic acid; it crystallises from benzene and petroleum in long, colourless needles, and melts at 102—103°.

The acetate and benzoate of benzeneazo- α -naphthol yield the corresponding hydrazo-compounds on reduction.

Acetylbenzenehydrazo- α -naphthol crystallises from benzene and petroleum in white leaflets, and melts at 157°.

Benzoylbenzenehydrazo- α -naphthol crystallises in small prisms, melts at 162°, and is easily soluble in alcohol, ether, and benzene.

Acetylorthonitrophenylazobenzene, obtained by heating the azo-compound with acetic anhydride, separates from alcohol in yellow crystals, and melts at 109°. On reduction with zinc-dust and acetic acid, it yielded products which were difficult to obtain crystalline. On reduction with zinc and hydrochloric acid, orthophenylenediamine was obtained.

The authors formulate all the above compounds as hydrazones of quinones, and maintain that the results are in agreement with these formulæ. They also discuss the two most powerful arguments in favour of the old formulæ, namely, the behaviour of hydroxyazo-compounds on alkylation, and their formation from diazo-salts and phenols, and show that they do not necessarily compel the acceptance of the old formula. E. C. R.

Cryoscopic Experiments. By H. GOLDSCHMIDT (*Ber.*, 24, 2317—2323).—Diazoamido-compounds dissolved in aromatic amines very easily undergo change into amidoazo-compounds in the presence of salts of aromatic amines. The author has instituted a series of experiments to determine if the hydrochlorides of aniline bases which are electrolytes in aqueous solution are also capable of dissociation when dissolved in amines. The method employed was to observe the lowering of the freezing point of the solution. Paratoluidine was employed as the solvent (Eykman, *Zeit. physikal. Chem.*, 4, 497). Diazoamido-compounds, amidoazo-compounds, aromatic amines, and their salts were examined. The results show that the electrolytes do not give a larger molecular depression than the non-electrolytes. The non-electrolytes give numbers agreeing with Eykman's; the electrolytes give numbers distinctly lower.

The molecular depressions of diazoamido-compounds, amidoazo-compounds, and aromatic amines are near together, and are near to the number determined by Eykman for many compounds, that is, about 51. Aniline gives a smaller constant than β -naphthylamine.

Paratoluidine hydrochloride, benzylamine hydrochloride, and trimethylphenylium iodide give a molecular depression of about 40. Aniline, pseudocumidine, and β -naphthylamine hydrochlorides give very large molecular depressions, the explanation being that in solution in paratoluidine these salts are decomposed with formation of the free base and paratoluidine hydrochloride. The observed

molecular depressions were about equal to the sum of the depressions of the free base and paratoluidine hydrochloride.

The author has studied the conversion of diazoamidobenzene into amidoazotoluene by paratoluidine hydrochloride in paratoluidine solution. On adding paratoluidine hydrochloride to the solution of the diazoamido-compound, a lowering of the freezing point was observed, corresponding with the evolution of 2 mols. of aniline, as expressed in the equation

The author is engaged on the further study of these phenomena.

E. C. R.

Action of Carbonyl Sulphide, Carbonyl Chloride, and Alkyl Chlorocarbonates on Phenylhydrazine. By G. HELLER (*Annalen*, 263, 269—283).—*Phenylhydrazine phenylsemithiocarbazate*, $\text{C}_{13}\text{H}_{16}\text{N}_4\text{O}$, is obtained in crystals when carbonyl sulphide is passed into a well-cooled, ethereal solution of phenylhydrazine; it melts at $82\text{--}84^\circ$ with decomposition, when quickly heated, and is only sparingly soluble in water, benzene, ether, and light petroleum, but more readily in alcohol and chloroform. It is unstable, reduces Fehling's solution on boiling, and has, probably, the constitution $\text{NHPh}\cdot\text{NH}\cdot\text{CO}\cdot\text{SH}\cdot\text{NH}_2\cdot\text{NHPh}$. When treated with warm alcoholic ammonia, it is converted into a crystalline compound of the composition $\text{C}_7\text{H}_{11}\text{N}_3\text{OS}$; this substance is readily soluble in water, warm alcohol, and acetone, but more sparingly in ether, chloroform, and benzene, and is probably the ammonium salt of the acid. In aqueous solutions of this ammonium salt, metallic salts produce precipitates which are decomposed on boiling, with formation of the sulphide of the metal; the free acid cannot be isolated. When phenylhydrazine phenylsemithiocarbazate is heated in open vessels at a temperature above its melting point, it is completely decomposed, leaving a residue of phenylhydrazine; but when the dry salt is heated in sealed tubes it is converted into diphenylcarbazine (m. p. 163°), carbamide, aniline, diphenylcarbamide, carbon bisulphide, and ammonia.

Diphenylcarbazine, $\text{NPh}\cdot\text{N}\cdot\text{CO}\cdot\text{NH}\cdot\text{NHPh}$, is obtained when diphenylcarbazine is boiled for about 10 minutes with alcoholic potash, and the cold, filtered solution acidified with dilute sulphuric acid. It crystallises from benzene in orange red needles, melts at 157° with decomposition, and is readily soluble in alcohol, benzene, and chloroform, but insoluble in water; it dissolves in cold, concentrated sulphuric acid, yielding an intensely carmine-red solution. Its alkaline solution reduces Fehling's solution, gives precipitates with solutions of metallic salts, and is readily reduced by alcohol and zinc-dust, with formation of diphenylcarbazine.

Phenylhydrazine and carbonyl chloride combine readily in ethereal solution, forming diphenylcarbazine, phenylhydrazine hydrochloride, and a small quantity of a compound of high melting point, the nature of which was not determined; under the same conditions, phenylhydrazine and thionyl chloride yield diphenylthiocarbazine and phenylhydrazine hydrochloride.

Ethyl phenylcarbazate, $\text{NPh}\cdot\text{NH}\cdot\text{COOEt}$, is obtained when an ethereal solution of ethyl chlorocarbonate is gradually added to a well-cooled ethereal solution of phenylhydrazine, with constant shaking; it crystallises from hot water in yellowish needles, melts at $86-87^\circ$, and is only sparingly soluble in cold water, but readily in alcohol, acetone, benzene, chloroform, ether, and hot water. It reduces Fehling's solution on warming, dissolves freely in concentrated mineral acids, and, on oxidation with mercuric oxide in chloroform solution, it seems to be converted into an azo-compound of the constitution $\text{NPh}\cdot\text{N}\cdot\text{COOEt}$; when heated with aniline at $210-215^\circ$ it is converted into diphenylsemicarbazide (m. p. $172-173^\circ$). The *acetyl* derivative, $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O}_3$, crystallises from water in slender, colourless needles, sinters together at 97° , melts at $102-103^\circ$, and is only sparingly soluble in ether and light petroleum, but more readily in alcohol, benzene, acetone, chloroform, and glacial acetic acid.

Methyl phenylcarbazate, $\text{NPh}\cdot\text{NH}\cdot\text{COOMe}$, prepared from methyl chlorocarbonate in like manner, crystallises from water in prisms, melts at $115-117^\circ$, and resembles the ethyl salt in properties. When heated at $230-240^\circ$ for some time, it is decomposed into methyl alcohol and diphenylurazine (m. p. 264°), identical with the compound obtained by Pinner (*Ber.*, 21, 2330) from phenylsemicarbazide; the constitution of diphenylurazine is most probably expressed by the formula $\begin{array}{c} \text{NPh}\cdot\text{NH}\cdot\text{CO} \\ \text{CO}\cdot\text{NH}\cdot\text{NPh} \end{array}$. The ethyl salt undergoes an analogous decomposition into ethyl alcohol and diphenylurazine.

F. S. K.

Relations between Eurhodines, Indulines, and Safranines. By F. KEHRMANN and J. MESSINGER (*Ber.*, 24, 2167-2175; compare this vol., p. 746).—*Methylrosindulone*, $\text{C}_{17}\text{H}_{12}\text{N}_2\text{O}$, is deposited in crystals when hydroxynaphthaquinone is treated with methylorthophenylenediamine in concentrated alcoholic solution; it crystallises from a mixture of alcohol and benzene in vermilion needles having a green reflex, melts at $257-259^\circ$, and is rather sparingly soluble in ether, alcohol, and benzene, yielding yellowish-red solutions which show a vermilion fluorescence. Its solution in concentrated sulphuric acid is dichroic, being dirty green in thin, and dark purple-red in thick layers; on diluting with water the solution turns orange-red. The hydrochloride crystallises in brown needles having a green reflex, and is decomposed by water. On adding bromine-water to an acid alcoholic solution of methylrosindulone, until the solution smells of the halogen after shaking, and then immediately adding excess of sulphurous acid, a *bromo*-derivative is precipitated in red crystals; it separates from glacial acetic acid in green needles, decomposes at about 250° , but without melting, is very sparingly soluble in most ordinary organic solvents, and dissolves in concentrated sulphuric acid with a dark-green coloration. The constitution of methylrosindulone is, doubtless, expressed by the formula $\text{C}_6\text{H}_4\langle\overset{\text{N}}{\text{NMe}}\rangle\text{C}_{10}\text{H}_8\text{O}$.

Methoxynaphthaphenazine, $\text{C}_6\text{H}_4\langle\overset{\text{N}}{\text{N}}\rangle\text{C}_{10}\text{H}_6\cdot\text{OMe}$, is formed, together

with methylrosindulone, when the eurhodole, prepared from hydroxynaphthaquinone and orthophenylenediamine as previously described, is boiled with methyl iodide and soda in methyl alcoholic solution. The two products are precipitated with water, the precipitate dissolved in boiling alcohol, the solution mixed with concentrated hydrochloric acid, and the methoxynaphthaphenazine carefully precipitated with water; on adding ammonia to the filtrate, methylrosindulone, identical with the compound just described, is precipitated. Methoxynaphthaphenazine crystallises from boiling alcohol in long, light-yellow needles, melts at $176-177^{\circ}$, and sublimes at a higher temperature. It is insoluble in alkalis, but moderately easily soluble in boiling alcohol, benzene, glacial acetic acid, &c., and it dissolves in concentrated sulphuric acid yielding an intensely yellow solution, from which a salt is precipitated in almost colourless needles on the addition of water; its solutions do not give a precipitate with bromine-water.

The above experiments prove that α -naphthaeurhodole exists in two tautomeric modifications, and its constitution may, therefore, be expressed both by the quinoneimide formula $C_6H_4<\overset{N}{\underset{NH}{\rightleftharpoons}}C_{10}H_6O$ and by the hydroxy-formula $C_6H_4<\overset{N}{\underset{N}{\rightleftharpoons}}C_{10}H_6OH$; it is almost superfluous to remark that the constitution of eurhodoles and eurhodines can be expressed by the quinoneimide formula only when they contain a hydroxy- or amido-group in the para-, or perhaps also in the ortho-, position to one of the azine-nitrogen atoms; this is probably also true in the case of the safranines.

F. S. K.

Benzylthiocarbimide. By V. MEYER (*Annalen*, 264, 125—127).—An attempt to prepare an alkyl derivative of benzylthiocarbimide was unsuccessful; when benzylthiocarbimide is treated with benzyl chloride and sodium ethoxide in alcoholic solution, benzyl sulphide is formed.

Hydroxylamine is not very rapidly decomposed by boiling, concentrated soda, and the distillate obtained from such a mixture frequently contains considerable quantities of the nitrogenous base.

F. S. K.

Compounds prepared from Methylphenylchloroformamide and Diphenylchloroformamide. By E. LELLMANN and E. BENZ (*Ber.*, 24, 2108—2116; see also Lellman and Barhüfer, *Abstr.*, 1887, 935).—Methylphenylchloroformamide readily acts on potassium phenate in alcoholic solution, yielding potassium chloride and *phenyl methylphenylcarbamate*, $NPhMe \cdot COOPh$, which forms large, colourless crystals, melts at 58° , and is readily soluble in alcohol, ether, chloroform, and benzene. *Orthonitrophenyl methylphenylcarbamate*,

is prepared in a similar manner from potassium orthonitrophenate, and crystallises in monosymmetric prisms

$$(a : b : c = 1.34084 : 1 : 1.09509, \beta = 100^{\circ} 38').$$

It melts at 110° , and is sparingly soluble in cold, readily in hot, alcohol. The *paranitrophenyl* and *metanitrophenyl* salts are both crystalline compounds, and melt at $69-70^{\circ}$ and 105° respectively.

Orthamidophenyl methylphenylcarbamate, $\text{NPhMe} \cdot \text{COO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2$, is obtained by reducing the orthonitro-compound with stannous chloride and hydrochloric acid, and crystallises from alcohol in slender needles melting at 103° . The *paramido*-compound forms needles melting at 104° , and the *metamido*-compound is a yellow, crystalline powder melting at 94° . *Paracresyl methylphenylcarbamate*,

is prepared in the same way as the phenyl compound, and forms slender needles melting at 62° .

Paranitrophenyl diphenylcarbamate, $\text{NPh}_2 \cdot \text{COO} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$, crystallises in slender, pale-yellow needles, and melts at 116° , whilst the *metanitro*-compound forms nacreous plates, and melts at 90° . *Paramidophenyl diphenylcarbamate*, $\text{NPh}_2 \cdot \text{COO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2$, obtained by the reduction of the paranitro-compound, forms yellowish needles, and melts at 146° , whilst the *metamido*-compound crystallises in reddish needles, and melts at $132-133^{\circ}$. *Paracresyl diphenylcarbamate*, $\text{NPh}_2 \cdot \text{COO} \cdot \text{C}_6\text{H}_4\text{Me}$, crystallises from alcohol in silky, asbestos-like aggregates of needles, and melts at 81° .

Methyldiphenylchloroformamide also combines with amido-bases; thus with aniline it yields methylcarbanilide at the ordinary temperature, but on warming gives diphenylcarbamide almost exclusively. *Methylphenylmetanitrophenylcarbanilide*, $\text{NPhMe} \cdot \text{CO} \cdot \text{NH} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$, is readily obtained by the action of 2 mols. of metanitrilaniline on 1 mol. of methylphenylchloroformamide at 90° , and forms greenish-yellow needles which melt at 230° , and dissolve readily in hot alcohol. On reduction with stannous chloride and hydrochloric acid, it is converted into *methylphenylmetamidophenylcarbamide*,

which crystallises in white, matted needles, and, at $190-200^{\circ}$, gradually decomposes into methylaniline and metaphenylenecarbamide

Methylphenylchloroformamide also reacts with aromatic hydrocarbons in presence of aluminium chloride. Benzene is thus converted into benzoylmethylanilide, and toluene into *methylphenylparatoluamide*, $\text{C}_6\text{H}_4\text{Me} \cdot \text{CO} \cdot \text{NMePh}$; the latter crystallises in large, yellowish, monosymmetric crystals ($\alpha : b : c = 2.67609 : 1 : 2.35724$, $\beta = 108^{\circ} 44'$), melts at 70° , is readily soluble in alcohol, ether, chloroform, and light petroleum, and, on hydrolysis, yields paratoluic acid and methylaniline. *Methylphenylxyloylamide*, $\text{C}_6\text{H}_4\text{Me}_2 \cdot \text{CO} \cdot \text{NMePh}$ ($\text{CH}_3 : \text{CH}_3 : \text{CO} \cdot \text{NMePh} = 4 : 2 : 1$), is obtained in the same way from metaxylene, and crystallises from light petroleum in small, pale-yellow crystals melting at 54° . The corresponding $4 : 3 : 1$ -compound, prepared from orthoxylene, forms large, flesh-coloured, asymmetric crystals ($\alpha : b : c = 0.49009 : 1 : 0.55605$, $\alpha = 118^{\circ} 7' 20''$, $\beta = 109^{\circ} 44' 40''$, $\gamma = 58^{\circ} 83'$; $A = 111^{\circ} 33' 50''$, $B = 97^{\circ} 0' 50''$, $C =$

64° 6' 20"), and melts at 78°; whilst the 5:2:1-compound from paraxylene crystallises from ether in pink plates, and melts at 74°. The last three compounds all yield the corresponding xylic acids on hydrolysis.

H. G. C.

Seleno- and Thio-derivatives of Ethylamine and Propylamine. By V. COBLENTZ (*Ber.*, 24, 2131—2136): compare Gabriel and Laufer, *Abstr.*, 1890, 472).—*Thiocarbimidoethylphthalimide*,

prepared by heating bromethylphthalimide with potassium thiocarbimide at 100° in alcoholic solution, separates from alcohol in colourless crystals melting at 108°; when treated with 10 per cent. potash, it is converted into *ethyldisulphidediphtalamic acid*,

This acid separates from hot alcohol in colourless crystals, melts at 128—130°, and is decomposed by concentrated hydrochloric acid at 180° into phthalic acid and dithioethylamine (compare Coblenz and Gabriel, this vol., p. 817); the *picrate* of this base crystallises from hot alcohol in yellow needles, melts at 198—200°, and has the composition $\text{C}_4\text{H}_{12}\text{N}_2\text{S}_2\cdot 2\text{C}_6\text{H}_3\text{N}_3\text{O}_7$.

β-Selenocarbimidoethylphthalimide, $\text{C}_8\text{H}_4\text{O}_2\cdot\text{N}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{SeCN}$, obtained in like manner from potassium selenocyanide, is a colourless, crystalline compound melting at 124—125°; when boiled with 10 per cent. potash, it is converted into *ethyl-β-diselenidodiphtalamic acid*, $\text{Se}_2(\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{COOH})_2$, a yellowish, crystalline compound melting at 118—119°.

γ-Selenocarbimidopropylphthalimide, $\text{C}_{12}\text{H}_{10}\text{N}_2\text{SeO}_2$, prepared from bromopropylphthalimide and potassium selenocyanide, melts at 102°, and is converted into *propyl-γ-diselenidodiphtalamic acid*,

by hot potash; this acid separates from alcohol in crystals melting at 84°.

Diselenoethylamine hydrochloride, $\text{Se}_2(\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}_2)_2\cdot 2\text{HCl}$, is obtained when ethyl-β-diselenidodiphtalamic acid is heated at 180° with concentrated hydrochloric acid; it melts at 188°. The *picrate*, $\text{C}_4\text{H}_{12}\text{N}_2\text{Se}_2\cdot 2\text{C}_6\text{H}_3\text{N}_3\text{O}_7$, crystallises from alcohol in orange needles, and melts at 178°.

Diselenopropylamine hydrochloride, $\text{C}_6\text{H}_{16}\text{N}_2\text{Se}_2\cdot 2\text{HCl}$, prepared from propyl-γ-diselenidodiphtalamic acid in like manner, separates from alcohol in crystals melting at 170°; the *picrate*, $\text{C}_6\text{H}_{16}\text{N}_2\text{Se}_2\cdot 2\text{C}_6\text{H}_3\text{N}_3\text{O}_7$, forms orange crystals, and melts at 165°.

F. S. K.

Action of Alkali Hypochlorites and Hypobromites on some Imides and Phthalodiamide. By S. HOOGWERFF and W. A. VAN DOEP (*Rec. Trav. Chim.*, 10, 4—12).—Succinimide, treated in alkaline solution with potassium hypobromite, yields β-amidopropionic acid.

The imide (1 mol.) is dissolved in a solution containing potash

(6 mols.) and hypobromite (1 mol.), and heated for two hours at 50–60°. The liquid contains potassium β -amidopropionate; it is acidified with hydrochloric acid, evaporated to dryness, mixed with absolute alcohol, and dry hydrogen chloride passed through the mixture, which is then filtered, and the filtrate evaporated to dryness. The residue is dissolved in water, and treated on the water-bath with silver sulphate, again filtered, traces of silver precipitated with hydrogen sulphide, and finally it is boiled with baryta in excess. The barium salt now in solution is decomposed by sulphuric acid, and the filtrate evaporated. The melting point found by the authors for β -amidopropionic acid is 196°; it is given by Beilstein as 180°, and has been found by E. Mulder (*Ber.*, 9, 1902) to be 190°. The substance formed by the action of the hypobromite on the imide is

and in alkaline solution this undergoes transformation as follows:—

The authors suppose that the salt $\text{COBr}\cdot\text{NK}\cdot\text{C}_6\text{H}_4\cdot\text{COOK}$ is formed as an intermediate product (see *Rec. Trav. Chim.*, 8, 173). Phthalimide undergoes a similar reaction with the production of anthranilic acid. The imide is heated with alkaline hypobromite and potash at 80°, the resulting product is acidified with acetic acid, and the insoluble copper salt precipitated with copper acetate. The copper salt is suspended in water, and decomposed by hydrogen sulphide. The anthranilic acid obtained is 85 per cent. of that required by theory. The mechanism of the reaction is analogous to that described above, the compound $\text{NKBr}\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{COOK}$ being first formed and then decomposing. Phthalimide reacts in like manner with other alkaline or alkaline-earth hypobromites or with hypochlorites. The identity of the acid prepared with orthamidobenzoic acid was proved.

The sulphate of anthranilic acid crystallises with 1 mol. H_2O , not 2 mols. as usually stated. The anthranilic acid obtained from phthalimide is nearly pure. It may be further purified by crystallisation from water, but then becomes somewhat yellow in colour. A better method of purification consists in the recrystallisation of the sulphate from alcohol and the decomposition of the salt by the exact quantity of baryta solution of known strength. Liebig's method of recrystallising the calcium salt from water and decomposing it with acetic acid yields a very pure product. Solutions of anthranilic acid generally exhibit fluorescence; this becomes less marked on further purification, but is again intensified on exposure to light.

The retarding effect on alcoholic and acetic fermentations exercised by anthranilic acid is much inferior to that of salicylic acid. It requires from 3 to 5 parts of anthranilic acid to exert the same effect on the lactic fermentation as 1 part of salicylic acid. As the artificial salicylic acid of commerce is often contaminated with impurities which modify its therapeutic properties (see *Pharm. J. Trans.*, Nov.,

1890, and Fischer, *Pharm. Zeit.*, 1889, 42), the easy transformation of anthranilic acid into a very pure salicylic acid by nitrous acid becomes of some importance.

Phthalodiamide, treated with hypochlorite or, preferably, hypobromite in the same manner, yields benzoylenecarbamide. After heating at 80°, a current of carbonic anhydride is passed, and the carbamide deposited is recrystallised from glacial acetic acid. It is found to be identical with the benzoylenecarbamide prepared by Griess' method. If 2 mols. of hypobromite be employed to 1 of phthalodiamide, a benzoylenecarbamide bromide is obtained. The transformation of phthalodiamide into benzoylenecarbamide may be interpreted by the use of either the symmetrical or the unsymmetrical formula for the amide; Wislicenus' results (*Annalen*, 242, 40) render the latter probable.

The phthalimide reaction described above leaves open the question of the constitution of this imide; the ease with which phthalimide may be converted into an amide renders it probable that the amide and the imide possess an analogous constitution. Sandmeyer's experiments support the unsymmetrical formula (*Ber.*, 18, 1499); those of Kuhara (*Amer. Chem. J.*, 3, 26) and Auger (*Bull. Soc. Chim.*, [2], 49, 345) rather lead to its rejection. The authors have undertaken researches for the purpose of settling the constitution of phthalimide and its isomerides.

Assuming the unsymmetrical constitution for phthalodiamide, the first stage in the formation of benzoylenecarbamide may be given as $\text{CO} \begin{smallmatrix} \text{C}_6\text{H}_4 \\ \text{O} \end{smallmatrix} \text{C} \begin{smallmatrix} \text{NH}_2 \\ \text{NH}_2 \end{smallmatrix} + \text{KOB}r = \text{CO} \begin{smallmatrix} \text{C}_6\text{H}_4 \\ \text{O} \end{smallmatrix} \text{C} \begin{smallmatrix} \text{NH}_2 \\ \text{NH}_2 \end{smallmatrix} \text{NKBr} + \text{H}_2\text{O}$. A similar molecular migration has been noticed previously (*Rec. Trav. Chim.*, 9, 37) to that which now takes place in the alkaline solution, with formation of potassium orthoureidobenzoate,

This salt is unstable, and readily suffers transformation, even in alkaline solution, into the potassium salt of benzoylenecarbamide,

When dilute hydrochloric acid is added to a solution of phthalyl chloride in excess of ammonia, prepared in the cold, a substance is obtained isomeric with phthalimide. This β -imide has acid properties, dissolves in solution of potassium carbonate with evolution of carbonic anhydride, and is reprecipitated on adding hydrochloric acid to the solution. Boiling water decomposes it readily. Its melting point is generally found between 180° and 190°; when heated further, the mass melts, resolidifies, and is transformed into the α -imide (ordinary phthalimide). W. T.

Reduction of Trimethylgallamide; Acetyl-gallamide. By M. MARX (*Annalen*, 263, 249—259; compare Hutchinson, this vol., p. 561).—Trimethylgallamide, $\text{C}_6\text{H}_3(\text{OMe})_3 \cdot \text{CONH}_2$, can be prepared by gradually adding a concentrated solution of potash (3 mols.) in methyl

alcohol to a boiling mixture of methyl alcohol and methyl iodide (3 mols.) in which pure gallamide is suspended; it crystallises from dilute alcohol in colourless, lustrous prisms, melts at 176—177°, and is only sparingly soluble in water, but more readily in ether, alcohol, and chloroform; it is not acted on by mineral acids in the cold, but it is converted into trimethylgallic acid (m. p. 168—170°) by boiling soda.

Trimethylgallyl alcohol, $C_6H_2(OMe)_3 \cdot CH_2 \cdot OH$, is obtained, together with hexamethoxybenzile, and probably also the corresponding hydrobenzoin, when trimethylgallamide (20 grams) is reduced with 2½ per cent. sodium amalgam (1 kilo.) in alcoholic solution, dilute sulphuric acid being constantly added in order to keep the solution acid; when reduction takes place in strongly acid solution, the alcohol is the principal product, but in only slightly acid solution the best yield of the benzile is obtained; in alkaline solution, brown, resinous products are formed. The solution is filtered from the precipitated hexamethoxybenzile, evaporated until free from alcohol, filtered again to separate the crystals of hexamethoxybenzoin, and then extracted with ether; on evaporating the ethereal solution, the alcohol remains as an oil, mixed, however, with a little of the benzoin, from which it is separated by solution in a small quantity of ether. It is a yellowish oil, boils at 228° under a pressure of 25 mm., and is very readily soluble in alcohol, ether, and benzene, but only very sparingly in cold water; it dissolves in concentrated sulphuric acid with a deep-red coloration, and it is completely destroyed by concentrated hydrochloric acid at 100°.

Hexamethoxybenzile, $C_6H_2(OMe)_3 \cdot CO \cdot CO \cdot C_6H_2(OMe)_3$, crystallises in yellow, lustrous needles, melts at 189°, and is insoluble in water and alkalis, and only sparingly soluble in cold alcohol, but more readily in ether, chloroform, benzene, and glacial acetic acid. It dissolves in concentrated sulphuric acid with a bluish-green coloration which soon becomes of a lighter shade; it is not decomposed by boiling concentrated hydrochloric acid, and it combines with phenylhydrazine and with hydroxylamine.

Hexamethoxybenzilic acid, $OH \cdot C[C_6H_2(OMe)_3]_2 \cdot COOH$, can be obtained by melting the preceding compound with potash, but is best prepared by boiling it with 5 per cent. potash for about six hours. It crystallises from water in long, colourless prisms, melts at 175° with decomposition, and is readily soluble in alcohol, ether, and benzene, but only sparingly in water; with concentrated sulphuric acid, it gives a deep-blue coloration which soon changes to a dirty-green.

Hexamethoxydeoxybenzoin, $C_6H_2(OMe)_3 \cdot CO \cdot CH_2 \cdot C_6H_2(OMe)_3$, prepared by reducing hexamethoxybenzile with zinc-dust and acetic acid, crystallises from dilute alcohol in long, colourless needles, melts at 161—162°, and is insoluble in cold water and alkalis, but readily soluble in alcohol, ether, and chloroform; it dissolves in concentrated sulphuric acid, yielding a deep-red solution which quickly turns yellowish-brown. The corresponding *hydrobenzoin*, obtained in the preparation of trimethylgallyl alcohol, crystallises from dilute alcohol in colourless needles, melts at 217°, and is insoluble in water and alkalis; it does not reduce Fehling's solution, and it dissolves in concentrated sulphuric acid with a deep-red coloration.

uric acid with a deep-blue coloration which disappears after some hours' time.

Tetracetyl gallamide, $C_{15}H_{15}NO_8$, is deposited in crystals when gallamide (10 grams) is dissolved in warm acetic anhydride (50 grams), the solution heated for a few minutes, and then allowed to cool, crystallisation being promoted by rubbing; it separates from alcohol in colourless, lustrous prisms, melts at 210° , and is only sparingly soluble in benzene, alcohol, light petroleum, and glacial acetic acid, and insoluble in water and ether; it is decomposed by cold soda and by boiling water. The *triacetyl* derivative, $C_{14}H_{13}NO_7$, is obtained when the filtrate from the tetracetyl derivative is repeatedly evaporated with alcohol; it crystallises from water in colourless prisms, melts at 163° , and is moderately easily soluble in alcohol, but only sparingly in water, and insoluble in ether; it is probably identical with the impure acetyl derivative (m. p. about 150°) described by Schiff and Pons (Abstr., 1885, 796). F. S. K.

Acids of the Fumaric Series. By C. A. BISCHOFF (*Ber.*, 24, 2001—2025).—The compound obtained by heating malic dianilide with acetic anhydride, to which the formula $C_{25}H_{25}N_2O_4$ was given (Abstr., 1890, 1162), is now identified as fumaric dianilide, $C_{18}H_{14}N_2O_3$, since it is obtained from fumaric dichloride by the action of aniline, yields Anschütz's fumaranilic acid (m. p. 230 — 232°), the so-called diphenyl- α,γ -diketopiperazine- $\beta\delta$ -homocarboxylic acid of the author and Nastvogel (*loc. cit.*), when heated with 10 per cent. alcoholic potash (2 mol. prop.) in a reflux apparatus for three hours, and is converted into fumaric acid by treatment in amyl alcohol solution with sodium. The constitution of fumaric diparatoluidide (*loc. cit.*) has been confirmed by its synthesis from fumaric dichloride and paratoluidine.

The substance left undissolved when the product of the action of acetic anhydride on malic α -dinaphthalide is extracted successively with acetic acid, dilute ammonia, and water, and provisionally regarded as the acetyl derivative, $C_{26}H_{22}N_2O_4$ (*loc. cit.*), consists of about 40 per cent. of the acetyl derivative and 60 per cent. of fumaric α -dinaphthalide, and is separated into its constituents by extraction with alcohol, in which the former is soluble and the latter insoluble.

Acetomalic α -dinaphthalide,

melts at 232° , and, when heated in an oil-bath at 240 — 250° , decomposes into acetic acid and fumaric α -dinaphthalide; hence the proportion of the two constituents in the above product is dependent on the duration and temperature of the reaction. *Fumaric α -dinaphthalide*, $C_{24}H_{18}N_2O_3$, does not melt below 360° , and is practically insoluble in all the ordinary solvents, and only sparingly soluble in nitrobenzene or aniline. On treatment with 10 per cent. alcoholic potash, it yields fumaric acid, α -naphthylamine, and a small quantity of a compound which crystallises from acetone in slender needles, and consists probably of fumaronaphthyllic acid. Piperazine derivatives, therefore, are not obtained by the action of acetic anhydride on malic dianilide and

its homologues, and the further investigation of these compounds has been abandoned.

Acetomalaniil, $\text{CO} < \begin{array}{c} \text{NPh} \text{---} \text{CO} \\ \text{CH}(\text{OAc}) \cdot \text{CH}_2 \end{array}$, obtained by digesting malaniil dissolved in benzene with the calculated quantity of acetic chloride, is a colourless, crystalline substance which melts at 137° , and is readily soluble in most solvents, but very sparingly soluble in cold water. *Acetomalic β -naphthil*, $\text{C}_{16}\text{H}_{13}\text{NO}_4$, prepared in like manner from malic β -naphthil (*loc. cit.*), crystallises in colourless scales, and melts at 116° .

In an earlier paper, it has been shown that mesaconic and citraconic acids can be prepared from ethyl chloropropenyltricarboxylate (Abstr., 1890, 1101); the preparation of homologues of these acids from ethyl chlorobutenyltricarboxylate is now described.

When ethylic chlorobutenyltricarboxylate is hydrolysed by prolonged boiling with equal weights of hydrochloric acid (sp. gr. 1.2) and water, it is for the most part converted into ethylmaleic acid.

Ethyl sodiobutenyltricarboxylate is prepared by the action of sodium wire (6.9 grams) on a solution of ethyl butenyltricarboxylate (82 grams) in absolute ether (375 c.c.). and when the solution is treated with a 10 per cent. iodine solution (about 72 grams of iodine) until the colour no longer disappears, and the product is subsequently saponified with baryta, a mixture of ethylsuccinic acid and ethylmaleic acid is obtained.

Bromethylsuccinic acid (m. p. 202°), or the impure acid melting at 185° , obtained by the action of bromine on butenyltricarboxylic acid (this vol., p. 291), is converted into a mixture of ethylfumaric and ethylmaleic acids by boiling in a reflux apparatus for two days with about three times its weight of concentrated hydrochloric acid. Both the isomeric bromethylsuccinic acids (*loc. cit.*), on warming with an equal weight of caustic potash dissolved in five times its weight of alcohol, yield ethylmaleic acid.

Ethylsuccinic acid (15 grams), on careful bromination in a reflux apparatus at 200° with bromine (16 grams), distillation of the product, and conversion of the resulting anhydride into acid by treatment with barium carbonate and subsequent addition of hydrochloric acid to the concentrated filtrate, yields ethylmaleic acid, free from methylitaconic acid and products of higher melting point.

When ethylsuccinic anhydride (36 grams) is heated with chloroform (40 grams) and bromine (46 grams) for five hours at $130\text{--}140^\circ$, it is converted into bromethylsuccinic anhydride, and this, when heated at 180° , begins to decompose with the elimination of carbonic anhydride, and, on distillation at $220\text{--}250^\circ$, evolves hydrogen bromide in large quantity, yielding a yellow, oily distillate (28 grams) containing methylitaconic acid and ethylmaleic acid. Ethylfumaric acid is not formed in the reaction.

Ethylmaleic acid, obtained by these methods, is identical in properties with Fittig and Fränkel's methylcitraconic acid (Abstr., 1890, 585), and ethylfumaric acid is identical with the oxyptic acid of Demarçay (compare Walden, this vol., p. 1187).

Attempts to prepare dimethylfumaric acid by intramolecular change from the maleinoid form being unsuccessful, experiments have been made with the object of preparing it by other methods, but without success. A mixture of potassium propionate and pyruvic acid, when heated at 140° , gave pyrotritaric acid instead of dimethylfumaric acid, and the attempt to prepare Markownikoff and Krestowikoff's bibasic acid of the formula $C_6H_8O_4$ (Abstr., 1881, 1127) by the action of sodium wire on ethyl α -bromopropionate resulted in the production of so small a quantity of substance that it is as yet impossible to say whether or not this acid is dimethylfumaric acid.

Ethyl chlorobutenyltricarboxylate boils at 193° under 13 mm. pressure. Butenyltricarboxylic acid melts at 141° , instead of 119° (compare Polko, Abstr., 1888, 134), and isobutenyltricarboxylic acid at 148° instead of 120° (compare Barnstein, Abstr., 1888, 135).

W. P. W.

Action of Thiocarbimides on Hydroxylamine. By H. v. n. KALL (*Annalen*, 263, 260—268).—Phenylhydroxythiocarbamide (compare Voltmer, this vol., p. 558) melts at 108° , and is insoluble in water, benzene, and light petroleum, and only sparingly soluble in ether, but readily in alcohol and acetone.

Carbanilidophenylhydroxycarbamide, $NHPh \cdot CO \cdot N(OH) \cdot CO \cdot NHPh$, separates in crystals when a 10 per cent. aqueous solution of hydroxylamine is shaken with phenylthiocarbimide at the ordinary temperature; it melts at 178° with decomposition, and is readily soluble in hot alcohol, benzene, and chloroform, but only sparingly in ether and hot water, and insoluble in light petroleum, cold water, alkalis, and dilute hydrochloric acid.

Phenylhydroxycarbamide, $NHPh \cdot CO \cdot NH \cdot OH$, is deposited in reddish, granular crystals when phenylthiocarbimide is shaken with excess of an ice-cold solution of hydroxylamine; it separates from ether in colourless crystals, melts at 140° with decomposition, and is sparingly soluble in ether and water, but readily in hot alcohol and soda. It reduces Fehling's solution on warming, and combines readily with phenylthiocarbimide, forming carbanilidophenylhydroxycarbamide; it is decomposed by boiling 20 per cent. hydrochloric acid with liberation of hydroxylamine and formation of carbanilidohydroxycarbamide, but boiling alkalis decompose it into aniline, hydroxylamine, and carbonic anhydride.

Hydroxylamine thiocarbimide is formed when hydroxylamine sulphate is treated with barium thiocarbimide in cold, aqueous solution; when the filtered solution is warmed, sulphurous anhydride is evolved, sulphur is deposited, and ammonium sulphate, ammonium thiocarbimide, and ammonium amidosulphonate are produced.

F. S. K.

Aromatic Alkyl Ketones: their Oxidation by Potassium Permanganate. By A. CLAUS (*J. pr. Chem.* [2], 43, 531—537; compare Abstr., 1890, 769, 979; this vol., pp. 199, 564).—The salts of paraxylglycollic acid (this vol., p. 564) are characterised by their solubility; among the salts of the heavy metals, only the ferric and lead salts are precipitated by normal sodium paraxylglycollate.

Paracymyl ethyl ketone [$\text{Me} : \text{COEt} : \text{Pr} = 1 : 2 : 4$] is a colourless, strongly refractive liquid; it boils at 254° (uncorr.), and is volatile with steam; it dissolves in most organic solvents, but not in water; light gradually darkens it. When this ketone is reduced in aqueous alcoholic solution by sodium amalgam, it yields the *secondary alcohol*, $\text{C}_6\text{H}_4\text{MePr}\cdot\text{CHEt}\cdot\text{OH}$, a yellowish oil which boils about 300° , and will not solidify. Complete oxidation by nitric acid or permanganate converts the ketone into 4-methylisophthalic acid, showing that the ketone group and the propyl group are in the meta-position to each other. Limited oxidation with potassium permanganate converts it into paracymylglyoxylic acid (this vol., p. 199).

Paracymyl propyl ketone [$\text{Me} : \text{COPr} : \text{Pr} = 1 : 2 : 4$] is a colourless, strongly refractive liquid which boils at $265\text{--}266^\circ$ (uncorr.), and is hardly volatile with steam. Reduction by sodium amalgam converts it into the *secondary alcohol*, $\text{C}_6\text{H}_4\text{MePr}\cdot\text{CHPr}\cdot\text{OH}$, an oily, yellowish liquid. Oxidation by potassium permanganate converts the ketone into paracymylglyoxylic acid. A. G. B.

Synthesis of Peonol. Application of Perkin's Reaction to Aromatic Ketones. By Y. TAHARA (*Ber.*, 24, 2459—2462).—The substance (m. p. = 45°) isolated by Martin and Yagi (*Arch. Pharm.*, 1878, Part IV) from the root bark of *Peonia moutan*, by extraction with ether, has been recognised by Nagai (*Journ. Japan. Pharm. Soc.*, 1888, Nos. 77 and 81) as paramethoxyorthohydroxyphenyl methyl ketone, $\text{OMe}\cdot\text{C}_6\text{H}_3(\text{OH})\cdot\text{COMe}$, since it is converted into resacetophenone by hydrolysis, and its acetyl derivative, on oxidation and subsequent removal of the acetyl radicle, yields paramethoxysalicylic acid. According to Nagai, this substance, termed by him peonol, crystallises in colourless, lustrous needles of aromatic odour, melts at 50° , volatilises with steam, and is readily soluble in ether, alcohol, chloroform, benzene, and carbon bisulphide, but only sparingly in hot water. It dissolves also in caustic alkalis, forming well crystallised salts, but is insoluble in ammonia and alkaline carbonates. The solution in concentrated sulphuric acid is colourless, but that in concentrated nitric acid has an intense green colour. Ferric chloride colours the alcoholic solution dark violet. The methyl derivative crystallises in scales and melts at 40° ; the acetyl derivative melts at 46.5° .

The author has synthesised peonol by the partial methylation of resacetophenone in methyl alcohol solution with methyl iodide and the theoretical quantity of caustic potash, and finds that it is the sole product of the reaction.

Nagai (*loc. cit.*) states that when peonol is heated with acetic anhydride and anhydrous sodium acetate, it yields, in addition to acetylpeonol, two isomeric substances of the composition $\text{C}_{14}\text{H}_{12}\text{O}_4$, which melt at 130° and 160° respectively. These crystallise in colourless, lustrous, flat needles, are practically insoluble in water and ether, sparingly soluble in cold alcohol, and tolerably soluble in hot alcohol and acetic acid, and can be separated by boiling with 18 per cent. acetic acid, in which the former is the more soluble. Both

compounds are insoluble in cold alkalis, but dissolve with decomposition on boiling.

The author finds that the reaction of acetic anhydride and sodium acetate with peonol proceeds on the lines of the Perkin synthesis, and thus affords the first instance of the successful application of this reaction to ketones. A similar reaction is also obtained with resacetophenone, but acetophenone behaves like the majority of ketones. Details are reserved for a later communication.

W. P. W.

Derivatives of Ethyl Dinitrophenylacetate. By M. DITTRICH and V. MEYER (*Annalen*, 264, 129—149).—*Mesityl methyl ketone*, $C_6H_2Me_3\cdot COMe$, can be obtained by warming a carbon bisulphide solution of mesitylene with acetic chloride in presence of aluminium chloride; it is a liquid boiling at 235—236°, and having a very characteristic, unpleasant smell.

Mesitylglglyoxylic acid, $C_6H_2Me_3\cdot CO\cdot COOH$, is formed when mesityl methyl ketone is oxidised with an alkaline solution of potassium permanganate at 0°, as described by Glücksmann in the case of acetophenone (*Abstr.*, 1889, 1416); it separates from hot carbon bisulphide in well-defined, yellowish crystals, melts at 112—115° with previous softening, and is only sparingly soluble in carbon bisulphide and light petroleum, but readily in most of the other organic solvents, and also in boiling water.

Mesitylacetic acid, $C_6H_2Me_3\cdot CH_2\cdot COOH$, prepared by heating the preceding compound with hydriodic acid and amorphous phosphorus at 160° for six hours, crystallises from hot water in slender needles, melts at 166—167°, and is readily soluble in most ordinary solvents, except water and light petroleum.

Dinitromesitylacetic acid, $C_6(NO_2)_2Me_3\cdot CH_2\cdot COOH$, is formed when the acid is gradually introduced into fuming nitric acid, and the solution then boiled for some time; it crystallises from dilute alcohol in slender, lustrous needles, melts at 243°, and is rather more sparingly soluble than mesitylacetic acid. The *methyl* salt crystallises from alcohol in lustrous plates, melts at 140—141°, and resembles the acid in its behaviour with solvents; it is not acted on by diazobenzene chloride or diazobenzene sulphate in presence of an aqueous solution of sodium acetate.

Dinitromesitylglglyoxylic acid, $C_6(NO_2)_2Me_3\cdot CO\cdot COOH$, is best prepared by gradually adding mesitylglglyoxylic acid to cold fuming nitric acid (6 parts), keeping the solution for some time, and then pouring it on ice; it crystallises from hot water in slender needles; melts at 178—180°, decomposes at about 213°, and is only sparingly soluble in light petroleum, but more readily in the other ordinary solvents. The *hydrazone* crystallises from dilute alcohol in slender, yellow needles, and melts at 202° with decomposition. The *methyl* salt crystallises from alcohol in broad, lustrous needles, melts at 158—160°, and is only sparingly soluble in alcohol, ether, and light petroleum, but more readily in benzene and chloroform.

The *hydrazone*, $C_6(NO_2)_2Me_3\cdot C(N_2HPh)\cdot COOMe$, is obtained when methyl dinitromesitylglglyoxylate is boiled with excess of phenylhydrazine acetate in alcoholic solution; it crystallises from alcohol

in yellow needles, melts at 197—198° with previous softening, and decomposes at 210—220°. The corresponding acid,

is formed in small quantities when the methyl salt is boiled with concentrated potash for a short time, but most of the methyl salt remains unchanged; as, under these conditions, a condensation analogous to that which occurs in the case of the hydrazone of methyl dinitrophenylacetate (compare Meyer, *Abstr.*, 1889, 516) does not take place, it would seem that it is the nitro-group in the ortho-position to the carbon chain which is eliminated as potassium nitrite in the formation of nitrophenylindazolecarboxylic acid from the hydrazone of methyl dinitrophenylacetate.

Pseudocumyl methyl ketone, $\text{C}_6\text{H}_3\text{Me}_3\cdot\text{COMe}$, boils at 249—252°.

Pseudocumylglyoxylic acid, $\text{C}_6\text{H}_3\text{Me}_3\cdot\text{CO}\cdot\text{COOH}$, prepared by oxidising pseudocumyl methyl ketone by Glucksmann's method (*loc. cit.*), crystallises from light petroleum in colourless needles, melts at about 75°, and is very readily soluble in all the ordinary solvents except water and light petroleum. When treated with fuming nitric acid at -17°, it yields only resinous products; with weaker acid it is converted into a crystalline mononitro-derivative, which begins to decompose at 90° and melts at about 160°. F. S. K.

Preparation of Unsaturated Aromatic Acids. By L. EDELEMAN (*Bull. Soc. Chim.* [3], 5, 170—172).—In a previous communication, the author described the preparation of cinnamic acid according to the equation

(*Abstr.*, 1890, 891). He has since succeeded in preparing phenylangelic acid by heating at 120—125° during 40 hours benzaldehyde (1 mol.), butyric chloride (1 mol.), and anhydrous sodium acetate (3 mols.), and cinnamylangelic acid by similar treatment of cinnamaldehyde, butyric chloride, and sodium acetate. The corresponding acids are separated from the crude product of the reaction by boiling it with excess of sodium carbonate solution, extraction of the alkaline solution with ether to remove oily matter and excess of aldehyde, and decomposition of the sodium salt with hydrochloric acid. In the preparation of cinnamylangelic acid, a yellow substance melting at 90° is formed, which the author intends studying. The general formula for this reaction becomes:— $\text{R}\cdot\text{COH} + \text{R}'\text{CH}_2\cdot\text{COCl} + n\text{CH}_3\cdot\text{COONa} = \text{R}\cdot\text{CH}:\text{CH}\cdot\text{R}'\cdot\text{COOH} + \text{CH}_3\cdot\text{COOH} + \text{NaCl} + (n-1)\text{CH}_3\cdot\text{COONa}$.

T. G. N.

Action of Potassium Cyanide on Phthalaldehydic Acid. By C. GRAEBE and A. LANDRISSET (*Ber.*, 24, 2296—2297).—Diphtalyl is formed by the action of potassium cyanide on ethyl phthalaldehyde. The best results are obtained by warming a mixture of equal weights of the ethereal salt, potassium cyanide, and alcohol (95 per cent.). The yield amounts to 15 per cent. of the ethereal salt employed. The

results agree with those of Goldschmidt and Egger (*Monatsh*, **12**, 49), and the authors, like these chemists, assume that the orthoformal salt of phthalaldehydic acid here acts in its tautomeric form, $\text{CO} \left\langle \begin{smallmatrix} \text{C}_6\text{H}_4 \\ \text{O} \end{smallmatrix} \right\rangle \text{CH} \cdot \text{OEt}$.

In aqueous solution, the reaction takes place in a different way, and benzoindicarboxylic acid is formed. Phthalaldehydic acid was heated with 12–15 per cent. of potassium cyanide in aqueous solution for 20–30 minutes. The product, which is entirely soluble in sodium carbonate, was purified by means of the barium salt. The acid obtained from it is insoluble in cold water and other, sparingly soluble in hot water, decomposes at 112° , and gives diphtallic acid on oxidation with permanganate. Only a small yield of the benzoindicarboxylic acid is obtained. E. C. R.

Method for the Isolation of Aromatic Sulphonic Acids. By L. GATTERMANN (*Ber.*, **24**, 2121–2122).—Instead of the very troublesome method usually adopted for the isolation of aromatic sulphonic acids from the crude product of sulphonation, namely, by means of the barium, calcium, or lead salt of the acid, it is possible in many cases to effect a rapid and complete separation of the desired compound by first treating the crude product with water and then adding sodium chloride until the solution is saturated, when the sodium salt of the acid is deposited in crystals. This method can be very suitably employed for the isolation of benzene-, toluene-, xylene-, and mesitylene-sulphonic acids; it also gives good results in the case of phenol-, parasulphonic acid, phenoldisulphonic acid, and the metasulphonic derivatives of benzoic acid. A process of this kind is used to a considerable extent in the commercial preparation of certain sulphonic acids. F. S. K.

Action of Iodine in Presence of Sulphuric Acid on Calcium Benzenesulphonate. By ISTRATI and GLORIOSCO (*Bull. Soc. Chim.*, [3], **5**, 162–164).—Calcium benzenesulphonate (500 grams), iodine (50 grams), and sulphuric acid (1500 c.c.) were boiled together for 6½ hours, iodine (40 grams) and sulphuric acid (300 c.c.) being added in the interval. From the products of the reaction, iodobenzene, paradiiodobenzene, tetraiodobenzene, a francine and an iodo-derivative of calcium benzenesulphonate, $\text{C}_6\text{H}_4(\text{SO}_3)_2\text{Ca}$, were separated (compare previous abstract). T. G. N.

Derivatives of Benzoic Sulphinide. By R. DE ROODE (*Amer. Chem. J.*, **13**, 217–232).—A comparative study of the parahalogen derivatives of benzoic sulphinide, having especial regard to their flavours. Paranitrotoluene was converted successively into paranitrotoluene-, paratoluidine-, and paradiazotoluene-sulphonic acids, and then into the corresponding halogen sulphonic acids, sulphonic chlorides, and sulphonamides.

Purafuorotolueneortho-sulphonic acid, $\text{C}_6\text{H}_3\text{MeF} \cdot \text{SO}_3\text{H}$ [Me : SO_3H : F = 1 : 2 : 4], is made from the diazo-acid (100 grams), by dissolving

it in concentrated hydrofluoric acid (500 c.c.), and heating until nitrogen ceases to be evolved. The *calcium* and *barium* salts were prepared; the latter, $\text{Ba}(\text{C}_6\text{H}_4\text{O}_2\text{SF})_2 + \text{H}_2\text{O}$, crystallising in small, glistening scales; the *potassium* salt, with 2 mols. H_2O , forms similar but larger scales, very soluble in water. *Parachlorotoluenesulphonic acid* is made in a similar manner; the *barium* and *potassium* salts were prepared, the latter crystallising in light-yellow needles. *Parabromotoluenesulphonic acid* is formed in like manner; the *barium* and *potassium* salts were prepared; the latter crystallises in thin, lustrous scales. *Paraiodotoluenesulphonic acid* is made by treating the diazo-acid (50 grams), in the presence of alcohol (250 c.c.) and in the cold, with successive small quantities of concentrated hydriodic acid (57 grams). When the evolution of nitrogen ceases, the alcohol is distilled off, and the acid converted into the lead and potassium salts.

The dry potassium salts thus obtained are converted into the sulphochlorides and sulphonamides by successive treatment with phosphorus pentachloride and ammonia. *Parafluorotoluenesulphonamide*, $\text{C}_6\text{H}_4\text{MeF}\cdot\text{SO}_2\text{NH}_2$ [$\text{Me} : \text{SO}_2\text{NH}_2 : \text{F} = 1 : 2 : 4$], is made by treating potassium fluorotoluenesulphonate (50 grams) with phosphorus pentachloride (100 grams). The sulphonic chloride at first obtained is allowed after purification to drop slowly into strong aqueous ammonia (1 litre). The sulphonamide separates out as a bright-yellow solid, which dissolves easily in water and alcohol, and crystallises from these menstrua in large, transparent prisms, or long, white needles, and melts at 155° .

The sulphonamides are converted into the sulphinides by oxidation with alkaline permanganate. The amide (20 grams) is dissolved in water (2 litres) rendered alkaline with potash (8 grams), and the solution is kept at a boiling temperature while potassium permanganate (35 grams) in concentrated aqueous solution is gradually added. The sulphinide is precipitated from the colourless solution by hydrochloric acid, and purified by conversion into the calcium salt. The salts thus prepared form radial groups of white needles, and taste like the sulphimides. They all crystallise with $7\frac{1}{2}$ molecules of water.

The pure sulphinides are precipitated by hydrochloric acid from the aqueous solutions of their salts.

The *parafluorosulphinide*, $\text{C}_6\text{H}_4\text{F} < \begin{smallmatrix} \text{CO} \\ \text{SO}_2 \end{smallmatrix} > \text{NH}$ [$\text{CO} : \text{SO}_2 : \text{F} = 1 : 2 : 4$], crystallises from its aqueous solution in colourless needles or rhombs, and melts at 200° . It is very sweet, with a somewhat bitter after-taste.

The *parachlorosulphinide* crystallises from its aqueous solution in pearly scales, and melts at 218° . It is decidedly sweet, with a very bitter after-taste. When boiled with dilute hydrochloric acid in a reflux apparatus, it is converted into *acid ammonium parachlororhosphobenzoate*.

The *parabromosulphinide* is somewhat sweet, with a decidedly bitter after-taste.

The *paraiodosulphinide* crystallises from a hot aqueous solution in

fine, white needles melting at 230° . It is not at all sweet, and only slightly bitter. JN. W.

Orthosulphoparatoluic Acid and its Derivatives. By W. W. RANDALL (*Amer. Chem. J.*, 13, 256—273).—The various substances were prepared from "methylosaccharin" (paratoluic or methylbenzoic sulphinide), $C_6H_5Me < \begin{smallmatrix} CO \\ SO_2 \end{smallmatrix} > NH$ [$CO : SO_2 : Me = 1 : 2 : 4$], made from paratoluidine by the method of the Badische Anilin- und Soda-fabrik (Abstr., 1890, 382).

"Methylosaccharin" (*loc. cit.*) crystallises from water in fine, white needles, having the composition $C_8H_7NSO_3 + 1\frac{1}{2}H_2O$; it is slightly soluble in cold water and ether, readily in hot water and alcohol. At 190° it loses its water of crystallisation, and then gradually sublimes and decomposes; it melts at 249° . In taste it is at first intensely sweet, but afterwards bitter. It acts as a monobasic acid, the imido-hydrogen being replaceable. The barium salt, $Ba(C_8H_6NSO_3)_2 + 5H_2O$, crystallises from its aqueous solution in the triclinic form. The calcium salt crystallises in opaque, white needles, exceedingly soluble in water. The silver salt, $AgC_8H_6NSO_3 + 1\frac{1}{2}H_2O$, forms colourless, diamond-shaped, highly refractive crystals, soluble in water.

Orthosulphoparatoluic acid,

is prepared by heating "methylosaccharin" (25 grams) with dilute hydrochloric acid (100 c.c. acid and 500 c.c. water) in a reflux apparatus until it is all dissolved. The ammonium hydrogen orthosulphoparatoluate, $COOH \cdot C_6H_4Me \cdot SO_3NH_4$, which crystallises out, is treated with twice its weight of phosphorus pentachloride, and the mixture heated at 120° to drive off the phosphorus oxychloride formed. *Orthosulphoparatoluic chloride*, $COCl \cdot C_6H_4Me \cdot SO_2Cl$, thus obtained, forms crystals which melt at 59° , and are soluble in ether and light petroleum. It is converted into the acid by heating with water in a reflux apparatus. *Orthosulphoparatoluic acid* crystallises with $3\frac{1}{2}$ mo's H_2O in tetragonal prisms which are soluble in water, alcohol, and ether; the water of crystallisation is lost at 135° , and the anhydrous acid melts at 158° . It is dibasic, forming stable normal, and acid salts, which are not decomposed by boiling with strong alkalis, as stated by Fittica (*Liebig's Annalen*, 172, 328—329). The potassium salt is very soluble in water, and is converted by fusion with caustic potash into the potassium salt of orthodioxyparatoluic acid [$COOH : OH : Me = 1 : 2 : 4$]. The free acid is thrown down from the aqueous solution of the salt on the addition of hydrochloric acid. It melts at 177.5° (corr.), is readily soluble in hot water almost insoluble in cold, and with ferric chloride gives an iron colour. The ammonium salt, $(NH_4)_2C_8H_6SO_5 + 2H_2O$, is very soluble in water. The barium salt, $BaC_8H_6O_5$, forms fine needles. The calcium salt, $CaC_8H_6O_5 + H_2O$, crystallises in prisms, which lose water at 255° ; the anhydrous salt is

hygroscopic. The *magnesium* salt is deposited from its aqueous solution as a yellowish, gummy mass, but from alcoholic solution as a white, deliquescent, crystalline paste. The *silver* salt, $\text{Ag}_2\text{C}_6\text{H}_4\text{O}_8 + 1\frac{1}{2}\text{H}_2\text{O}$, is deposited from weak aqueous solution in colourless rhombic-hedra, but from concentrated solutions as a yellow, amorphous precipitate. It is only slightly soluble in water. The *acid potassium* salt, $\text{KC}_6\text{H}_7\text{SO}_5$, forms rhombic prisms soluble in water. The *acid ammonium* salt is formed during the preparation of the acid as above. The *acid barium* salt, $\text{Ba}(\text{C}_6\text{H}_7\text{SO}_5)_2 + 4\text{H}_2\text{O}$, crystallises from aqueous solution in long, colourless, efflorescent needles. The *acid calcium* salt, $\text{Ca}(\text{C}_6\text{H}_7\text{SO}_5)_2 + 4\text{H}_2\text{O}$, is very soluble in water, and crystallises in thin, cubical plates. The *acid magnesium* salt is very soluble in water.

Orthosulphoparatoluic anhydride, $\text{C}_6\text{H}_4\text{Me} < \begin{smallmatrix} \text{CO} \\ \text{SO}_2 \end{smallmatrix} > \text{O}$, appears to be formed when the dehydrated acid is heated with phosphoric anhydride at 145° . It forms a brilliant, fluorescent compound with resorcinol. Jx. W.

Hydrolysis of Sulphones. By R. ORRO (*Ber.*, 24, 1832—1836); compare Stuffer, *Abstr.*, 1890, 987, and this vol., p. 180; also, Autenrieth, this vol., pp. 540 and 1067). Trimethylene diphenylsulphone (m. p. $127-128^\circ$) is not acted on by boiling concentrated aqueous or alcoholic potash, but when heated with alcoholic potash at $115-120^\circ$, it is moderately easily decomposed into benzenesulphinic acid and a compound $\text{O}(\text{CH}_2\text{CH}_2\text{CH}_2\text{SOPh})_2$; the latter crystallises from alcohol in well-defined, hexagonal plates, melts at 85° , and is insoluble in water, but soluble in alcohol, ether, and chloroform.

Trimethyleneditolylsulphone, prepared by treating trimethylene bromide with sodium tolueneparasulphinate, crystallises from alcohol in lustrous plates melting at $124-125^\circ$; when heated with alcoholic potash at $115-120^\circ$, it is decomposed into toluenesulphinic acid and *ditolylsulphonepropyl ether*, $\text{O}(\text{CH}_2\text{CH}_2\text{CH}_2\text{SO}_2\text{C}_6\text{H}_7)_2$, a crystalline compound melting at $79-80^\circ$.

A *trisulphone* of the constitution $\text{SO}_2\text{Ph}\cdot\text{CH}_2\cdot\text{CH}(\text{SO}_2\text{Ph})_2$ can be obtained by treating sodium thiophenate with chlorethylene chloride, and oxidising the product with potassium permanganate; it separates from alcohol in small crystals, melts at $85-86^\circ$, and is completely decomposed by dilute potash, yielding benzenesulphinic acid.

F. S. K.

Hydrolysis of Sulphones and Ethereal Salts of Benzenesulphinic Acid. By E. BAUMANN (*Ber.*, 24, 2272—2277.—The author discusses the results obtained by Stuffer, Otto, and Autenrieth. Stuffer (*Abstr.*, 1890, 987; this vol., p. 180) has shown that those disulphones in which the sulphone groups are combined with neighbouring carbon atoms are easily hydrolysed by dilute potash with formation of sulphinic acids. These sulphones are sharply distinguished from the sulphones which are not capable of hydrolysis, or

are hydrolysed only with difficulty. To the latter belong the disulphones which, like sulphonal, contain the sulphone groups combined with the same carbon atom, or, like trimethylene disulphone, contain the sulphone groups combined with carbon atoms which are not neighbouring. Thus, propylene disulphone, $\begin{array}{c} \text{CH}_2\text{SO}_2\text{R} \\ | \\ \text{Me}\cdot\text{CH}\cdot\text{SO}_2\text{R}' \end{array}$ and ethylene disulphone, $\begin{array}{c} \text{CH}_2\text{SO}_2\text{R} \\ | \\ \text{CH}_2\text{SO}_2\text{R}' \end{array}$ are easily hydrolysed when warmed with dilute potash, whilst trimethylene disulphone, $\text{CH}_2(\text{CH}_2\text{SO}_2\text{R})_3$, is not altered by heating with concentrated aqueous or alcoholic potash on the water-bath at the ordinary pressure; only when heated in a sealed tube at 115—120° with alcoholic potash, does hydrolysis take place.

Many sulphones have been prepared which are hydrolysed as easily as ethereal salts, and this is not without bearing on the question whether ethereal salts of sulphinic acids exist isomeric with the sulphones. Otto (Abstr., 1888, 1231; 1885, 281) has prepared a number of ethereal salts of sulphinic acids, and has come to the conclusion that sulphones are represented by the constitution $\begin{array}{c} \text{R} \\ \diagup \quad \diagdown \\ \text{S} \end{array} \begin{array}{c} \text{O} \\ \diagdown \quad \diagup \\ \text{O} \end{array}$ and the ethereal salts of sulphinic acids by the constitution $\begin{array}{c} \text{R} \\ \diagup \quad \diagdown \\ \text{RO} \end{array} \text{S}=\text{O}$. These ethereal salts of sulphinic acids are not, however, known in a pure state. If substances like ethyl sulphone sulphonal, $\text{OMe}(\text{SO}_2\text{Et})_2\text{CH}_2\cdot\text{SO}_2\text{Et}$, which are easily hydrolysed with production of sulphinic acids are to be accepted as ethereal salts of sulphinic acids, they must, according to Otto, have a constitution different from that of sulphonal, which is one of the sulphones most difficult to hydrolyse. This view cannot, however, be accepted until the difficultly hydrolysable compounds isomeric with the former have been prepared, which will be the true sulphones. If the ethereal salts of sulphinic acids contain quadrivalent sulphur, on oxidation, they ought to yield ethereal salts of sulphonic acids. Otto and Rössing (Trans., 1886, 710) have, indeed, described experiments in which they obtained ethereal salts of sulphonic acids from ethyl benzene- and toluene-sulphinate; they did not, however, employ pure substances. The experiments of Stuffer and Autenrieth, on the other hand, show that their ethereal sulphinates, ethyl sulphone sulphonal, and similar compounds, when pure, are as stable to oxidising agents as the sulphones which cannot be hydrolysed or only with difficulty.

The author concludes that it is impossible to distinguish between sulphones and ethereal salts of sulphinic acids, and that the constitution of sulphinic acid is correctly represented by the formula $\begin{array}{c} \text{R} \\ \diagup \quad \diagdown \\ \text{H} \end{array} \text{S} \begin{array}{c} \text{O} \\ \diagdown \quad \diagup \\ \text{O} \end{array}$. The ease with which the sulphones are hydrolysed is determined by the position of the sulphonic groups in the molecule of the organic compound, and can be compared to the unequal capacity for hydrolysis displayed by the halogen substitution products.

E. C. R.
